Streams play a key role in the global carbon cycle. The balance between carbon intake through photosynthesis and carbon release via respiration influences carbon emissions from streams and depends on temperature. However, the lack of a comprehensive analysis of the temperature sensitivity of the metabolic balance in inland waters across latitudes and local climate conditions hinders an accurate projection of carbon emissions in a warmer future. Here, we use a model of diel dissolved oxygen dynamics, combined with high-frequency measurements of dissolved oxygen, light and temperature, to estimate the temperature sensitivities of gross primary production and ecosystem respiration in streams across six biomes, from the tropics to the arctic tundra. We find that the change in metabolic balance, that is, the ratio of gross primary production to ecosystem respiration, is a function of stream temperature and current metabolic balance. Applying this relationship to the global compilation of stream metabolism data, we find that a 1°C increase in stream temperature leads to a convergence of metabolic balance and to a 23.6% overall decline in net ecosystem productivity across the streams studied. We suggest that if the relationship holds for similarly sized streams around the globe, the warming-induced shifts in metabolic balance will result in an increase of 0.0194 Pg carbon emitted from such streams every year.

Streams play a significant role in the transport, storage and transformation of organic carbon globally^{1,2}. Recent estimates suggest that 0.8–1.8 petagrams (Pg) of carbon escape from streams and rivers to the atmosphere annually^{3,4}. This is comparable in size to the net annual terrestrial–atmosphere and net ocean–atmosphere carbon exchange⁵. Stream metabolism, which is governed by gross primary production (GPP) and ecosystem respiration (ER), contributes substantially to the overall carbon flux out of streams. A recent study has estimated that stream metabolism is responsible for up to 28% of the total carbon flux from streams to the atmosphere⁶, resulting in an estimated net flux of 0.12 Pg C per year⁷. As GPP and ER are both temperature-dependent processes, sustained climate warming has the potential to profoundly alter the rates of carbon flux in and out of streams. Over the past century, mean water temperature in US rivers and streams increased at a rate of 0.009–0.077 °C per year⁸, and stream temperatures are predicted to increase by 1–3 °C with the doubling of atmospheric CO₂ concentration⁹. Consequently, understanding the feedback between stream

metabolism and global warming is crucial when considering global or regional carbon cycles.

Although it is tempting to use well-quantified temperature responses of photosynthesis and respiration at the cellular level to predict ecosystem-level responses to warming, complex interactions among organisms and their abiotic environments can confound the temperature responses of cellular processes at higher levels of organization. Taken at face value, the differential temperature sensitivities of photosynthesis and respiration at the cellular level defined by activation energy in the Arrhenius equations (~30.9 and 62.7 kJ mol⁻¹ for photosynthesis and respiration, respectively¹⁰) prescribe a relatively faster increase in ER than GPP in response to warming. Consequently, we would predict that streams will become more heterotrophic (that is, lower GPP/ER) as climate continues to warm. However, the implicit assumption of such a prediction—that the activation energies of photosynthesis and respiration at the cellular level are appropriate for describing the temperature sensitivities of GPP and ER in streams at the ecosystem level—may not hold.

Intrinsic variation in the temperature dependence of multiple processes that comprise aggregated ecosystem rates can cause the temperature sensitivities of whole ecosystem processes to deviate from the temperature dependence of cellular-level responses. For example, variation in algal community composition can influence the temperature sensitivity of ecosystem-level GPP because the activation energy of photosynthesis varies across phyla of algae^{11,12}. Similarly, the chemical structure of organic compounds influences the activation energy of decomposition reactions, and thus variation in respiratory substrate composition can affect the temperature sensitivity of ER¹³. Alternatively, if ecosystem-level GPP and ER are influenced by other temperature-dependent processes, inferred temperature sensitivities of GPP and ER may reflect the influences of these processes and not necessarily the temperature sensitivities of cellular photosynthesis and respiration. For example, warming may accelerate the flux of nutrients and organic carbon from sediments to the water column¹⁴ and transport of nutrients across cell membranes¹⁵, both of which could result in amplified temperature sensitivities at the ecosystem level¹⁶. The temperature sensitivities of GPP and ER may reflect the temperature sensitivity of a process that constrains GPP or ER, such as nitrogen supply¹⁷. Conversely, the temperature sensitivities of GPP or ER at the ecosystem level can be muted by nutrient limitation^{18,19}. Finally, variation in the responses of different taxa to temperature variation can confound aggregate temperature sensitivity. Differential responses to warming across decomposer taxa have even been shown to cancel each other out, resulting in no net change in ecosystem carbon flux in response to warming²⁰.

