# Covariate-Adjusted Precision Matrix Estimation with an Application in Genetical Genomics 

T. Tony Cai,<br>Department of Statistics, The Wharton School, University of Pennsylvania, Philadelphia, Pennsylvania 19104, USA<br>Hongzhe Li,<br>Department of Biostatistics and Epidemiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania 19104, USA<br>Weidong Liu, and<br>Department of Mathematics, Institute of Natural Sciences and MOE-LSC, Shanghai Jiao Tong University, Shanghai 200240, China<br>Jichun Xie<br>Department of Statistics, Fox School of Business, Temple University, Philadelphia, Pennsylvania 19122, USA

## Summary

Motivated by analysis of genetical genomics data, we introduce a sparse high dimensional multivariate regression model for studying conditional independence relationships among a set of genes adjusting for possible genetic effects. The precision matrix in the model specifies a covariate-adjusted Gaussian graph, which presents the conditional dependence structure of gene expression after the confounding genetic effects on gene expression are taken into account. We present a covariate-adjusted precision matrix estimation method using a constrained $\ell_{1}$ minimization, which can be easily implemented by linear programming. Asymptotic convergence rates in various matrix norms and sign consistency are established for the estimators of the regression coefficients and the precision matrix, allowing both the number of genes and the number of the genetic variants to diverge. Simulation shows that the proposed method results in significant improvements in both precision matrix estimation and graphical structure selection when compared to the standard Gaussian graphical model assuming constant means. The proposed method is also applied to analyze a yeast genetical genomics data for the identification of the gene network among a set of genes in the mitogen-activated protein kinase pathway.

## Keywords

Constrained $l_{1}$ penalization; Gaussian graphical model; high-dimensionality; multivariate regression

## 1. Introduction

Genetical genomics experiments measure both genetic variants and gene expression data on the same subjects. Such data have provided important insights into gene expression
regulations in both model organisms and humans (Brem \& Kruglyak, 2005; Cheung \&
Spielman, 2002). For a given gene, a typical analysis of such data sets is to identify the genetic loci or single nucleotide polymorphisms that are linked or associated with the expression level of this gene. Depending on the locations of the genetic variants, they are often classified as distal trans-linked loci or proximal cis-linked loci. However, the genetic architecture for many gene expressions may be complex due to possible multiple genetic effects and gene-gene interactions, and poorly estimated genetic architecture may compromise inference on the dependency structures of genes at the transcriptional level. Although a single gene analysis can be effective in identifying the associated genetic variants, gene expressions of many genes are highly correlated due to either shared genetic variants or other unmeasured common regulators. One important biological problem is to study the conditional independence among these genes at the expression level.

Gaussian graphical models have been applied to infer the relationship between genes at the transcriptional level (Segal et al., 2005; Li \& Gui, 2006; Peng et al., 2009a), where the precision matrix for multivariate normal data has an interpretation of conditional dependence. Compared with marginal dependence, conditional dependence can capture the direct "link" between two variables when other variables are conditioned on. Since the gene expression variation of a gene can usually be explained by a small subset of other genes, the precision matrix for gene expression data is expected to be sparse. Estimation of highdimensional Gaussian graphical models has been an active area of research in recent years. Meinshausen \& Buhlmann (2006) proposed a neighborhood selection procedure by identifying edges for each node in the graph using $\ell_{1}$ penalized regression. This approach reduces the graphical model estimation problem to a collection of separate high dimensional variable selection problems that have been well studied. Estimation of the precision matrix and the graphical structure can also be obtained through a penalized maximum likelihood approach, see, for example, Friedman et al. (2008), Rothman et al. (2008) and Yuan \& Lin (2007). Friedman et al. (2008) proposed a fast block coordinate descent algorithm to solve the penalized likelihood maximization problem. Cai et al. (2011) proposed a constrained $l_{1}$ minimization estimator for precision matrix and obtained the results on convergence rates and sign consistency.

Although a direct application of the Gaussian graphical model to gene expression data alone provides some insights into gene regulation at the expression level, it ignores the effects of genetic variants on gene expression. One important observation from many genetical genomics experiments is that the gene expression level of many genes is inheritable and can be partially explained by genetic variation (Brem \& Kruglyak, 2005; Cheung \& Spielman, 2002). Since some genetic variants have effects on the expression of multiple genes and therefore may serve as confounders while detecting the association between the genes, ignoring the effects of genetic variants on the gene expression levels can lead to both false positive and false negative associations in the gene network graph. The effect of genetic variants on gene expression therefore needs to be adjusted in estimating the high dimensional precision matrix.

The problem can be formulated as joint estimation of multiple regression coefficients and precision matrix. Most of the available approaches use a group-wise regularization term
where the multiple regressions can be fitted jointly (Turlach et al., 2005; Peng et al., 2009b; Obozinski et al., 2011). Rothman et al. (2010) focuse on improving estimation of regression co-efficients by incorporating the covariance information. Similarly, Yin \& Li (2011) proposed a penalized estimation method for sparse conditional Gaussian graphical model that iteratively estimates the regression coefficients and precision matrix. Li et al. (2012) developed a method that is based on a combination of kernel-based estimate of the means and regularized estimate of the precision matrix.

In this paper, we present a two-stage constrained $\ell_{1}$ minimization approach for covariateadjusted precision matrix estimation, where we use a constrained $\ell_{1}$ minimization approach to first estimate the regression coefficient matrix and then estimate the precision matrix using the estimated regression coefficients in the first stage. Different from the approaches of Rothman et al. (2010) and Yin \& Li (2011), our approach does not make the multivariate normal assumption on the error distribution. The method can be easily implemented by linear programming. An R package of our method has been developed and is available on the CRAN (http://cran.r-project.org/). We provide the rates of convergence and the estimation bounds for the estimates of both the regression coefficient matrix and the precision matrix in various matrix norms, allowing both the number of the covariates and the number of the response variables to diverge as the sample size approaches infinity. In addition, a simple thresholding on the estimated precision matrix is proposed to recover the support of the covariate-adjusted precision matrix and is shown to provide consistent support recovery. The method is applied to a yeast genetical genomics data to demonstrate its application.

## 2. Two-stage Covariate-Adjusted Precision Matrix Estimation

### 2.1. Covariate Adjusted Gaussian Graphical Model

We consider a genetical genomics experiment. Let $y=\left(y_{1}, \ldots, y_{p}\right)^{\mathrm{T}}$ denote the random vector of expression levels for $p$ genes, $x=\left(x_{1}, \ldots, x_{q}\right)^{\mathrm{T}}$ denote the random vector of the numerical values of $q$ genetic markers. We consider the following multivariate regression model

$$
\begin{equation*}
y=\Gamma_{0} x+z \tag{1}
\end{equation*}
$$

where $\Gamma_{0}$ is a $p \times q$ unknown coefficient matrix, $z$ is a $p \times 1$ random vector with mean zero, covariance matrix $\sum_{0}=\left(\sigma_{i j}^{0}\right)$ and precision matrix $\Omega_{0}=\left(\omega_{i j}^{0}\right)=\sum_{0}^{-1}$. We assume that $x$ and $Z$ are independent and we have $n$ independent identically distributed observations ( $x_{k}, y_{k}$ ) ( $k=$ $1, \ldots, n$ ) from (1).

In genetical genomics data, each row of $\Gamma_{0}$ is assumed to be sparse since each gene is expected to have only a few genetic regulators. The precision matrix $\Omega_{0}$ is also expected to be sparse, since typical genetic networks have limited links. If $z$ follows a multivariate normal distribution, the conditional independence of $z_{i}$ and $z_{j}$ is equivalent to $\omega_{i j}=0$ and the matrix $\Omega_{0}$ has an interpretation of conditional dependence and can be used to construct a
conditional dependence graph. To be more specific, let $G=(V, E)$ be a graph representing conditional independence relations between the components of $y$. The vertex set $V$ has $p$ components $y_{1}, \ldots, y_{p}$ and the edge set $E$ consists of pairs $(i, j)$, where $(i, j) \in E$ if there is an edge between $y_{i}$ and $y_{j}$. The edge between $y_{i}$ and $y_{j}$ is excluded from $E$ if and only if $z_{i}$ and $z_{j}$ are independent given all other $z_{k}$ 's $(k \neq i, j)$. We are interested in detecting the non-zero entries of $\Omega_{0}$ in order to construct a conditional independence graph for $y$ after the effects of the covariates $x$ on $y$ are adjusted. Such a graphical model is called the covariate-adjusted Gaussian graphical model.

