Foreword

On 26–27 June 2008, the BIS held its Seventh Annual Conference on “Whither monetary policy? Monetary policy challenges in the decade ahead” in Luzern, Switzerland. The event brought together senior representatives of central banks and academic institutions to exchange views on this topic. BIS Paper 45 contains the opening address of William R White (BIS), the contributions of the policy panel on “Beyond price stability – the challenges ahead” and speeches by Edmund Phelps (Columbia University) and Martin Wolf (Financial Times). The participants in the policy panel discussion chaired by Malcolm D Knight (BIS) were Martin Feldstein (Harvard University), Stanley Fischer (Bank of Israel), Mark Carney (Bank of Canada) and Jean-Pierre Landau (Banque de France). The papers presented at the conference and the discussants’ comments are released as BIS Working Papers 273 to 277.

Conference programme

Thursday 26 June

- 10:00 Registration and refreshments
- 11:00 Opening remarks: [William White](#) (Bank for International Settlements)
Chair: Guillermo Ortiz, Bank of Mexico
- 11:15 **Session 1: In search of monetary stability: the evolution of policy regimes**
Paper title: *In search of monetary stability: the evolution of monetary policy. Some reflections. Experience – Lessons – Open issues*
Author: [Otmar Issing](#) (Centre for Financial Studies)
Discussants: [José de Gregorio](#) (Central Bank of Chile)
[Allan Meltzer](#) (Carnegie Mellon University)
- 12:45 Lunch
Chair: [Durmus Yilmaz](#) (Central Bank of the Republic of Turkey)
- 14:15 **Session 2: Monetary policy communication**
Paper title: *Talking about monetary policy: The virtues (and vices?) of central bank communication*
Author: [Alan Blinder](#) (Princeton University)
Discussants: [Benjamin Friedman](#) (Harvard University)
[Y V Reddy](#) (Reserve Bank of India)
- 15:45 Coffee break
Chair: Tito Mboweni, South African Reserve Bank
- 16:15 **Session 3: Expectations formation: beyond rational expectations**
Paper title: *Inflation expectations, uncertainty and monetary policy*
Author: [Christopher Sims](#) (Princeton University)
Discussants: [Athanasios Orphanides](#) (Central Bank of Cyprus)
[Lars Svensson](#) (Sveriges Riksbank)
- 18:00 End of day one
- 19:00 Reception followed by formal dinner
Keynote address by [Edmund Phelps](#) (Columbia University)

Friday 27 June

- Chair: [Donald Kohn](#) (Board of Governors of the Federal Reserve System)
- 09:00 **Session 4: Changes in monetary policy transmission**
- Paper title: *Has the monetary transmission process in the euro area changed? Evidence based on VAR estimates*
- Author: [Axel Weber](#) (Deutsche Bundesbank)
- Discussants: [Marvin Goodfriend](#) (Carnegie Mellon University)
[Arminio Fraga Neto](#) (Gávea Investimentos)
- 10:30 Coffee break
- Chair: Hamad Saud Al-Sayari (Saudi Arabian Monetary Agency)
- 11:00 **Session 5: Price stability and the external dimension**
- Paper title: *China's financial conundrum and global imbalances*
- Authors: [Ronald McKinnon](#) (Stanford University) and
[Gunther Schnabl](#) (Leipzig University)
- Discussants: [Ricardo Caballero](#) (Massachusetts Institute of Technology)
[Michael Mussa](#) (The Peterson Institute for International Economics)
- 12:30 Lunch
- Luncheon remarks by [Martin Wolf](#) (Financial Times)
- Chair: [Lucas Papademos](#) (European Central Bank)
- 14:00 **Session 6: Credit frictions and monetary policy analysis**
- Paper title: *Credit frictions and optimal monetary policy*
- Author: [Michael Woodford](#) (Columbia University)
- Discussants: [Olivier Blanchard](#) (Massachusetts Institute of Technology)
[Charles Goodhart](#) (London School of Economics)
- 15:30 Coffee break
- 16:00 **Panel discussion: Beyond price stability: the challenges ahead**
- Chair: [Malcolm Knight](#) (Bank for International Settlements)
- Panellists: [Martin Feldstein](#) (Harvard University)
[Stanley Fischer](#) (Bank of Israel)
[Mark Carney](#) (Bank of Canada)
[Jean-Pierre Landau](#) (Banque de France)
- 17:30 Close of conference