In addition to the inherent complexity in ecosystem-level temperature sensitivities of GPP and ER, the varied approaches employed to quantify them also have the potential to influence the inferred ecosystem-level temperature dependence of GPP and ER. Incubations of stream substrata at different temperatures^{21,22} or mesocosm warming experiments²³ do not include the entire focal ecosystem and may not encompass the processes key for determining the temperature sensitivities of GPP and ER at the ecosystem level. Comparisons among streams or within one stream over seasons^{17,24–28} yield ecosystem-level estimates of temperature sensitivities, but temperature-independent differences among streams or seasons due to hydrology²⁹, geomorphology²², nutrient availability^{30,31} and light availability²⁶ can easily confound the responses of GPP and ER to temperature. These confounding factors render the estimated temperature dependence not purely a response to temperature, but an integrated response to the suite of temperature-dependent and -independent differences across streams or seasons.

Given the complexity of ecosystem-level temperature sensitivities and the challenges associated with quantifying them, it is not surprising that various patterns have been reported. Some studies have found consistent temperature sensitivities of ER at the ecosystem and cellular levels^{21,23,27,28}, but others have demonstrated considerable deviation of ecosystem-level activation energies of GPP^{23,27,32} and ER^{17,25} from the values of their cellular analogues. In studies that simultaneously examined the temperature dependence of GPP and ER in streams, a shift towards heterotrophy with warming has been observed in some instances^{23,27}, but a recent synthesis based on geothermal streams concluded that warming increases GPP and ER to the same extent and results in no net change in metabolic balance³². To date, simultaneous quantification of the temperature dependence of GPP and ER have been constrained to mesocosm incubations or geothermal streams. Thus, there is still uncertainty about whether streams will become more heterotrophic (decreasing GPP/ER and net ecosystem productivity (NEP)) or more autotrophic (increasing GPP/ER and NEP) at the continental scale in response to continued warming. Simultaneously quantifying the ecosystem-level temperature sensitivities of GPP and ER in streams across broad bioclimatic regions is key to resolving such uncertainty.

Here, we estimate the temperature sensitivities of GPP and ER in streams from six distinct biomes. We utilize the response of dissolved oxygen (DO) concentration to diel temperature variation and dynamic models of DO concentration to infer the temperature dependence of GPP and ER for each stream over multiple days³³. Compared to studies that analyse streams along spatial or seasonal temperature gradients, we avoid the implicit assumption that differences in stream metabolism along the temperature gradient are mainly attributed to temperature differences, and thus minimize the influence of factors that covary spatially or seasonally with temperature³⁴. Moreover, this dynamic modelling approach allows us to estimate the temperature dependence of GPP and ER for each stream, and thus characterize stream to stream variation in the temperature sensitivity of whole-stream metabolism. Combining dynamic models with high-resolution time series of light, temperature and DO in streams across six biomes allows us to quantify the temperature dependence of stream metabolism across latitude, and refine predictions of the feedback between stream metabolic balance and global warming.

Estimating activation energies of GPP and ER

We estimated the ecosystem-level activation energies of GPP and ER in streams across six biomes by modelling diel changes in DO concentration. The six distinct biomes, which span a wide range of latitude (13°S–68°N), include tropical forest (Luquillo Experimental Forest, Puerto Rico (LUQ)), tropical savanna (Litchfield National Park, North Territory, Australia (AUS)), tall-grass prairie (Konza Prairie, KS, USA (KNZ)), temperate rain-forest (Andrews Experimental Forest, OR, USA (AND)), boreal forest (Caribou-Poker Creeks Research Watershed, AK, USA (CPC)) and arctic tundra (Toolik Lake Field Station, AK, USA (ARC)). In each biome, we measured DO concentration, photosynthetically active radiation, and water temperature at a 5 or 10 min interval for 1–2 weeks in multiple stream reaches throughout a watershed. We modelled the response of DO concentration to diel temperature variation to estimate ecosystem-level activation energies of GPP and ER. Specifically, we modelled the dynamics of DO concentration as

$$\frac{d[O_2]}{dt} = GPP - ER + K ([O_2]_{\text{sat}} - [O_2]) \quad (1)$$

Here, $[O_2]_{\text{sat}}$ is the saturated DO concentration and can be calculated from temperature and barometric pressure³⁵. GPP, ER and K are instantaneous rates of primary production, respiration and reaeration, respectively. We modified previously published models of aquatic metabolism^{36–38} by using the Arrhenius equation to describe the temperature dependence of GPP and ER. Specifically, GPP, ER and K were modelled as

$$GPP = P_{\text{max}} \tanh\left(\frac{\alpha I}{P_{\text{max}}}\right) e^{-\frac{E_{ap}}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right)} \quad (2)$$

$$ER = R_{T_0} e^{-\frac{E_{ar}}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right)} \quad (3)$$

$$K = K_{20} \times 1.024^{T-20} \quad (4)$$

Here, P_{max} ($\text{mg O}_2 \text{ l}^{-1} \text{ min}^{-1}$) is the maximum primary production rate, α ($\text{mg O}_2 \text{ l}^{-1} \text{ s m}^{-2} \mu\text{E}^{-1} \text{ min}^{-1}$) is the slope of the light response curve of primary production at low light intensity, R_{T_0} ($\text{mg O}_2 \text{ l}^{-1} \text{ min}^{-1}$) is the respiration rate at reference temperature T_0 (K), which we set at the average daily water temperature across