Estimation of $\Gamma_{0}$ in (1) in high dimensional setting, where $p$ and $q$ can be larger than $n$, has been extensively studied. Most of the available approaches use a group-wise regularization term where the $p$ regressions can be fitted jointly (Turlach et al., 2005; Peng et al., 2009b; Obozinski et al., 2011). Rothman et al. (2010) and Yin \& Li (2011) developed $\ell_{1}$-penalized estimation methods that iteratively estimate $\Gamma_{0}$ and $\Omega_{0}$. Rothman et al. (2010) focus on improving estimation of $\Gamma_{0}$ by incorporating $\Omega_{0}$. The work of Yin \& Li (2011) aims to improve the estimate of $\Omega_{0}$ after the effects of the covariates on the means are taken into account, which is also the focus of the present paper.

### 2.2. Estimation of $\Gamma_{0}$

When $q=1$, many methods have been developed for estimation of $\Gamma_{0}$, including the methods based on the $\ell_{1}$ minimization (Tibshirani, 1996) and the Dantzig selector (Candès \& Tao, 2007). We propose to develop a method for estimating $\Gamma_{0}$ using a constrained $\ell_{1}$ minimization that can be treated as a multivariate extension of the Dantzig selector. For a matrix $A=\left(a_{i j}\right) \in \mathbb{R}^{p \times q}$, define the element-wise $\ell_{1}$ norm by $|A|_{1}=\sum_{i=1}^{p} \sum_{j=1}^{q}\left|a_{i j}\right|$ and the element-wise $l_{\infty}$ norm by $/ A / /_{\infty}=\max _{i, j} / a_{i j} /$.

Let $\bar{y}=n^{-1} \sum_{k=1}^{n} y_{k}, \bar{x}=n^{-1} \sum_{k=1}^{n} x_{k}, \bar{z}=n^{-1} \sum_{k=1}^{n} z_{k}$. Then

$$
\begin{equation*}
y_{k}-\bar{y}=\Gamma_{0}\left(x_{k}-\bar{x}\right)+z_{k}-\bar{z} . \tag{2}
\end{equation*}
$$

Set $S_{x y}=n^{-1} \sum_{k=1}^{n}\left(y_{k}-\bar{y}\right)\left(x_{k}-\bar{x}\right)^{\mathrm{T}}$ and $S_{x x}=n^{-1} \sum_{k=1}^{n}\left(x_{k}-\bar{x}\right)\left(x_{k}-\bar{x}\right)^{\mathrm{T}}$. We propose to estimate $\Gamma_{0}$ by the solution to the following the optimization problem:

$$
\begin{equation*}
\hat{\Gamma} \in \underset{\Gamma \in R^{p \times q}}{\arg \min }\left\{|\Gamma|_{1}:\left|S_{x y}-\Gamma S_{x x}\right|_{\infty} \leq \lambda_{n}\right\}, \tag{3}
\end{equation*}
$$

where $\lambda_{n}$ is a tuning parameter. This optimization problem is equivalent to the following $p$ optimization problems:

$$
\begin{equation*}
\min \left|\gamma_{i}\right|_{1}, \text { subject to }\left|S_{x y, i}-\gamma_{i}^{\mathrm{T}} S_{x x}\right|_{\infty} \leq \lambda_{n} \quad(i=1, \ldots, p) \tag{4}
\end{equation*}
$$

where $\Gamma=\left(\gamma_{1}, \ldots, \gamma_{p}\right)^{\mathrm{T}}$ and $S_{x y}=\left(S_{x y, 1}, \ldots, S_{x y, p}\right)^{\mathrm{T}}$. This is exactly the Dantzig selector formulation in the usual regression analysis for the $i$ th regression and its solution can therefore be obtained by solving the corresponding linear programming problem. This simple observation is useful for the implementation and technical analysis. In this paper and the R package we developed, the procedure is implemented by a linear programming optimization using the primal dual and interior point algorithm.

### 2.3. Estimation of $\Omega_{0}$

After plugging the estimator $\hat{\Gamma}$ given in (3) into equation (2), we can estimate $\Omega_{0}$ by the method of constrained $\ell_{1}$-minimization proposed in Cai et al. (2011). Let

$$
S_{y y}=\frac{1}{n} \sum_{k=1}^{n}\left(y_{k}-\hat{\Gamma} x_{k}\right)\left(y_{k}-\hat{\Gamma} x_{k}\right)^{\mathrm{T}}
$$

The precision matrix $\Omega_{0}$ is then estimated by the solution to the optimization problem

$$
\begin{equation*}
\hat{\Omega}_{1} \in \underset{\Omega \in R^{p \times p}}{\arg \min }\left\{|\Omega|_{1}:\left|I_{p \times p}-S_{y y} \Omega\right|_{\infty} \leq \tau_{n}\right\}, \tag{5}
\end{equation*}
$$

where $\tau_{n}$ is a tuning parameter. Let $\hat{\Omega}_{1}=\left(\hat{\omega}_{i j}^{1}\right)$ be a solution to (5). This constrained $\ell_{1}$ minimization approach is the same as the one proposed in Cai et al. (2011), except that $S_{y y}$ depends on the estimated coefficient matrix $\hat{\Gamma}$. Since no symmetry condition on $\hat{\Omega}_{1}$ is imposed, as a result, the solution may not be symmetrical in general. The final estimator of $\Omega_{0}$, denoted by $\hat{\Omega}=\left(\hat{\omega_{i j}}\right)$, is obtained by symmetrizing the estimator as follows:

$$
\begin{equation*}
\hat{\Omega}=\left(\hat{\omega}_{i j}\right), \text { where } \hat{\omega}_{i j}=\hat{\omega}_{j i}=\hat{\omega}_{i j}^{1} I\left(\left|\hat{\omega}_{i j}^{1}\right| \leq\left|\hat{\omega}_{j i}^{1}\right|\right)+\hat{\omega}_{j i}^{1} I\left(\left|\hat{\omega}_{i j}^{1}\right|>\left|\hat{\omega}_{j i}^{1}\right|\right) \text {, } \tag{6}
\end{equation*}
$$

where $I(\cdot)$ is the indicator function. As in (4), the problem (5) can be decomposed into $p$ optimization problems. For $i=1, \ldots, p$, let $\hat{\omega_{i}}$ be the solution of the convex optimization problem

$$
\begin{equation*}
\min \left|\omega_{i}\right|_{1} \text { subject to }\left|e_{i}-S_{y y} \omega_{i}\right|_{\infty} \leq \tau_{n} \tag{7}
\end{equation*}
$$

where $\omega_{i}$ is a vector in $\mathbb{R}^{p}, e_{i}$ is a standard unit vector in $\mathbb{R}^{p}$ with 1 in the $i$-th coordinate and 0 in all other coordinates. This can also be solved using the primal dual and interior point algorithm.