Credit frictions and optimal monetary policy¹

Vasco Cúrdia² and Michael Woodford³

Abstract

We extend the basic (representative-household) New Keynesian [NK] model of the monetary transmission mechanism to allow for a spread between the interest rate available to savers and borrowers, that can vary for either exogenous or endogenous reasons. We find that the mere existence of a positive average spread makes little quantitative difference for the predicted effects of particular policies. Variation in spreads over time is of greater significance, with consequences both for the equilibrium relation between the policy rate and aggregate expenditure and for the relation between real activity and inflation.

Nonetheless, we find that the *target criterion* – a linear relation that should be maintained between the inflation rate and changes in the output gap – that characterises optimal policy in the basic NK model continues to provide a good approximation to optimal policy, even in the presence of variations in credit spreads. We also consider a “spread-adjusted Taylor rule,” in which the intercept of the Taylor rule is adjusted in proportion to changes in credit spreads. We show that while such an adjustment can improve upon an unadjusted Taylor rule, the optimal degree of adjustment is less than 100 percent; and even with the correct size of adjustment, such a rule of thumb remains inferior to the targeting rule.

It is common for theoretical evaluations of alternative monetary policies – most notably, the literature that provides theoretical foundations for inflation targeting – to be conducted using models of the monetary transmission mechanism that abstract altogether from financial frictions.⁴ There is generally assumed to be a single interest rate – “*the* interest rate” – that is at once the policy rate that constitutes the operating target for the central bank, the rate of return that all households and firms receive on savings, and the rate at which anyone can borrow against future income. In models with more complete theoretical foundations, this is justified by assuming frictionless financial markets, in which all interest rates (of similar maturity) must be equal in order for arbitrage opportunities not to exist. It is also common to assume a representative household, and firms that maximise the value of their earnings streams to that household, so that there is no need for credit flows in equilibrium in any event; such models imply that a breakdown of credit markets would have no allocative significance. Many of the quantitative DSGE models recently developed in central banks and other policy institutions share these features.⁵

Such models abstract from important complications of actual economies, even those that are financially quite sophisticated. Sizeable spreads exist, on average, between different interest rates; moreover, these spreads are not constant over time, especially in periods of financial stress. And “tighter” financial conditions, indicated by increases in the size of credit spreads, are commonly associated with lower levels of real expenditure and employment. This poses obvious questions for the practical application of much work in the theory of monetary policy.⁶ If a model is to be calibrated or estimated using time series data, which actual interest rate should be taken to correspond to “the interest rate” in the model? When the model is used to give advice about how interest rates should respond to a particular type of shock, which actual interest rate (if any) should be made to respond in the way that “the interest rate” does in the model? How large an error is likely to be made by abstracting from credit frictions, with regard to the model’s predictions for the variables that appear in it? Moreover, some questions clearly cannot even be addressed using models that abstract from credit frictions. Most notably, how should a central bank respond to a “financial shock” that increases the size of the spreads resulting from credit frictions?

This paper seeks to address these questions by presenting a simple extension of the basic “New Keynesian” model (as developed, for example, in Woodford, 2003) in which a credit friction is introduced, allowing for a time-varying wedge between the interest rate available to households on their savings and the interest rate at which it is possible to borrow. Financial intermediation matters for the allocation of resources due to the introduction of heterogeneity in the spending opportunities currently available to different households. While the model remains highly stylised, it has the advantage of nesting the basic New Keynesian model (extensively used in normative monetary policy analysis) as a special case, and of introducing only a small number of additional parameters, the consequences of which for conclusions about the monetary transmission mechanism and the character of optimal policy can be thoroughly explored. The approach taken also seeks to develop a tractable model, with as small a state space as is consistent with an allowance for financial frictions and heterogeneity, and hence only modestly greater complexity than the basic New Keynesian model.