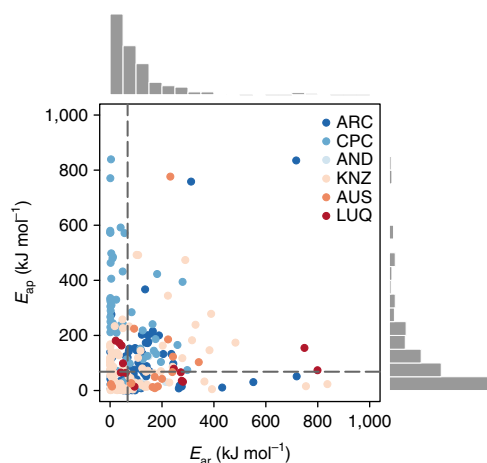

Fig. 1 | Ecosystem-level activation energies of GPP and ER in streams.

Each point represents estimated E_{ap} and E_{ar} in a particular stream reach on one day. Histograms on the axes show the frequency distributions of E_{ap} and E_{ar} . Dashed lines are the medians of the frequency distributions.

all days for each stream reach, K_{20} (min^{-1}) is the reaeration coefficient at 20 °C, I ($\mu\text{E m}^{-2} \text{s}^{-1}$) is photosynthetically active radiation, T (K) is water temperature, R ($8.314 \text{ kJ mol}^{-1} \text{ K}^{-1}$) is the ideal gas constant, and E_{ap} (kJ mol^{-1}) and E_{ar} (kJ mol^{-1}) are the activation energies of GPP and ER, respectively. We used a Bayesian approach to estimate the parameters (P_{\max} , α , R_{T_0} , K_{20} , E_{ap} , E_{ar}) in the model³⁹, and calculated daily GPP, ER, GPP/ER and NEP using the estimated parameters and associated light and temperature profiles (see Methods).

The estimated ecosystem-level activation energies exhibited significant variability both within and across biomes (Fig. 1), and were not significantly correlated with GPP, ER or NEP (Supplementary Fig. 1–3). The activation energies of GPP and ER varied substantially from the activation energies of photosynthesis and respiration at the cellular level. Specifically, activation energies ranged from 0.5 to 839.2 kJ mol^{-1} for GPP and from 0.4 to 837.2 kJ mol^{-1} for ER. The median activation energies of GPP and ER were 68.2 kJ mol^{-1} and 67.5 kJ mol^{-1} , respectively, which is consistent with a recent study quantifying the temperature sensitivity of GPP and ER in streams along a geothermal gradient³². However, this does not necessarily imply that warming will increase GPP and ER to the same extent. Due to the nonlinear nature of temperature dependence and substantial variability in the activation energies of GPP and ER, simply using the central tendency of the estimated activation energies will not accurately describe the thermal response of stream metabolism within and across biomes. The inherent variation in activation energies underscores the importance of quantifying the thermal response of stream metabolism using the activation energies of GPP and ER for individual streams rather than using the mean or median activation energies across all streams.

$E_{ap} - E_{ar}$ decreases with GPP/ER and temperature

Simultaneous quantification of the activation energies of GPP and ER allowed us to evaluate the thermal response of stream metabolic balance across biomes. A common measure of metabolic balance in streams is the ratio of GPP to ER, which, for our formulation of the instantaneous rates of GPP and ER, is

$$\frac{\text{GPP}}{\text{ER}} = \frac{P_{\max} \tanh\left(\frac{\alpha I}{P_{\max}}\right)}{R_{T_0}} e^{-\frac{E_{ap}-E_{ar}}{R}\left(\frac{1}{T}-\frac{1}{T_0}\right)} \quad (5)$$

The formulation of GPP/ER has the form of an Arrhenius equation, and thus $E_{ap} - E_{ar}$ is the apparent activation energy of GPP/ER and determines how instantaneous metabolic balance changes with temperature. A positive $E_{ap} - E_{ar}$ means that GPP/ER will increase as temperature increases and a negative $E_{ap} - E_{ar}$ means GPP/ER will decrease as temperature increases.

Despite significant variation in both E_{ap} and E_{ar} (Fig. 1) and a lack of correlation between E_{ap} , E_{ar} and GPP, ER and NEP (Supplementary Fig. 1–3), we observed that $E_{ap} - E_{ar}$ decreases significantly with daily GPP/ER (Fig. 2a; linear mixed effects model, $F_{1,39.14} = 8.23$, $P = 0.0066$) and daily mean water temperature (Fig. 2b; linear mixed effects model, $F_{1,44.28} = 8.4$, $P = 0.0058$). The negative correlation between $E_{ap} - E_{ar}$, GPP/ER and stream temperature gives rise to a prediction for how metabolic balance will change in response to warming. Specifically, GPP/ER in streams with higher temperature and higher current GPP/ER is predicted to decrease in response to warming, whereas in streams with lower temperature and lower current GPP/ER it is expected to increase. The exact pattern of changes in stream metabolic balance globally will depend on the effect sizes of GPP/ER and temperature, as well as the spatial distribution of temperature and daily GPP/ER around the globe.