### 2.4. Tuning parameter selection

Two tuning parameters $\lambda_{n}$ and $\tau_{n}$ need to be selected. We tune these two parameters together via a $L$-fold cross-validation, where the Bregman divergence can be use to measure the
model fit. Specifically, we divide all the samples in the training dataset into $L$ disjoint subgroups, also known as folds, and denote the index of subjects in the 1 th fold by $T_{l}$ for $l=$ $1, \ldots, L$. The $L$-fold cross-validation score is defined as

$$
\operatorname{CV}\left(\lambda_{n}, \tau_{n}\right)=\sum_{l=1}^{L}\left[\log \operatorname{det}\left\{\hat{\Omega}_{-l}\left(\lambda_{n}, \tau_{n}\right)\right\}-\operatorname{tr}\left\{S_{y y l} \hat{\Omega}_{-l}\left(\lambda_{n}, \tau_{n}\right)\right\}\right]:
$$

where $n_{l}$ is the size of the $l$ th fold $T_{l}$ and

$$
S_{y y l}=n_{l}^{-1} \sum_{k=1}^{n_{l}}\left\{y_{k}-\hat{\Gamma}_{-l}\left(\lambda_{n}\right) x_{k}\right\}\left\{y_{k}-\hat{\Gamma}_{-l}\left(\lambda_{n}\right) x_{k}\right\}^{\mathrm{T}}
$$

with $\hat{\Omega}_{-\Lambda}\left(\boldsymbol{\lambda}_{n}, \boldsymbol{\tau}_{n}\right)$ and $\hat{\Gamma}_{-\wedge}\left(\boldsymbol{\lambda}_{n}\right)$ being the estimates of based on the sample $\left(\cup_{l=1}^{L} T_{l}\right) \backslash T_{l}$ with $\boldsymbol{\lambda}_{n}$ and $\tau_{n}$ as the tuning parameters. Then, we choose $\left(\lambda_{n}^{*}, \tau_{n}^{*}\right)=\operatorname{agrmax} \operatorname{CV}\left(\lambda_{n}, \tau_{n}\right)$ as the best tuning parameters, which are used to obtain the final estimates of the regression coefficients and precision matrix based on the whole training set. Here the maximization of $\operatorname{CV}\left(\boldsymbol{\lambda}_{n}, \boldsymbol{\tau}_{n}\right)$ with respect to $\left(\lambda_{n}, \tau_{n}\right)$ is achieved via a grid search.

## 3. Rates of Convergence of the Estimators

### 3.1. Convergence rates of $\hat{\Gamma}-\Gamma_{0}$

In this section, we present theoretical properties of the estimators $\hat{\Gamma}$ and $\hat{\Omega}$. We first introduce the matrix norms used in the rest of the paper. For a matrix $A=\left(a_{i j}\right) \in \mathbb{R}^{p \times q}$, define the spectral norm as $\|A\|_{2}=\max _{/ x_{2}=1 / A x / 2}$, the matrix $L_{\infty}$ norm as
$\|A\|_{L_{\infty}}=\max _{1 \leq i \leq p} \sum_{j=1}^{q} \mid a_{i j}$, and the Frobenius norm as $\|A\|_{F}=\left(\sum_{i, j} a_{i j}^{2}\right)^{1 / 2}$. The notation $A>0$ means that $A$ is positive definite. Write $x=\left(x_{1}, \ldots, x_{q}\right)^{\mathrm{T}}, z=\left(z_{1}, \ldots, z_{p}\right)^{\mathrm{T}}$ and $u=$ $z^{\mathrm{T}} \Omega_{0}=\left(u_{1}, \ldots, u_{p}\right)$. The following conditions are needed for establishing the rate of convergence.
(A1) Let $\log (p \wedge q)=o(n)$. Suppose that there exist some $\eta>0$ and $K>0$ such that

$$
E\left\{\exp \left(\eta x_{i}^{2}\right)\right\} \leq K, \quad E\left\{\exp \left(\eta z_{j}^{2} / \sigma_{j j}^{0}\right)\right\} \leq K, \quad E\left\{\exp \left(\eta u_{j}^{2} / \omega_{j j}^{0}\right)\right\} \leq K
$$

for all $i=1, \ldots, q$ and $j=1, \ldots, p$. Furthermore, $\max _{1 \leq j \leq p} \sigma_{j, j}^{0} \leq K$.
(A2) The regression coefficient matrix $\Gamma_{0}$ belongs to the following class with $0 \leq \delta_{1}<$ 1 :

$$
\mathscr{V}_{\delta_{1}}=\mathscr{V}_{\delta_{1}}\left\{s_{1}(q)\right\}=\left\{\Gamma \in \mathbb{R}^{p \times q}: \max _{1 \leq i \leq p} \sum_{j=1}^{q}\left|\gamma_{i j}\right|^{\delta_{1}} \leq s_{1}(q)\right\} .
$$

> (A3) The precision matrix $\Omega_{0}=\left(\omega_{i j}^{0}\right)_{p \times q}$ belongs to the following class with $0 \leq \delta_{2}<$ 1: $\mathscr{U}_{\delta_{2}}=\mathscr{U}_{\delta_{2}}\left\{s_{2}(p)\right\}=\left\{\Omega \succ 0:\|\Omega\|_{L_{\infty}} \leq M_{p}, \quad \max _{1 \leq i \leq p} \sum_{j=1}^{p}\left|\omega_{i j}\right|^{\delta_{2}} \leq s_{2}(p), \lambda_{\max }(\Omega) / \lambda_{\min }(\Omega) \leq C_{0}\right\}$.
(A4)
There exists some $N_{q}>0$ such that the matrix $l_{\infty}$ norm of $\sum_{x}^{-1}$ satisfies

$$
\left\|\sum_{x}^{-1}\right\|_{L_{\infty}} \leq N_{q}, \text { where } \Sigma_{X}=\operatorname{cov}(x)
$$

Condition (A1) is a sub-Gaussian condition on $x, z$ and $z^{T} \Omega_{0}$, where the variance of $u_{j}$ is $\omega_{j i}^{0}$. The dimensions $p$ and $q$ are of the order $\exp \{o(n)\}$. Conditions (A2) and (A3) assume the uniformity class of matrices for the regression coefficient matrix and the precision matrix, where $\mathscr{V}_{0}$ and $\mathscr{U}_{0}$ are classes of matrices with the sparsity measurements of $s_{1}(q)$ and $s_{2}(p)$, respectively. Similar parameter spaces have also been used in Bickel \& Levina (2008) and Cai et al. (2011). Conditions (A2) and (A3) also bound the matrix $L_{\infty}$ norm of $\Gamma_{0}$ and $\Omega_{0}$. Finally, condition (A4) bounds the matrix $L_{\infty}$ norm of the inverse covariance matrix of $x$.

The estimation error $\hat{\Gamma}-\Gamma_{0}$ can be measured by different matrix norms: the matrix $L_{\infty}$ norm, the Frobenius norm and the entry-wise $l_{\infty}$ norm. The matrix $L_{\infty}$ norm measures the accuracy of the estimation of $\Gamma_{0}$. The Frobenius norm is also a reasonable measure on the accuracy of the estimation of $\Gamma_{0}$ and can be viewed as the sum of squared errors for estimating individual rows. The element-wise $\ell_{\infty}$ norm can be used to recover the support of $\Gamma_{0}$ by a further thresholding step. We have the following rates of convergence for the estimator $\hat{\Gamma}$ in matrix $L_{\infty}$ and the Frobenius norm.

Theorem 1—Suppose (A1), (A2) and (A4) hold. Let $\Gamma_{0} \in \mathscr{V}_{\delta_{1}}$ and $\lambda_{n}=C_{1}[\{\log (p q)\} /$ $n]^{1 / 2}$, where $C_{1}>0$ is a sufficiently large constant. If

$$
\begin{equation*}
s_{1}(q)=o\left[N_{q}^{\delta_{1}-1}\left\{\frac{n}{\log (p q)}\right\}^{\left(1-\delta_{1}\right) / 2}\right] \tag{8}
\end{equation*}
$$

then with probability greater than $1-O\left\{(p q)^{-1}\right\}$, we have

$$
\begin{equation*}
\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}} \leq C N_{q}^{1-\delta_{1}} s_{1}(q)\left\{\frac{\log (p q)}{n}\right\}^{\left(1-\delta_{1}\right) / 2} \tag{9}
\end{equation*}
$$

and

$$
\begin{equation*}
\frac{1}{p}\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{F}^{2} \leq C N_{q}^{2-\delta_{1}} s_{1}(q)\left\{\frac{\log (p q)}{n}\right\}^{1-\delta_{1} / 2} \tag{10}
\end{equation*}
$$

for some constant $C>0$.