⁴ See, for example, Clarida *et al.*, (1999) or Woodford (2003), among many other references.

⁵ The models of Smets and Wouters (2003, 2007) provide an especially influential example.

⁶ The current generation of DSGE models has been criticised on this ground by Issing (2006) and Goodhart (2007), among others.

Among the questions to be addressed are the following: If the parameters determining the degree of heterogeneity and the size of credit frictions are calibrated so as to match both the volume of bank credit and the spread between bank deposit and lending rates in the US economy, how much of a difference does this make (relative to the frictionless baseline) for the model's predictions for the response of the economy to various types of shocks, under a given monetary policy rule? How much of a difference does it make for the implied responses to real disturbances under an optimal monetary policy? How much of a difference does it make for the form of the quadratic stabilisation objective that would correspond to the maximisation of average expected utility? How much of a difference does it make for the form of the optimal target criterion for monetary stabilisation policy? And how should policy optimally respond to a "financial shock"?

The model also provides perspective on "rules of thumb" for policy in times of financial turmoil proposed in the recent literature. For example, McCulley and Toloui (2008) and Taylor (2008) propose that the intercept term in a "Taylor rule" for monetary policy should be adjusted downward in proportion to observed increases in spreads.⁷ Here we use our simple model to ask whether it is correct to say that the "natural" or "neutral" rate of interest is lower when credit spreads increase (assuming unchanged fundamentals otherwise), and to the extent that it is, how the size of the change in the natural rate compares to the size of the change in credit spreads. We also ask whether it is approximately correct to say that a proper response to a "financial shock" is to conduct policy according to the same rule as under other circumstances, except with the operating target for the policy rate adjusted by a factor that is proportional to the increase in credit spreads; and again, to the extent that such an approximation is used, we ask what proportion of adjustment should be made.

Other authors have argued that if financial disturbances are an important source of macroeconomic instability, a sound approach to monetary policy will have to pay attention to the balance sheets of financial intermediaries. It is sometimes suggested that policy should respond to variations in the growth rate of monetary or credit aggregates, rather than – as in the case of both the Taylor rule and conventional prescriptions for "flexible inflation targeting" – seeking to determine the appropriate level of short-term interest rates purely on the basis of observations of or projections for measures of inflation and real activity. Here we consider two possible interpretations of such proposals: as an argument for *targeting* monetary and/or credit aggregates, or at least adopting a target criterion that involves such variables along with others; or as an argument for their special value as *indicators*, so that such variables should receive substantial weight in the central bank's reaction function. We address the first issue by deriving an optimal target criterion for monetary policy, under certain simplifying assumptions, and seeing to what extent it involves either money or credit. We address the second issue, under assumptions that are arguably more realistic, by computing the optimal responses to shocks, and asking what kinds of indicator variables would allow a simple rule of thumb to bring about equilibrium responses of this kind.

Of course, we are not the first to investigate ways in which New Keynesian [NK] models can be extended to allow for financial frictions of one type or another. A number of authors have analysed DSGE models with financial frictions of one type or another.⁸ Many of the best-

⁷ Similarly, Meyer and Sack (2008) propose, as a possible account of recent U.S. Federal Reserve policy, a Taylor rule in which the intercept – representing the Fed's view of "the equilibrium real funds rate" – has been adjusted downward in response to credit market turmoil, and use the size of increases in spreads in early 2008 as a basis for a proposed magnitude of the appropriate adjustment.