We hypothesize that the negative relationship between $E_{ap} - E_{ar}$ and GPP/ER may stem from competition and coexistence among autotrophs and heterotrophs in the benthic community. Because a higher activation energy means a greater relative increase in reaction rates in response to warming⁴⁰, it allows organisms with high temperature sensitivity to grow more quickly as temperature increases. Thus, it is possible for organisms with lower metabolic rate and higher thermal responsiveness to compete and coexist with those having higher metabolic rate but lower thermal responsiveness in a fluctuating environment^{41,42}. More generally, the tradeoff between rate and responsiveness to temperature can be viewed as an example of nonlinearity of competition as a coexisting mechanism⁴³.

Warming induces asymmetric convergence in GPP/ER

Because activation energy is proportional to the percentage change in reaction rate in an Arrhenius equation⁴⁰, the fact that daily GPP/ER and temperature predict $E_{ap} - E_{ar}$ indicates that they also predict the percentage change in GPP/ER ($\Delta\text{GPP/ER}$) as temperature increases. We performed a simulated warming experiment to calculate $\Delta\text{GPP/ER}$ under 1 °C warming, and established a relationship between $\Delta\text{GPP/ER}$ and predictors of $E_{ap} - E_{ar}$, namely daily GPP/ER and mean water temperature. Specifically, we added 1 °C to each recorded water temperature, which represents a realistic estimate of stream temperature in the next century⁸. Using the observed light trajectories, the elevated temperature trajectories, and parameters in the DO model (equations (1), (2), (3) and (4)) estimated from field data, we calculated the daily GPP, ER and then the proportional change in GPP/ER ($\Delta\text{GPP/ER}$) under this warming scenario for each stream in our data set. We analysed the effects of daily GPP/ER and mean water temperature on $\Delta\text{GPP/ER}$ in a linear mixed effects model. As expected, $\Delta\text{GPP/ER}$ decreased significantly with both daily GPP/ER (Fig. 3a, $F_{1,39.29} = 12.50$, $P = 0.0011$) and temperature (Fig. 3b, $F_{1,42.41} = 7.60$, $P = 0.0086$). Quantitatively, $\Delta\text{GPP/ER}$ can be predicted based on the fixed effects in the model as $\Delta\text{GPP/ER} = 0.46 - 0.45 \times \text{GPP/ER} - 0.019 \times \text{temperature}$.

To establish how warming is likely to affect the metabolic balance in streams globally, we assembled a stream metabolism data set of daily GPP, ER and mean water temperature based on two previous synthesis studies^{32,44}, and applied the linear model for $\Delta\text{GPP/ER}$ as a function of both GPP/ER and mean water temperature to the compiled data set. We selected data within the range of daily GPP/ER (0.016–0.978) and daily mean temperature (2.2–26.3 °C) found in our study, resulting in a total of 236 metabolism estimates (Supplementary Materials). After quantifying the GPP/ER under a

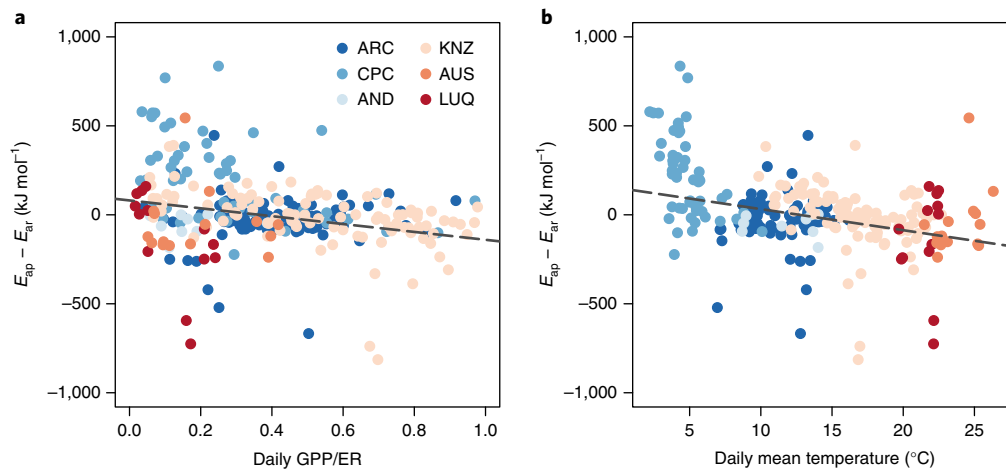

Fig. 2 | Relationship between $E_{ap} - E_{ar}$, current GPP/ER and mean daily temperature. a,b, Relationship between $E_{ap} - E_{ar}$ and daily GPP/ER (**a**) and daily mean temperature (**b**). Dashed lines are predictions based on fixed effects in the linear mixed effects model ($E_{ap} - E_{ar} = 236.92 - 221.20 \times \text{GPP/ER} - 11.86 \times \text{temperature}$). In each panel, the prediction line is evaluated at the mean of the other covariate.