Theorem 1 shows that the regression coefficients matrix $\Gamma_{0}$ can be estimated consistently under the Frobenius norm if the sparsity $s_{1}(q)$ of $\Gamma_{0}$ is of order $o\left[N_{q}^{\delta_{1}-2}\{n / \log (p q)\}^{1-\delta_{1} / 2}\right]$. The requirement on the dimensions $p$ and $q$ is mild as they only appear in the logarithmic term. To see this, if $s_{1}(q)=O\left(n^{r 1}\right)$ for some $r_{1}<1-\delta_{1} / 2$ and $N_{q}$ is bounded, then $p$ and $q$ can be as large as $\exp \left(n^{I 2}\right)$ for some $r_{2}<1-\delta_{1} / 2-r_{1}$.

Theorem 2—Under the conditions of Theorem 1, with probability greater than 1 $O\left\{(p q)^{-1}\right\}$, we have

$$
\begin{equation*}
\left|\hat{\Gamma}-\Gamma_{0}\right|_{\infty} \leq C_{0} N_{q}\left\{\frac{\log (p q)}{n}\right\}^{1 / 2} \tag{11}
\end{equation*}
$$

for some constant $C_{0}>0$.
The rate under the element-wise $l_{\infty}$ norm is critical to the support recovery. Define $\tilde{\Gamma}_{t h r}=$ $\left(\tilde{\gamma}_{i j}\right)$ with

$$
\tilde{\gamma}_{i j}=\hat{\gamma}_{i j} I\left[\left|\hat{\gamma}_{i j}\right| \geq C_{0} N_{q}\left\{\frac{\log (p q)}{n}\right\}^{1 / 2}\right]
$$

where $\left(\hat{\gamma}_{i j}\right)=\hat{\Gamma}$. Let $S\left(\Gamma_{0}\right)=\left\{(i, j): \gamma_{i j}^{0} \neq 0\right\}$ be the true support of the coefficient matrix $\Gamma_{0}$ and $\gamma_{\text {min }}=\min _{(i, j) \in S\left(\Gamma_{0}\right)}\left|\gamma_{i j}\right|$.

Theorem 3-Suppose the conditions in Theorem 1 hold and

$$
\begin{equation*}
\gamma_{\min } \geq 2 C_{0} N_{q}\left\{\frac{\log (p q)}{n}\right\}^{1 / 2} \tag{12}
\end{equation*}
$$

then with probability greater than $1-O\left\{(p q)^{-1}\right\}$, we have $S\left(\tilde{\Gamma}_{t h r}\right)=S\left(\Gamma_{0}\right)$.
The lower bound condition (12) requires that the magnitude of the non-zero entries in $\Gamma_{0}$ cannot be too small in order to recover the support.

### 3.2. Convergence rates of $\hat{\Omega}-\Omega_{0}$

We consider the rate of $\hat{\Omega}-\Omega_{0}$ under the spectral norm and the element-wise $l_{\infty}$ norm. The rate under the spectral norm is important because it can lead to the consistency of the estimation of eigenvalues and eigenvectors and it is essentially needed in developing theoretical properties for various statistical inference problems when the estimator of the precision matrix is used.

Theorem 4-Suppose (A1) - (A4) and (8) hold. Let $\Gamma_{0} \in \mathscr{V}_{\delta_{1}}, \Omega_{0} \in \mathscr{U}_{\delta_{2}}$ and

$$
\begin{equation*}
s_{1}(q) \leq C\left(1+M_{p}\right)^{-1} N_{q}^{-2+\delta_{1}}\left\{\frac{n}{\log (p q)}\right\}^{\left(1-\delta_{1}\right) / 2} \tag{13}
\end{equation*}
$$

Let $\tau_{n}=C_{2}[\{\log (p q)\} / n]^{1 / 2}$, where $C_{2}>0$ is a sufficiently large constant. Then with probability greater than $1-O\left\{(p q)^{-1}\right\}$, we have

$$
\begin{equation*}
\left\|\hat{\Omega}-\Omega_{0}\right\|_{2} \leq C M_{p}^{1-\delta_{2}} s_{2}(p)\left\{\frac{\log (p q)}{n}\right\}^{\left(1-\delta_{2}\right) / 2} \tag{14}
\end{equation*}
$$

for some constant $C>0$.

The condition (13) on the sparsity $s_{1}(q)$ of $\Gamma_{0}$ ensures that $\Gamma_{0}$ can be well estimated with certain rate so that $y-\hat{\Gamma}_{0} x$ can be used to replace the oracle one $y-\Gamma_{0} x$. The convergence rate in (14) is optimal. In fact, as shown in an unpublished 2010 technical report available from the first author, even if $\Gamma_{0}=0$ or is known in advance, the minimax optimal rate of estimation of $\Omega_{0}$ is still $O\left\{M_{p}^{1-\delta_{2}} s_{2}(p)(\log p / n)^{\left(1-\delta_{2}\right) / 2}\right\}$. If $q=O(p)$, then the rate in (14) is the same as the oracle optimal rate and thus is also optimal.

The next theorem shows the convergence rate under the element-wise $l_{\infty}$ norm, which is useful for the recovery of the support of $\Omega$.

Theorem 5—If (A1) - (A4) and (8) hold, we have with probability greater than 1 $O\left\{(p q)^{-1}\right\}$,

$$
\begin{equation*}
\left|\hat{\Omega}-\Omega_{0}\right|_{\infty} \leq C M_{p}\left\{\frac{\log (p q)}{n}\right\}^{1 / 2} \tag{15}
\end{equation*}
$$

where $C>0$ is a constant.
The proofs of these two theorems are given in the Appendix. The key is to account for the estimation error and uncertainty of $\hat{\Gamma}_{0}$ in evaluating the estimation error of $\hat{\Omega}_{0}$. This is in contrast to the estimation of $\Omega_{0}$ in Cai et al. (2011) when $\Gamma_{0}$ is assumed to be zero. As shown
in an unpublished 2010 technical report available from the first author, the minimax optimal rate under the element-wise $l_{\infty}$ norm for estimating the precision matrix is $O\left\{M_{p}(\log p /\right.$ $\left.n)^{1 / 2}\right\}$ when $\Gamma_{0}=0$ or is known. Hence covariate-adjusted $\ell_{1}$ minimization can achieve the same optimal rate as the case that $\Gamma_{0}$ is known.

## 4. Graphical Model Selection Consistency

When the error term $z$ in (1) is assumed to follow $N\left(0, \Omega_{0}^{-1}\right)$, recovery of the support of the precision matrix $\Omega_{0}$ is closely related to the covariate-adjusted graphical model selection. When $\Gamma_{0}=0$, the problem reduces to Gaussian graphical model selection. We consider the setting when $\Omega_{0}$ belongs to $\mathscr{U}_{0}$ and are interested in estimating the support of $\Omega_{0}$,
$S\left(\Omega_{0}\right)=\left\{(i, j): \omega_{i j}^{0} \neq 0\right\}$ when $\Gamma_{0} \neq 0$. Define $\theta_{\min }=\min _{(i, j) \in S\left(\Omega_{0}\right)}\left|\omega_{i j}^{0}\right|$. As long as $\theta_{\min } \geq$
$2 M_{p} \tau_{n}$, using the rate under the element-wise $l_{\infty}$ norm given in Theorem 5, we have following result.

## Theorem 6

Suppose (A1) - (A4) and (8) hold. Further suppose that $\theta_{\min }>2 M_{p} \tau_{n}$. Then for all $\omega_{i j} \neq 0$, the probability of $\hat{\omega}_{i j} \neq 0$ tends to one.