⁸ Probably the most influential early example was the model of Bernanke *et al.*, (1999). More recent contributions include Christiano *et al.* (2003, 2007a, 2007b), Gertler *et al.* (2007), and Iacoviello (2005). Faia and Monacelli

known contributions introduce obstacles to the willingness of savers to lend to borrowers, but assume that borrowers directly borrow from the suppliers of savings. A number of recent papers, however, are like ours in explicitly introducing intermediaries and allowing for a spread between the interest received by savers and that paid by borrowers; examples include Hulsewig *et al.* (2007), Teranishi (2008), Sudo and Teranishi (2008), and Gerali *et al.* (2008).⁹

In general, these models have been fairly complex, in the interest of quantitative realism, and the results obtained are purely numerical. Our aim here is somewhat different. While the interest of such analyses is clear, especially to policy institutions seeking quantitative estimates of the effects of particular contemplated actions, we believe that it is also valuable to seek analytical insights of the kind that can only be obtained from analyses of simpler, more stylised models. Here we focus on the consequences for monetary policy analysis of two basic features of economies – heterogeneity of non-financial economic units, of a kind that gives the financial sector a non-trivial role in the allocation of resources; and costs of financial intermediation, that may be subject to random variation for reasons relating largely to developments in the financial sector – in the simplest possible setting, where we do not introduce other departures from the basic NK model.

Two recent contributions have aims more closely related to ours. Like us, Goodfriend and McCallum (2007) consider a fairly simple NK model, with new model elements limited to those necessary to allow for multiple interest rates with different average levels (including, like us, a distinction between bank lending rates and the policy rate).¹⁰ As in the present paper, a primary goal is to “investigate quantitatively how much a central bank can be misled by relying on a [NK] model without money and banking when managing its interbank-rate policy instrument”. De Fiore and Tristani (2007) also propose a simple generalisation of the basic NK model in order to introduce a distinction between loan rates and the policy; also like us, they consider how financial frictions affect the “natural rate of interest,” and the role of such a concept in inflation determination in an economy with credit frictions.

The approaches taken by these authors nonetheless differ from ours in important respects. In particular, unlike us, Goodfriend and McCallum assume a representative-household model; as a consequence, financial intermediation matters for resource allocation in their model only because they assume that certain liabilities of banks (transactions balances) play a crucial role in facilitating transactions. We instead treat the fact that some (but not all) financial intermediaries finance (some) of their lending by providing accounts that are useful as means of payment as inessential to the primary function of financial intermediaries in the economy; and in our model, for the sake of simplicity, we assume that intermediaries finance themselves entirely by issuing deposits that supply no transactions services at all (so that in equilibrium, deposits must pay the same interest rate as government debt). De Fiore and Tristani instead have two types of infinite-lived agents (“households” and “entrepreneurs,” following Bernanke *et al.*, 1999), one of which saves while the other borrows; but in their model, unlike ours, agents belong permanently to one of these categories, and one is tempted to identify the division between them with the

(2007) consider how two different types of financial frictions affect welfare-based policy evaluation, though from a perspective somewhat different than the one taken here; they compare alternative simple rules, rather than computing optimal policy, as we do, and compute the welfare associated with a particular rule under a complete specification of shocks, rather than considering what a given simple rule implies about the equilibrium responses to shocks considered individually. Cúrdia (2008) considers optimal policy in the spirit of the present paper, but in a more complex model with features specific to emerging-market economies.

⁹ See Gerali *et al.* (2008, sec. 2) for a more detailed discussion of prior literature.

¹⁰ This paper provides a quantitative analysis of type of model first proposed by Goodfriend (2005).

division between households and firms in the flow of funds accounts. This would be desirable, of course, if one thought that the model did adequately capture the nature of that division, as the model would yield additional testable predictions. But in fact, there are both saving units and borrowing units at a given point in time, both in the household sector and in the firm sector; and a saving unit at one point in time need not be a saving unit forever. We accordingly prefer not to introduce a distinction between households and firms (or “households” and “entrepreneurs”) at all, and also not to assume that the identities of our savers and borrowers are permanent.¹¹ In addition, De Fiore and Tristani, like Goodfriend and McCallum, assume that money must be used in (some) transactions, while we abstract from transactions frictions of this kind altogether in order to simplify our analysis.¹²

We develop our model in section 1, and compare its structure with that of the basic NK model. We then consider, in section 2, the implications of the model for the equilibrium effects of a variety of types of exogenous disturbances, under a given assumption about monetary policy (such as that it conform to a “Taylor rule”), and ask to what extent the basic NK model gives incorrect answers to these questions. Section 3 considers optimal monetary policy in the context of our model, defined to mean a policy that maximises the average expected utility of households, and again considers how different the conclusions are from those derived from the basic NK model. We also consider the extent to which various simple rules of thumb, such as versions of the Taylor rule (Taylor, 1993), can usefully approximate optimal policy. Section 4 summarises our conclusions.