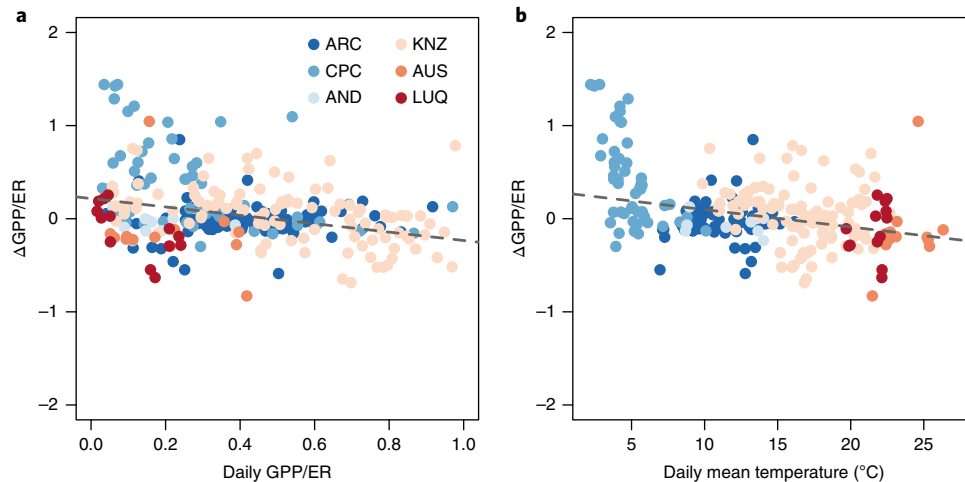

Fig. 3 | Proportional change in GPP/ER under 1°C warming as a function of current daily GPP/ER and mean water temperature. a,b, $\Delta\text{GPP/ER}$ as a function of daily GPP/ER (**a**) and daily mean temperature (**b**). Dashed lines are predictions based on fixed effects in the linear mixed effects model ($\Delta\text{GPP/ER} = 0.46 - 0.45 \times \text{GPP/ER} - 0.019 \times \text{temperature}$). In each panel, the prediction line is evaluated at the mean of the other covariate.

1°C increase in temperature for streams in the compiled data set, two patterns of warming-induced changes in stream metabolic balance emerged. First, the GPP/ER of streams converged under a 1°C temperature increase, shown as a decrease in the inter-site variability of GPP/ER (Fig. 4a). Second, the convergence in metabolic balance is asymmetric. The magnitude of the decrease in GPP/ER in streams with high temperatures and high daily GPP/ER was larger than the magnitude of the increase in GPP/ER in streams with low temperatures and low daily GPP/ER. Such asymmetry suggests that warming will influence the metabolic balance of streams with high temperature and daily GPP/ER more substantially, which translates to such streams becoming stronger carbon sources (that is, lower GPP/ER).

Implications for the global carbon cycle

We quantified warming-induced changes in NEP, the difference between GPP and ER, based on the simulated warming experiment. We estimated that a 1°C increase in temperature will increase GPP from 0.89 to 1.12 g O₂ m⁻² day⁻¹ and ER from 3.45

to 4.27 g O₂ m⁻² day⁻¹ on average across the streams we studied. Scaling our findings to similarly sized streams globally with an estimated benthic area of 2.75 × 10⁵ km² (refs 7,45), a photosynthetic quotient of 1.2 (molar ratio of O₂ to C) and a respiratory quotient of 0.85 (molar ratio of C to O₂)⁴⁶, we predict that streams will become 23.6% more heterotrophic, with NEP shifting from -0.0822 to -0.1016 Pg C year⁻¹ globally (Table 1 and Fig. 4c), in response to a 1°C increase in temperature. Although our prediction of shifting towards more net heterotrophy in response to warming is consistent with predictions based on metabolic theory¹⁰, it differs importantly in that it results from the asymmetric convergence of metabolic balance, not a universal shift towards heterotrophy for all streams (Fig. 4d).