Sign consistency can be achieved by further thresholding the entries of $\hat{\Omega}$. Let

$$
\hat{\Omega}_{r}=\left(\hat{\omega}_{i j}^{r}\right), \quad \hat{\omega}_{i j}^{r}=\hat{\omega}_{i j} I\left(\left|\hat{\omega}_{i j}\right| \geq \tau_{n}^{\prime}\right)
$$

where $\tau_{n}^{\prime}$ is a tuning parameter which will be specified later. Define
$\Psi=\left\{\operatorname{sign}\left(\omega_{i j}^{0}\right): i=1, \ldots, p, j=1, \ldots, p\right\}$ and $\hat{\Psi}=\left\{\operatorname{sign}\left(\hat{\omega}_{i j}^{r}\right): i=1, \ldots, p, j=1, \ldots, p\right\}$ be the vector of the signs of the elements of the true and the estimated precision matrix, where $\operatorname{sign}(\mathrm{t})$ is defined as

$$
\operatorname{sign}(\mathrm{t})=\left\{\begin{array}{cc}
1, & t>0, \\
0, & t=0, \\
-1, & t<0
\end{array}\right.
$$

We have the following theorem on sign consistency of the estimator $\hat{\Psi}$, i.e., the estimator not only recovers the sparsity pattern of $\Omega_{0}$, but also recovers the signs of the nonzero elements.

## Theorem 7

Let $\tau_{n}^{\prime}=4 M_{p} \tau_{n}$. Suppose that $\theta_{\min }>2 \tau_{n}^{\prime}$. Then under the conditions of Theorem 4, as $n$ and $p$ tend to infinity, we have with probability tending to one, $\hat{\Psi}=\Psi$.

Theorem 7 shows that the support of $\Omega_{0}$ can be recovered exactly if the minimum of the nonzero entries in $\Omega_{0}$ has a lower bound that is not too small. The lower bound condition is necessary in order to recover the support exactly. In fact, as shown in an unpublished 2010
technical report available from the first author, suppose that $\Gamma_{0}=0$ or is known in advance, if
$\theta_{\min } \leq c \tau_{n}^{\prime}$ for a sufficiently small constant $c>0$, then for any estimator of $\Omega_{0}$, it is not possible to recover the support exactly uniformly over the class of $s_{2}(p)$ sparse precision matrices.

In practice, since the estimator obtained from (6) is already sparse, we do not further threshold the estimator. Although the sign consistency cannot be guaranteed, under weaker conditions, we can still get an estimator with its properties stated in Theorem 6.

## 5. Simulation Results

In this section simulation studies are carried out to evaluate the numerical performance of the proposed procedure and to compare it with other methods for precision matrix estimation and support recovery. Four models are considered with their dimensions and sample size $p$, $q, n, \operatorname{pr}\left(\Gamma_{i j} \neq 0\right)$ and $\operatorname{pr}\left(\Omega_{i j} \neq 0, i \neq j\right)$ presented in Table 1. For each model, we generate a $p \times$ $q$ coefficient matrix $\Gamma$ and a $p \times p$ precision matrix $\Omega$ with $\operatorname{pr}\left(\Gamma_{i j} \neq 0\right)$ and $\operatorname{pr}\left(\Omega_{i j} \neq 0 / i \neq j\right)$ shown in Table 1. If $\Gamma_{i j} \neq 0$ or $\Omega_{i j} \neq 0(i \neq j)$, we generate $\Gamma_{i j}$ or $\Omega_{i j}(i \neq j)$ from $\operatorname{Unif}([0.5,1]$ $\mathrm{U}[1,0.5])$. The diagonal of $\Omega$ is set to be a common value so that the condition number of $\Omega$ is equal to $p$. This is to make sure that $\Omega$ is positive definite and invertible. Let $\Sigma=\Omega^{-1}$. We generate $n \times q$ design matrix $X$ and a $n \times p$ random error matrix so that $X_{i j}$ and $Z_{i j}$ independently follow $\mathrm{N}(0,1)$ distribution. The $n \times p$ outcome matrix is set to be $Y=X \Gamma+$ $\pi \Sigma^{1 / 2}$ 。

Model 1 has small values of $p$ and $q$ and is considered to mimic the applications on finding small-scale gene regulatory pathways or constructing networks in social sciences. Models 24 have moderate or large $p$ and $q$, simulating the settings in most genomic applications.

The performance of our proposed method is compared with several other methods, including those of Cai et al. (2011) and Friedman et al. (2008) that ignore the covariate effects and that of Yin \& Li (2011). For all these estimators, the tuning parameters are chosen using five-fold cross validation by maximizing the cross-validated log-likelihood function,

$$
\log \operatorname{det}(\Omega)-\operatorname{tr}\left(S_{y y} \Omega\right)
$$

where $S_{y y}=n^{-1} \sum_{k=1}^{n}\left(y_{k}-\bar{y}\right)\left(y_{k}-\bar{y}\right)^{\mathrm{T}}$ for the methods of Cai et al. (2011) and Friedman et al. (2008), and $S_{y y}=n^{-1} \sum_{k=1}^{n}\left(y_{k}-\hat{\Gamma} x_{k}\right)\left(y_{k}-\hat{\Gamma} x_{k}\right)^{\mathrm{T}}$ for our method and that of Yin \& Li (2011), with $\hat{\Gamma}$ computed from the training data set. The final estimates are obtained using the chosen tuning parameters on the full data sets. No extra thresholding is applied to the estimators.

Several different measures are used to compare the performance of these estimators. The estimation error $\hat{\Omega}-\Omega$ is evaluated in terms of the spectral norm, Frobenius norm and $\ell_{1}$ norm. The graph structure recovery is evaluated by the mis-specification rate, specificity, sensitivity and Matthews correlation coefficient, which are defined as the following:

$$
\begin{gathered}
\operatorname{MISR}\left(\Omega_{0}, \hat{\Omega}\right)=\frac{\mathrm{FN}+\mathrm{FP}}{p(p-1)}, \quad \mathrm{SPE}=\frac{\mathrm{TN}}{\mathrm{TN}+\mathrm{FP}}, \quad \mathrm{SEN}=\frac{\mathrm{TP}}{\mathrm{TP}+\mathrm{FN}}, \\
\mathrm{MCC}=\frac{\mathrm{TP}-\mathrm{FP} \times \mathrm{FN}}{\{(\mathrm{TP}+\mathrm{FP})(\mathrm{TP}+\mathrm{FN})(\mathrm{TN}+\mathrm{FP})(\mathrm{TN}+\mathrm{FN})\}^{1 / 2}} .
\end{gathered}
$$

Here, TP, TN, FP, FN are the numbers of true positives, true negatives, false positives and false negatives, respectively, where true positives are the non-zero entries of the nondiagonal elements of $\Omega$. The performances over 50 replications are reported in Tables 2 and 3.

For the estimation error (Table 2), when $\log (p q) / n$ is small or moderate as in Models 1 and 2, the performance of our method is comparable to that of the method in Yin \& Li (2011). As $\log (p q) / n$ increases, the proposed estimator has the smallest estimation errors. In terms of graph structure recovery (Table 3), adjusting for covariates yields better performance in general as shown by the proposed method and the method of Yin \& Li (2011). Our procedure performs better than the other methods for Models 2-4, and it has a comparable performance as the method of Yin \& Li (2011) for Model 1.

The results presented in Tables 2 and 3 depend on the tuning parameters, which are selected by 5 -fold cross-validation for all the estimators. To further compare the performance on graph structure recovery, we obtain the receiver operating characteristic curve for each simulated dataset by varying the turning parameter $\boldsymbol{\tau}_{n}$. The tuning parameter for the regression coefficients, $\boldsymbol{\lambda}_{n}$, for our method and that of Yin $\& \mathrm{Li}$ (2011) is fixed at the value selected by the cross validation. Figure 1 shows the receiver operating characteristic curves averaged over 50 replications. Our method has a comparable performance with that of Yin \& Li (2011) for Model 1 and has better performance in the other models. Figure 1 also demonstrates that without adjusting for the covariate effects, existing precision matrix estimation methods perform poorly in terms of support recovery. The value of $\log (p q) / n$ is the key factor that determines the performance of these methods. When it is large as in Model 3, all the methods perform rather poorly. In Model 4, the dimension of the parameters $p^{2}+p q$ is eleven times that of Model 3 and the sample size is only twice as large. However, since model 4 has a smaller $\log (p q) / n$ ratio, all methods have better performance than for Model 3.