1. A new Keynesian model with financial frictions

Here we sketch a model that introduces heterogeneity of the kind needed in order for financial intermediation to matter for resource allocation, and a limit on the degree of intermediation that occurs in equilibrium, with a minimum of structure. We stress the similarity between the model presented here and the basic New Keynesian [NK] model, and show how the standard model is recovered as a special case of the one developed here. This sets the stage for a quantitative investigation of the degree to which credit frictions of an empirically realistic magnitude change the predictions of the model.

¹¹ In fact, De Fiore and Tristani list as an important “undesirable property” of their model the fact that in it, “households and entrepreneurs are radically different agents” (p. 23), as the predicted equilibrium behavior of “households” as a group does not look much like that of the aggregate household sector in actual economies.

¹² Goodfriend and McCallum justify the introduction of a cash-in-advance constraint in their model, stating (footnote 6) that “medium-of-exchange money is implicitly central to our analysis because it is by managing the aggregate quantity of reserves, which banks hold to facilitate transactions, that monetary policy affects interest rates.” However, while in their model, banks hold reserves at the central bank only because of a reserve requirement proportional to transactions balances, this need not be true in actual economies, a number of which (such as Canada) have abolished reserve requirements. Moreover, it is possible in principle for a central bank to control the interest rate in the interbank market for central-bank deposits without there being any demand for such reserves *other* than as a riskless store of value, as discussed in Woodford (2003, chap. 2). Hence there is no need to introduce a demand for money for transactions purposes in our model, in order for it to be possible to suppose that the central bank controls a short-term nominal interest rate, that will correspond to the rate at which banks can fund themselves.

1.1 Financial frictions and aggregate demand

We depart from the assumption of a representative household in the standard model, by supposing that households differ in the utility that they obtain from current expenditure. Each household i seeks to maximise a discounted intertemporal objective of the form

$$E_0 \sum_{t=0}^{\infty} \beta^t \left[u^{\tau_t(i)}(c_t(i); \xi_t) - \int_0^1 v(h_t(j; i); \xi_t) dj \right],$$

where $\tau_t(i) \in \{b, s\}$ indicates the household's "type" in period t . Here $u^b(c; \xi)$ and $u^s(c; \xi)$ are two different period utility functions, each of which may also be shifted by the vector of aggregate taste shocks ξ_t . As in the basic NK model, there is assumed to be a continuum of differentiated goods, each produced by a monopolistically competitive supplier; $c_t(i)$ is a Dixit-Stiglitz aggregator of the household's purchases of these differentiated goods. The household similarly supplies a continuum of different types of specialised labor, indexed by j , that are hired by firms in different sectors of the economy; the additively separable disutility of work $v(h; \xi)$ is the same for each type of labor, and can be shifted by the taste shock.¹³

Each agent's type $\tau_t(i)$ evolves as an independent two-state Markov chain. Specifically, we assume that each period, with probability $1 - \delta$ (for some $0 \leq \delta < 1$) an event occurs which results in a new type for the household being drawn; otherwise it remains the same as in the previous period. When a new type is drawn, it is b with probability π_b and s with probability π_s , where $0 < \pi_b, \pi_s < 1$, $\pi_b + \pi_s = 1$. (Hence the population fractions of the two types are constant at all times, and equal to π_τ for each type τ .) We assume moreover that

$$u_c^b(c; \xi) > u_c^s(c; \xi)$$

for all levels of expenditure c in the range that occur in equilibrium. (See Figure 1, where these functions are graphed in the case of the calibration discussed below.¹⁴ Hence a change in a household's type changes its relative impatience to consume,¹⁵ given the aggregate state ξ_t ; in addition, the current impatience to consume of all households is changed by the aggregate disturbance ξ_t .