The predictions for how GPP/ER and NEP will change with warming do not come without caveats. The predicted changes in GPP/ER and NEP are based on the temperature sensitivity of metabolism for the current state of stream ecosystems, and changes in streams and adjacent terrestrial ecosystems concurrent with warming may complicate this prediction. For exam-

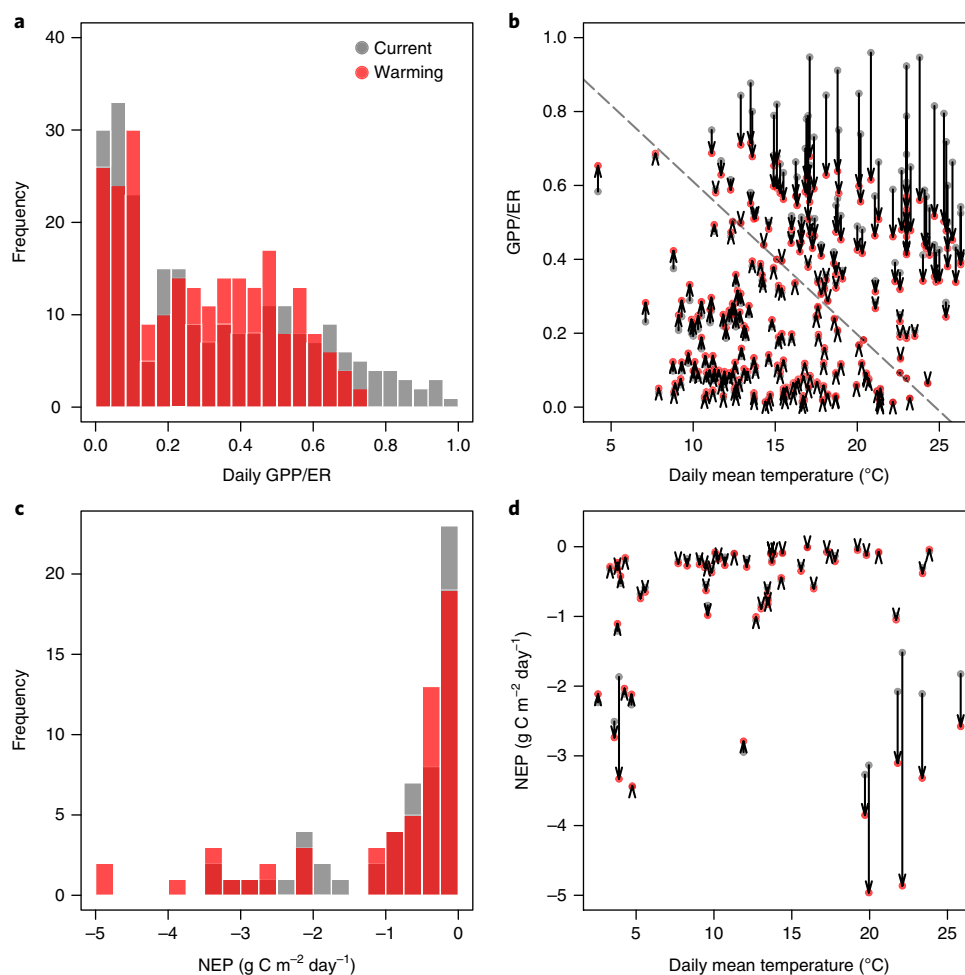

Fig. 4 | Predicted changes in GPP/ER and NEP under 1°C warming. **a,c.** Frequency distribution of GPP/ER (**a**) and NEP (**c**) currently and with a 1°C increase in temperature. **b,d.** Changes in GPP/ER (**b**) and NEP (**d**) with a 1°C increase in temperature. The dashed line in **b** is the isocline defined by the fixed effects from the linear mixed effects model ($0.46 - 0.45 \times \text{GPP/ER} - 0.019 \times \text{temperature} = 0$), where GPP/ER is insensitive to temperature changes.

Table 1 | Global estimates of stream GPP, ER and NEP currently and under 1°C increase in temperature

	GPP	ER	NEP
Current	0.0281 ± 0.0036	0.1103 ± 0.0151	-0.0822 ± 0.0127

Data are shown as mean \pm s.e.m. Unit, Pg C year⁻¹.

ple, warming is expected to change the quantity and quality of allochthonous carbon inputs by stimulating soil organic matter decomposition⁴⁷ and altering riparian communities⁴⁸. Thermal adaptation of benthic communities⁴⁹ and changes in hydrology or nutrient availability^{30,50} may further amplify or damp the predicted convergence of metabolic balance. Despite these caveats, our predictions are based on findings from streams that encompass a broad range of biotic and abiotic conditions, providing a robust basis for assessing the effects of warming on stream metabolic balance across the globe. Incorporating the warming response of stream metabolic balance identified in this study into comprehensive analyses will improve our ability to quantify the feedback between carbon dynamics in streams and future climate changes.