## 6. Analysis of Yeast Data

We illustrate our method using the yeast genetical genomics data set generated by Brem \& Kruglyak (2005). The data set contains 112 yeast segregants grown from a cross involving BY4716 and wild isolate RM11-1a. RNA was isolated and cDNA was hybridized to microarrays with 6,216 yeast genes assayed on each array. Each of the 112 segregants were individually genotyped at 2,956 marker positions. Due to the small sample size and limited perturbation to the biological system, it is not possible to construct a gene network for all 6,216 genes. We instead focused our analysis on two sets of genes that are biologically relevant: the first set of 54 genes that belong to the yeast mitogen-activated protein kinase signaling pathway provided by the Kyoto Encyclopedia of Genes and Genomes database (Kanehisa et al., 2010), another set of 1,207 genes of the proteinprotein interaction network
obtained from a previously compiled set by Steffen et al. (2002) combined with protein physical interactions deposited in the Munich Information center for Protein Sequences (Mewes et al., 2002).

The first set of genes include 54 genes that belong to the yeast mitogen-activated protein kinase signaling pathway. Figure 2 displays the illustrative pathway structure, showing how yeast genes respond to different cellular signals. Some gene nodes such as Ste20, Ste11 and Ste7 appear in multiple locations on this pathway. This directed signaling pathway explains how yeast cells respond to different cellular signals.

To apply our method, we first select the genetic markers based on simple screening. There are 188 markers that are marginally associated with at least two of the 54 genes with $p$-value less than or equal to $0 \cdot 01$. A total of 702 such associations are observed, suggesting there is a large pool of possible confounders. We apply our method to this set of 54 genes and 188 markers and use 5 -fold cross validation to choose the tuning parameters as $\lambda=0.15$ and $\tau$ $=0 \cdot 24$. The covariate-adjusted estimation results in selecting 51 links among the 54 genes. In addition, the method identifies 597 non-zero entries for the coefficient matrix, indicating many gene expression levels are affected by genetic variants. There are 528 pairs of genes sharing at least one common genetic variant. Figure 3 shows the graph constructed by our method based on the estimated precision matrix. While we do not expect that the estimated conditional Gaussian graph can fully recover the true mitogen-activated protein kinase signaling pathway, we observe the estimated undirected graph indeed has biological meanings. For example, Fus1, Fus3, Ste12, Ste20, Ste18, Ste11, Dig2 and Cdc42 are linked together, suggesting strong interaction mechanism between these genes. These genes all involve in the yeast pheromone and mating process. In contrast, genes Sho1, Ste20, Ste11, Ctt 1 , Glo1, Ypd1 and Msn4 are linked since they all participate in osmolyte synthesis. Finally, genes Swi4, Bni1, Bck1 and Fks1 are linked due to their interaction in the cell wall remodeling process.

For comparison we also obtain the Gaussian graph estimated by constrained $l_{1}$ penalization of Cai et al. (2011) and the estimation of Friedman et al. (2008) without adjusting for the genetic effects on gene expressions. We use 5 -fold cross-validation to choose the tuning parameter for both methods, resulting $\lambda=0 \cdot 20$ and $\lambda=0 \cdot 15$, respectively. The method of Cai et al. (2011) identifies 146 links and the method of Friedman et al. (2008) identified 543 links. Both graphs include too many links and are hard to interpret biologically.

For the second data set, we analyze genes that belong to the yeast protein-protein interaction network (Steffen et al., 2002). We select 1,207 genes with variance greater than $0 \cdot 05$. Fivefold cross-validation chooses the tuning parameters as $\lambda=0 \cdot 15$ and $\tau=0 \cdot 20$, leading to an estimated covariate-adjusted Gaussian graph with 3,588 links out of 727,821 possible links. In contrast, the method of Friedman et al. (2008) identifies 25,117 links with an optimal tuning parameter $\lambda=0 \cdot 23$, and the method of Cai et al. (2011) identifies 5,983 links with the selected tuning parameter $\boldsymbol{\lambda}=0 \cdot 18$. Again, it seems that the covariate-adjusted Gaussian graphical model gives a sparser graph than the standard Gaussian graphical model when the genetic effects on gene expressions are ignored.

## 7. Extension

The two stage procedure introduced in this paper can be extended to yield an iterative procedure. For fixed tuning parameters $\lambda_{n}$ and $\boldsymbol{\tau}_{n}$, given the current estimate of $\Omega_{0}$, say $\hat{\Omega}_{0}$, one can estimate $\Gamma_{0}$ by solving the optimization problem

$$
\hat{\Gamma} \in \underset{\Gamma \in R^{p \times q}}{\arg \min }\left\{|\Gamma|_{1}:\left|S_{x \hat{\Omega}_{0} y}-\Gamma S_{x \hat{\Omega}_{0} x}\right|_{\infty} \leq \lambda_{n}\right\},
$$

where $S_{x \hat{\Omega}_{0} y}=n^{-1} \sum_{k=1}^{n}\left(y_{k}-\bar{y}\right) \hat{\Omega}_{0}^{-1}\left(x_{k}-\bar{x}\right)^{\mathrm{T}}$ and $S_{x \hat{\Omega}_{0} x}=n^{-1} \sum_{k=1}^{n}\left(x_{k}-\bar{x}\right) \hat{\Omega}_{0}^{-1}\left(x_{k}-\bar{x}\right)^{\mathrm{T}}$. One can then iteratively update $\Gamma_{0}$ and $\Omega_{0}$ until convergence. This however increases the computational time dramatically.

## Acknowledgments

This research is supported by NIH grants, an NSF grant, the startup fund from SJTU and a grant from the National Science Foundation of China. Xie thanks Dr. Axel Kholmeyer's help in organizing the cluster for computation.

## Appendix - Proofs of the Theorems

The first lemma is an exponential inequality from Cai \& Liu (2011) on the partial sums of independent random variables.

## Lemma 1

Let $\xi_{1}, \cdots, \xi_{n}$ be independent random variables with mean zero. Suppose that there exists some $\mathrm{t}>0$ and $\overline{\mathrm{B}}_{\mathrm{n}}$ such that $\sum_{k=1}^{n} E\left\{\xi_{k}^{2} e^{t\left|\xi_{k}\right|}\right\} \leq \bar{B}_{n}^{2}$. Then uniformly for $0<x \leq{\overline{B_{n}}}_{n}$,

$$
\begin{equation*}
\operatorname{pr}\left(\sum_{k=1}^{n} \xi_{k} \geq C_{t} \bar{B}_{n} x\right) \leq \exp \left(-x^{2}\right) \tag{A1}
\end{equation*}
$$

where $C_{t}=t+t^{-1}$.

## Proof of Theorems 1 and 2

Without loss of generality, we assume that $E(x)=0$. Recall that $E(z)=0$. We show that with probability greater than $1-O\left\{(p q)^{-1}\right\}$,

$$
\begin{equation*}
\left|S_{x y}-\Gamma_{0} S_{x x}\right|_{\infty} \leq \lambda_{n} \tag{A2}
\end{equation*}
$$

To prove (A2), it suffices to show that

$$
\begin{equation*}
\left|\frac{1}{n} \sum_{k=1}^{n}\left(z_{k}-\bar{z}\right)\left(x_{k}-\bar{x}\right)^{\mathrm{T}}\right|_{\infty} \leq \lambda_{n} \tag{A3}
\end{equation*}
$$

Taking $\xi_{k}=z_{k i} x_{k j}$ in Lemma 1 and noting that $\max _{i, j} E \exp \left(t / z_{k i} x_{k j}\right) \leq K$ for all $|t| \leq \min (\eta$, $\eta / K$ ), we have

$$
\begin{equation*}
\max _{i, j} \operatorname{pr}\left(n^{-1}\left|\sum_{k=1}^{n} z_{k i} x_{k j}\right| \geq \lambda_{n} / 2\right) \leq 2(p q)^{-2} \tag{A4}
\end{equation*}
$$