The coexistence of the two types with differing impatience to consume creates a social function for financial intermediation. In the present model, as in the basic New Keynesian model, all output is consumed either by households or by the government;¹⁶ hence intermediation serves

¹³ As in Woodford (2003), the vector ξ_t may contain multiple elements, which may or may not be correlated with one another, so that the notation makes no assumption about correlation between disturbances to the utility of consumption and disturbances to the disutility of work.

¹⁴ In the equilibrium discussed below, in the case of small enough disturbances, equilibrium consumption by the two types varies in neighborhoods of the two values \bar{c}^b and \bar{c}^s shown in the figure.

¹⁵ As explained below, all households have the same expectations regarding their marginal utilities of expenditure far in the future. Hence if type b households have a higher current marginal utility of expenditure, they also have a higher valuation of current (marginal) expenditure relative to future expenditure; thus we may say that they are more impatient to consume.

¹⁶ The "consumption" variable is therefore to be interpreted as representing all of private expenditure, not only consumer expenditure. In reality, one of the most important reasons for some economic units to wish to borrow from others is that the former currently have access to profitable *investment* opportunities. Here we treat these opportunities as if they were opportunities to *consume*, in the sense that we suppose that the expenditure opportunities are valuable to the household, but we abstract from any consequences of current expenditure for

an allocative function only to the extent that there are reasons for the intertemporal marginal rates of substitution of households to differ in the absence of financial flows. The present model reduces to the standard representative-household model in the case that one assumes that $u^b(c; \xi) = u^s(c; \xi)$.

We shall assume that most of the time, households are able to spend an amount different from their current income *only* by depositing funds with or borrowing from financial intermediaries, and that the same nominal interest rate is available to all savers, and that a (possibly) different nominal interest is available to all borrowers,¹⁷ independent of the quantities that a given household chooses to save or to borrow. (For simplicity, we shall also assume in the present exposition that only one-period riskless nominal contracts with the intermediary are possible for either savers or borrowers.) The assumption that households cannot engage in financial contracting other than through the intermediary sector introduces the financial friction with which the paper is concerned.

Our analysis is simplified (though this may not be immediately apparent!) by allowing for an additional form of financial contracting. We assume that households are able to sign state-contingent contracts with one another, through which they may insure one another against both aggregate risk and the idiosyncratic risk associated with a household's random draw of its type, but that households are *only intermittently* able to receive transfers from the insurance agency; between the infrequent occasions when a household has access to the insurance agency, it can only save or borrow through the financial intermediary sector mentioned in the previous paragraph. The assumption that households are *eventually* able to make transfers to one another in accordance with an insurance contract signed earlier means that despite our assumption of infinite-lived households, households' respective marginal utilities of income do not eventually become more and more dispersed as a result of their differing individual type histories. This facilitates aggregation (so that our model still has a low-dimensional state space), and allows us to obtain stationary equilibrium fluctuations and to use local methods to characterise them. At the same time, the fact that households may go for years *without* access to insurance transfers means that there remains a non-trivial financial friction for the banking sector to partially mitigate.¹⁸

To simplify the presentation, we assume here that the random dates on which a given household i has access to the insurance agency are the same dates as those on which it draws a new type. Thus with probability δ each period, household i is unable to receive any insurance transfer in the current period, and also retains the same type as in the previous period. With probability $1 - \delta$, it learns at the beginning of the period that it has access to the insurance agency. In this case, it receives a net transfer $T_t(i)$ (under the terms of an insurance contract signed far in the past), that may depend on the history of aggregate disturbances through the current period, and

future productivity. For discussion of the interpretation of "consumption" in the basic New Keynesian model, see Woodford (2003, pp. 242-243).

¹⁷ Here "savers" and "borrowers" identify households according to whether they choose to save or borrow, and not by their "type". We assume that at any time, each household is able to save or borrow (or both at once, though it would never make sense to do so) at market interest rates. In the equilibrium described below, it turns out that a household i borrows in period t if and only if $\tau_t(i) = b$, but this is a consequence of optimisation rather than an implication of a participation constraint.