Methods

Study sites and data collection. We conducted this study in six watersheds representing distinct biomes, including tropical forest (LUQ), tropical savanna (AUS), tallgrass prairie (KNZ), temperate rainforest (AND), boreal forest (CPC) and arctic tundra (ARC). Within each watershed, we selected 6–12 streams across a range of stream sizes to capture the physical gradients within the watershed. A detailed description of the study sites can be found in previous work⁵¹. In each stream, we recorded DO concentration, water temperature and barometric pressure using a YSI ProODO handheld optical DO meter (YSI Instruments), and photosynthetically active radiation using an Odyssey Irradiance logger (DataFlowSystems) at a single location in each stream. The DO meter was calibrated with water-saturated air immediately before deployment. The readings from the irradiance logger were converted to photosynthetically active radiation based on a comparison with a calibrated sensor. We recorded these data at intervals of 5 min (ARC) or 10 min (all other sites) for 1–14 days. We collected data during base flow periods (February–March 2013 and March 2014 for LUQ, July–August 2013 for AUS, May–June 2013 and April–June 2014 for KNZ, July–August 2015 for AND, July–August 2013 and 2014 for CPC, July–August 2013 and 2014 for ARC). In total, we collected 709 daily DO trajectories from 69 stream reaches across the six biomes.

Estimating activation energies of GPP and ER. We modelled the dynamics of DO concentration with equations (1), (2), (3) and (4) and employed a Bayesian approach for parameter estimation^{39,52–54}. Specifically, for a given set of parameters, we used the Runge–Kutta fourth-order method implemented in the R package *deSolve*⁵⁵ with a step size of 2.5 min to numerically solve the differential equations describing DO dynamics (equations (1), (2), (3) and (4)) and obtained a trajectory of modelled DO concentration. Numerically solving the differential equations with high accuracy requires the interpolation of discrete measurements of light and temperature. To this end, we used linear interpolation to approximate continuous trajectories of light and temperature from discrete measurements. We assumed that the differences between modelled and measured DO were independent and identically distributed normal random errors. Based on this assumption of error distribution, we computed the likelihood for any given set of parameters. We used uniform priors for all parameters in the model, setting the lower bound of the uniform priors at 0 and upper bound at values significantly larger than found in previous studies to ensure that the posterior inferences were not overly constrained by the prior distributions. In particular, we set the upper bound of the uniform prior for E_{ap} and E_{ar} at 1000 kJ mol^{-1} , which is significantly higher than found in the existing literature^{17,21–23,25,27,28}. We used Markov Chain Monte Carlo to sample the posterior distributions of the parameters. Specifically, we implemented the adaptive random walk Metropolis–Hasting algorithm⁵⁶ with the function *metrop* in R package *mcmc*⁵⁷. We ran each Markov chain for half a million iterations and used a burn-in period of 300,000 iterations to ensure stationarity. We performed visual inspection and Geweke diagnostics⁵⁸ of the trace plots with the R package *coda*⁵⁹ for proper mixing and convergence of the Markov chains. All parameters in the model (P_{max} , R_{T_0} , α , E_{ap} , E_{ar} , K_0) were simultaneously estimated. We used posterior means of the parameters for further statistical analyses.

We made two special considerations when estimating parameters. First, low diel variability in temperature in some streams prevented us from estimating E_{ap} and E_{ar} with confidence. Thus, we only used E_{ap} and E_{ar} estimates with 95% highest posterior density intervals narrower than 500 kJ mol^{-1} for further statistical analyses. This is to ensure that the estimated E_{ap} and E_{ar} are mainly determined by the data, not by the uniform priors. With this selection criteria, we obtained 292 estimated E_{ap} and E_{ar} from 48 reaches based on the 709 daily DO trajectories collected from 69 reaches. The choice of 500 kJ mol^{-1} as the threshold is arbitrary. Such an arbitrary choice influences the number of estimated E_{ap} and E_{ar} for further statistical analyses, but does not affect the findings of this study (Supplementary Fig. 6). Second, when estimating parameters, we divided the data from the same stream into individual days, and estimated a unique set of parameters for each stream on each day, considering the potential for day to day variation of the parameters for the same stream.

To obtain the posterior distributions of daily GPP and ER, we numerically integrated the instantaneous rates of GPP and ER over a day based on each iteration of parameters in the Markov chain. We performed the same diagnostics of Markov chains to ensure stationarity, proper mixing, and convergence. We obtained the posterior distributions of GPP/ER by taking the ratio of the trace of daily GPP and ER. We reported the means of posterior distributions as point estimates for daily GPP, ER and GPP/ER. The estimated E_{ap} , E_{ar} , daily GPP, ER and basic site information are included in the Supplementary Materials.