By Lemma 1, we have
$\operatorname{maxpr}_{j}\left[\left|\bar{x}_{j}\right| \geq C\{\log (p q) / n\}^{1 / 2}\right] \leq 2(p q)^{-2}, \quad \operatorname{maxpr}_{i}\left[\left|\bar{z}_{i}\right| \geq C\{\log (p q) / n\}^{1 / 2}\right] \leq 2(p q)^{-2}$
for some constant $C>0$. This implies (A3). Let $\hat{\Gamma}=\left(\hat{\gamma}_{i j}\right)=\left(\hat{\gamma}_{1}, \ldots, \hat{\gamma}_{p}\right)^{\mathrm{T}}$ be the solution of (3). Then by (A2), we have $\left|\left(\hat{\Gamma}-\Gamma_{0}\right) S_{x x}\right| \leq 2 \lambda_{n}$. Moreover, by the equivalence between (3) and (4), we have $\sum_{j=1}^{q}\left|\hat{\gamma}_{i j}\right| \leq \sum_{j=1}^{q}\left|\gamma_{i j}^{0}\right|$ for all $1 \leq i \leq p$. Set
$\left\|\Gamma_{0}\right\|_{L_{\infty}}=\max _{1 \leq i \leq p} \sum_{j=1}^{q}\left|\gamma_{i j}^{0}\right|$. We have $\left\|\hat{\Gamma} / / L_{\infty} \leq\right\| \Gamma_{0} \|_{L_{\infty}}$. Also by Lemma 1, we have

$$
\operatorname{pr}\left[\left|\sum_{x}-S_{x x}\right|_{\infty} \geq C\{\log (p q) / n\}^{1 / 2}\right] \leq 2(p q)^{-1}
$$

for some constant $C>0$. Then, with probability greater than $1-O\left\{(p q)^{-1}\right\}$, we have

$$
\begin{gathered}
\left|\left(\hat{\Gamma}-\Gamma_{0}\right) \sum_{x}\right|_{\infty} \leq\left|\left(\hat{\Gamma}-\Gamma_{0}\right) S_{x x}\right|_{\infty}+\left|\left(\hat{\Gamma}-\Gamma_{0}\right)\left(\sum_{x}-S_{x x}\right)\right|_{\infty} \\
\leq 2 \lambda_{n}+C\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}}\{\log (p q) / n\}^{1 / 2}
\end{gathered}
$$

It follows that

$$
\begin{gather*}
\left|\hat{\Gamma}-\Gamma_{0}\right|_{\infty} \leq\left|\left(\hat{\Gamma}-\Gamma_{0}\right) \sum_{x}\right|_{\infty}\left\|\sum_{x}^{-1}\right\|_{L_{1}} \\
\leq 2\left\|\left.\sum_{x}^{-1}\right|_{L_{1}} \lambda_{n}+C \mid \sum_{x}^{-1}\right\|_{L_{1}}\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}}\{\log (p q) / n\}^{1 / 2} . \tag{A5}
\end{gather*}
$$

Let $t_{n}=\hat{\Gamma}-\Gamma_{0} / \infty$. Define

$$
\begin{gathered}
h_{j}=\left(h_{j 1}, \ldots, h_{j q}\right)^{\mathrm{T}}=\hat{\gamma}_{j}-\gamma_{j}^{0}, \\
h_{j}^{1}=\left(\hat{\gamma}_{j i} I\left\{\left|\hat{\gamma}_{j i}\right| \geq 2 t_{n}\right\}: 1 \leq i \leq q\right)^{\mathrm{T}}-\gamma_{j}^{0} ; \\
h_{j}^{2} \\
=h_{j}-h_{j}^{1} .
\end{gathered}
$$

Then

$$
\left|h_{j}^{2}\right|_{1}-\left|h_{j}^{1}\right|_{1}+\left|\gamma_{j}^{0}\right|_{1} \leq\left|h_{j}^{2}\right|_{1}+\left|h_{j}^{1}+\gamma_{j}^{0}\right|_{1}=\left|h_{j}+\gamma_{j}^{0}\right|_{1} \leq\left|\gamma_{j}^{0}\right|_{1} .
$$

So we have $\left|h_{j}\right|_{1} \leq 2\left|h_{j}^{1}\right|_{1}$. It suffices to estimate $\left|h_{j}^{1}\right|_{1}$. We have

$$
\begin{gathered}
\left|h_{j}^{1}\right|_{1}=\sum_{i=1}^{q}\left|\hat{\gamma}_{j i} I\left\{\left|\hat{\gamma}_{j i}\right| \geq 2 t_{n}\right\}-\gamma_{j i}^{0}\right| \\
=\sum_{i=1}^{q}\left|\hat{\gamma}_{j i}-\gamma_{j i}^{0}\right| I\left\{\left|\hat{\gamma}_{j i}\right| \geq 2 t_{n}\right\}+\sum_{i=1}^{q}\left|\gamma_{j i}^{0}\right| I\left\{\left|\hat{\gamma}_{j i}\right|<2 t_{n}\right\} \\
\leq \sum_{i=1}^{q} t_{n} I\left\{\left|\gamma_{j i}^{0}\right| \geq t_{n}\right\}+\sum_{i=1}^{q}\left|\gamma_{j i}^{0}\right| I\left\{\left|\gamma_{j i}^{0}\right|<3 t_{n}\right\} \\
\leq t_{n}^{1-\delta_{1}} \sum_{i=1}^{q}\left|\gamma_{j i}^{0}\right|^{\delta_{1}}+\left(3 t_{n}\right)^{1-\delta_{1}} \sum_{i=1}^{q}\left|\gamma_{j i}^{0}\right|^{\delta_{1}} .
\end{gathered}
$$

Therefore,

$$
\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}} \leq C s_{1}(q) N_{q}^{1-\delta_{1}} \lambda_{n}^{1-\delta_{1}}+C\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}}^{1-\delta_{1}} s_{1}(q) N_{q}^{1-\delta_{1}} \lambda_{n}^{1-\delta_{1}}
$$

If $\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}} \leq 1$, then we have $\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}} \leq C s_{1}(q) N_{q}^{1-\delta_{1}} \lambda_{n}^{1-\delta_{1}}$. If $\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}}>1$, then by (8), we have for $n$ large,

$$
\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}} \leq C s_{1}(q) N_{q}^{1-\delta_{1}} \lambda_{n}^{1-\delta_{1}}+\frac{1}{2}\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L_{\infty}}
$$

Thus (9) holds with probability greater than $1-O\left\{(p q)^{-1}\right\}$. By (9) and (8), we have $\| \hat{\Gamma}-$ $\Gamma_{0} \|_{L_{\infty}} \leq 1$ with probability greater than $1-O\left\{(p q)^{-1}\right\}$. This, together with (A5), implies (11). Finally, (10) follows from (9), (11) and the inequality $p^{-1}\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{F}^{2} \leq\left|\hat{\Gamma}-\Gamma_{0}\right|_{\infty}\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{L \infty}$.

$$
\hat{\sum}_{z}=\frac{1}{n} \sum_{k=1}^{n} z_{k} z_{k}^{\mathrm{T}}
$$

We suppose that

$$
\begin{equation*}
\left|\left(S_{y y}-\hat{\sum_{z}}\right) \Omega_{0}\right|_{\infty} \leq \tau_{n} \tag{A6}
\end{equation*}
$$

and

$$
\begin{equation*}
\left|\left(\hat{\sum_{z}}-\sum_{0}\right) \Omega_{0}\right|_{\infty} \leq \tau_{n} \tag{A7}
\end{equation*}
$$

Then we have

$$
\left|I_{p \times p}-S_{y y} \Omega_{0}\right|_{\infty}=\left|\left(S_{y y}-\sum_{0}\right) \Omega_{0}\right|_{\infty} \leq 2 \tau_{n} .
$$

It follows that

$$
\left|\hat{\Omega}_{1}-\Omega_{0}\right|_{\infty} \leq\left|\left(I_{p \times p}-\Omega_{0} S_{y y}\right) \hat{\Omega}_{1}\right|_{\infty}+\left|\Omega_{0}\left(I_{p \times p}-S_{x x} \hat{\Omega}_{1}\right)\right|_{\infty} \leq 2\left\|\Omega_{0}\right\|_{L_{1}} \tau_{n} .
$$

This proves Theorem 5. Following the arguments as the proof of Theorem 1, we can get Theorem 4.

It remains to prove (A6) and (A7). Write $\Delta_{n}=\hat{\Gamma}-\Gamma_{0}$. Then we have

$$
S_{x x}=\frac{1}{n} \sum_{k=1}^{n}\left(z_{k}-\Delta_{n} x_{k}\right)\left(z_{k}-\Delta_{n} x_{k}\right)^{\mathrm{T}} .
$$

We now prove that with probability greater than $1-O\left\{(p q)^{-1}\right\}$,

$$
\begin{equation*}
\left|\frac{1}{n} \sum_{k=1}^{n} z_{k} x_{k}^{\mathrm{T}} \Delta_{n}^{\mathrm{T}}\right|_{\infty} \leq C M_{p}^{-1}\left\{\frac{\log (p q)}{n}\right\}^{1 / 2} \tag{A8}
\end{equation*}
$$

and

$$
\begin{equation*}
\left|\frac{1}{n} \sum_{k=1}^{n} \Delta_{n} x_{k} x_{k}^{\mathrm{T}} \Delta_{n}^{\mathrm{T}}\right|_{\infty} \leq C M_{p}^{-1}\left\{\frac{\log (p q)}{n}\right\}^{1 / 2} \tag{A9}
\end{equation*}
$$

First, recall that

$$
\begin{equation*}
\operatorname{maxpr}_{i, j}\left(n^{-1}\left|\sum_{k=1}^{n} z_{k i} x_{k j}\right| \geq \lambda_{n} / 2\right) \leq C(p q)^{-2} \tag{A10}
\end{equation*}
$$

Write $\Delta_{n}=\left(\delta_{i j}\right), x_{k}=\left(x_{k 1}, \ldots, x_{k q}\right)^{\mathrm{T}}$ and $z_{k}=\left(z_{k 1}, \ldots, z_{k p}\right)^{\mathrm{T}}$. To prove (A8), we only need to show that with probability greater than $1-O\left\{(p q)^{-1}\right\}$,

$$
\max _{i, l}\left|\frac{1}{n} \sum_{k=1}^{n}\left(z_{k i} x_{k 1} \delta_{l 1}+\cdots+z_{k i} x_{k q} \delta_{l q}\right)\right| \leq C\left\{\frac{\log (p q)}{n}\right\}^{1 / 2} .
$$

By (9), (13) and (A10),

$$
\begin{gather*}
\left.\max _{i, l}\left|\frac{1}{n} \sum_{k=1}^{n} \sum_{j=1}^{q} z_{k i} x_{k j} \delta_{l j}\right| \leq\left\|\hat{\Gamma}-\Gamma_{0}\right\|_{l_{\infty}} \max _{i, j} \right\rvert\, \frac{1}{n} \sum_{k=1}^{n} z_{k i} x_{k j} \\
\leq C M_{p}^{-1} \max _{i, j}\left|\frac{1}{n} \sum_{k=1}^{n} z_{k i} x_{k j}\right| \\
\leq C M_{p}^{-1}\{\log (p q) / n\}^{1 / 2} . \tag{A11}
\end{gather*}
$$

Thus (A8) holds. It remains to show (A9), which is equivalent to show that with probability greater than $1-O\left\{(p q)^{-1}\right\}$,

$$
\begin{equation*}
\max _{i, l}\left|\frac{1}{n} \sum_{k=1}^{n} \sum_{j=1}^{q} \delta_{i j} x_{k j} \sum_{j=1}^{q} \delta_{l j} x_{k j}\right| \leq C M_{p}^{-1}\left\{\frac{\log (p q)}{n}\right\}^{1 / 2} . \tag{A12}
\end{equation*}
$$

By Lemma 1, we can get

$$
\operatorname{maxpr}_{j}\left(\frac{1}{n} \sum_{k=1}^{n} x_{k j}^{2} \geq C\right)=O\left\{(p q)^{-2}\right\}
$$

for some constant $C>0$. By (11), (9) and (13),

$$
\max _{i} \frac{1}{n} \sum_{k=1}^{n}\left(\sum_{j=1}^{q} \delta_{i j} x_{k j}\right)^{2} \leq \max _{i} \sum_{j=1}^{q} \delta_{i j}^{2} \frac{1}{n} \sum_{k=1}^{n} x_{k j}^{2} \leq C M_{p}^{-1}\left\{\frac{\log (p q)}{n}\right\}^{1 / 2}
$$

with probability greater than $1-O\left\{(p q)^{-1}\right\}$. This implies (A12).
We next prove (A7). Write

$$
\left(\hat{\sum_{z}}-\sum_{0}\right) \Omega_{0}=\frac{1}{n} \sum_{k=1}^{n}\left(z_{k} z_{k}^{\mathrm{T}} \Omega_{0}-E z_{k} z_{k}^{\mathrm{T}} \Omega_{0}\right)
$$

Note that $\operatorname{var}\left(z_{k i}\right)=\sigma_{i i}^{0}$ and $\operatorname{var}\left\{\left(z_{k}^{\mathrm{T}} \Omega_{0}\right)_{j}\right\}=\omega_{j j}^{0}$. By assumption (A2), $\max _{i} \sigma_{i i}^{0} \max _{j} \omega_{j j}^{0} \leq C_{0}$. By Lemma 1, we have

$$
\max _{i, j}\left[\left|\frac{1}{n} \sum_{k=1}^{n}\left(z_{k i}\left(z_{k}^{\mathrm{T}} \Omega_{0}\right)_{j}-E z_{k i}\left(z_{k}^{\mathrm{T}} \Omega_{0}\right)_{j}\right)\right| \geq C\left\{\frac{\log (p q)}{n}\right\}^{1 / 2}\right] \leq C(p q)^{-2}
$$

for some bounded constant $C$ depending only on $C_{0}, \eta$ and $K$. This yields (A7).

Fig. 1.
The average receiver operating characteristic curves obtained by varying the tuning parameter $\tau_{n}$. The upper left panel is for Model 1, the upper right panel is for Model 2, the bottom left panel is for Model 3 and the bottom right panel is for Model 4. The solid, dotted, dashed and dashed-dotted curves represent the methods of Friedman et al. (2008), Cai et al. (2011), Yin \& Li (2011) and our method, respectively. The solid and the dotted curves overlap in the bottom plots.

Fig. 2.
The yeast mitogen-activated protein kinase signaling pathway, illustrating the signaling paths in responses to different signals. Some genes appear in multiple paths. The figure is downloaded from http://www.wikipathways.org/index.php/Pathway:WP510

Fig. 3.
Covariate-adjusted conditional independence graph constructed based on the estimated covariate-adjusted precision matrix for the 54 genes on the yeast mitogen-activated protein kinase signaling pathway.

Table 1
Fours models and the parameters used in the simulations.

|  | Parameters |
| :---: | :---: |
| Model 1 | $p=60, q=30, n=100, \operatorname{pr}\left(\Gamma_{i j} \neq 0\right)=5 / q$, and $\operatorname{pr}\left(\Omega_{i j} \neq 0 / i \neq j\right)=5 / p$ |
| Model 2 | $p=200, q=200, n=200, \operatorname{pr}\left(\Gamma_{i j} \neq 0\right)=30 / q$, and $\operatorname{pr}\left(\Omega_{i j} \neq 0 / i \neq j\right)=5 / p$ |
| Model 3 | $p=200, q=200, n=100, \operatorname{pr}\left(\Gamma_{i j} \neq 0\right)=30 / q$, and $\operatorname{pr}\left(\Omega_{i j} \neq 0 / i \neq j\right)=5 / p$ |
| Model 4 | $p=800, q=300, n=200, \operatorname{pr}\left(\Gamma_{i j} \neq 0\right)=30 / q$, and $\operatorname{pr}\left(\Omega_{i j} \neq 0 / i \neq j\right)=10 / p$ |