Simulated warming experiment. With parameter estimates in the DO model (equations (1), (2), (3) and (4)) for the 292 days of metabolism, we performed a simulated warming experiment to assess the response of stream metabolic balance to temperature increase. We added 1°C to each individual measurement of water temperature. This warming scenario represents a 1°C increase in daily mean temperature without changing the daily temperature variability. Using the estimated parameters in the DO model, the observed light trajectories and the elevated temperature trajectories, we calculated the daily GPP and ER under this warming scenario following the procedure outlined above. We performed the same diagnostics

of the trace plots of daily GPP and ER in the simulated warming experiment. In total, we successfully calculated 288 daily GPP and ER under the 1°C warming scenario. The daily GPP and ER under the current temperature and the 1°C warming scenario were used to calculate the proportional change in GPP/ER ($\Delta\text{GPP/ER}$) as

$$\Delta\text{GPP/ER} = \frac{\text{GPP/ER}_{\text{warming}} - \text{GPP/ER}_{\text{current}}}{\text{GPP/ER}_{\text{current}}} \quad (6)$$

where $\text{GPP/ER}_{\text{current}}$ and $\text{GPP/ER}_{\text{warming}}$ are daily GPP/ER currently and under the 1°C warming scenario, respectively. The relationship between $\Delta\text{GPP/ER}$, currently daily GPP/ER and mean daily stream temperature was then applied to the global metabolism data set to calculate GPP/ER under 1°C warming.

We also used results from the simulated warming experiment to evaluate how warming influences NEP in streams globally. Because we measured metabolism for several days in each stream, we first calculated the average GPP and ER for each stream over time and then the average GPP and ER over all streams with a 1°C increase in temperature. The broad range of biotic and abiotic conditions encompassed in the streams we studied provided a robust basis to extrapolate globally. Thus, we scaled up the average GPP and ER across the streams in our study to a global scale using an estimated benthic area of $2.75 \times 105 \text{ km}^2$ for similarly sized streams globally^{7,45}. The estimated global stream area corresponded to first- to fifth-order streams, and is appropriate for the size range of streams we sampled in this study. Finally, we converted metabolism from units of oxygen to carbon using a photosynthetic quotient of 1.2 (molar ratio of O_2 to C) and a respiratory quotient of 0.85 (molar ratio of C to O_2)⁴⁶.

Statistical analyses. We analysed the pattern of $E_{ap} - E_{ar}$ as a function of current daily GPP/ER and daily mean temperature with a linear mixed effects model. Because we estimated a unique set of activation energies for each stream on each day, estimates of multiple days from the same stream could be correlated. Therefore, we included random effects of each stream nested in biome in the model to account for the repeated measurements. We treated the same streams measured in different years as different streams when specifying the random effects. Specifically, we started with a full model and performed backwards model selection to build the most parsimonious model. The fixed effects of the full model included daily GPP/ER, daily mean water temperature, and their interaction. The random effects of the full model included a random intercept and random slopes of both daily GPP/ER and mean water temperature for the stream nested in biome. We first fit the full model using maximum likelihood and selected the structure of random effects based on the Akaike information criterion (AIC). We found that eliminating the biome-specific random slopes and intercepts led to a slight decrease in AIC ($\Delta\text{AIC} = -0.86$), but eliminating the stream-level random intercepts ($\Delta\text{AIC} = 54.4$), random slopes of daily GPP/ER ($\Delta\text{AIC} = 22.7$) or random slope of daily mean water temperature ($\Delta\text{AIC} = 10.8$) all resulted in substantial increases in AIC. Therefore, we ultimately specified the random effects with a random intercept and random slopes of GPP/ER and mean water temperature for each stream in our final model. We then refit the model with restricted maximum likelihood and used *F*-tests with the Kenward–Roger approximation of degrees of freedom⁶⁰ to select the fixed effects. We found no significant interaction between daily GPP/ER and mean water temperature ($F_{1,25,71} = 0.24$, $P = 0.63$). Thus, the most parsimonious model included daily GPP/ER and mean water temperature as fixed effects, and a random intercept and slopes of both daily GPP/ER and mean water temperature for each stream. We tested whether the fixed effects slopes of daily GPP/ER and mean water temperature were zero using the *F*-test with the Kenward–Roger approximation of degree of freedom to evaluate whether daily GPP/ER or mean water temperature had a significant effect on $E_{ap} - E_{ar}$.

Given that the percentage change in reaction rate is proportional to the activation energy in the Arrhenius equation⁴⁰, and that $E_{ap} - E_{ar}$ is the activation energy of GPP/ER (equation (5)), it follows that predictors of $E_{ap} - E_{ar}$ should also be predictors of $\Delta\text{GPP/ER}$. Therefore, we analysed the effects of daily GPP/ER and mean water temperature on $\Delta\text{GPP/ER}$ using the same modelling structure as the most parsimonious model for $E_{ap} - E_{ar}$ without performing the model selection. We fit all the linear mixed effects models using the function *lmer* in the R package *lme4*⁶¹. The *F*-test with the Kenward–Roger approximation of degrees of freedom was implemented using the R package *pbrtest*⁶². All statistical analyses were performed in R 3.4.1⁶³.

Data availability. The compiled metabolism data and estimates of activation energies, GPP and ER from streams we sampled are available in the Supplementary Information.