¹⁸ A similar device is commonly used in models of "liquidity," where access to frictionless financial intermediation is assumed to be possible only at discrete points in time, and that only a smaller class of exchanges are possible at interim dates. See, eg Lucas and Stokey (1984), Lucas (1990), Fuerst (1992), or Lagos and Wright (2005). Here we use a similar device to facilitate aggregation, but without doing so in a way that implies that the allocative consequences of financial frictions are extremely transitory.

also on i 's type history through the previous period (but not on its type in period t , which is not yet known). After receiving the insurance transfer, household i learns its new type (an independent drawing as explained above), and then makes its spending, saving and borrowing decisions as in any other period, but taking into account its new type and its post-transfer financial wealth.

Household i 's beginning-of-period (post-transfer) nominal net financial wealth $A_t(i)$ is then given by

$$A_t(i) = [B_{t-1}(i)]^+ \left(1 + i_{t-1}^d\right) + [B_{t-1}(i)]^- \left(1 + i_{t-1}^b\right) + D_t^{int} + T_t(i), \quad (1)$$

where $B_{t-1}(i)$ is the household's nominal net financial wealth at the end of period $t - 1$;

$$[B]^+ \equiv \max(B, 0), \quad [B]^- \equiv \min(B, 0);$$

i_t^d is the (one-period, riskless nominal) interest rate that savers receive at the beginning of period $t + 1$ on their savings deposited with intermediaries at the end of period t , while i_t^b is the interest rate at which borrowers are correspondingly able to borrow from intermediaries in period t for repayment at the beginning of period $t + 1$; and D_t^{int} represents the distributed profits of the financial intermediary sector. We assume that each household owns an equal share in the intermediary sector,¹⁹ and so receives an equal share of the distributed profits each period; profits are distributed each period as soon as the previous period's loans and depositors are repaid. Note that the final term $T_t(i)$ is necessarily equal to zero in any period in which household i does not have access to the insurance agency. A household's end-of-period nominal net financial wealth $B_t(i)$ is correspondingly given by

$$B_t(i) = A_t(i) - P_t c_t(i) + \int W_t(j) h_t(j; i) dj + D_t + T_t^g, \quad (2)$$

where P_t is the Dixit-Stiglitz price index in period t (and hence the price of the composite consumption good); $W_t(j)$ is the wage of labor of type j in period t ; D_t represents the household's share in the distributed profits of goods-producing firms; and T_t^g is the net nominal (lump-sum) government transfer received by each household in period t .

Any pair of identically situated households with access to the insurance agency will contract with one another so that if, in any state of the world at some future date, they again each have access to the insurance agency at the same time, a transfer will take place between them that equalises their marginal utilities of income at that time (if each has behaved optimally in the intervening periods). Given that they have identical continuation problems at that time (before learning their new types), as functions of their post-transfer financial wealths, such an agreement will ensure that their post-transfer financial wealths are identical (again, if each has behaved optimally).²⁰ If we suppose that at some time in the past, all households originally started with identical financial wealth and access to the insurance agency, then they should have contracted so that in equilibrium, in each period t , all those households with access to the insurance agency in period t will obtain identical post-transfer financial wealth. If we suppose, finally, that transfers

¹⁹ We do not allow trading in the shares of intermediaries, in order to simplify the discussion of households' saving and borrowing decisions. Euler equations of the form (12)–(13) below would still apply, however, even if households could also trade the shares of either banks or goods-producing firms.

²⁰ It is important to note, however, that the contractual transfer $T_t(i)$ is only contingent on the history of aggregate and individual-specific exogenous states, and not on the actual wealth that household i has at the beginning of period t . Thus a spendthrift household is not insured an equal post-transfer wealth as other households, regardless of how much it has spent in past periods.

through the insurance agency must aggregate to zero each period (because the agency does not accumulate financial assets or borrow), then each household with access to the insurance agency at the beginning of period t must have post-transfer wealth equal to

$$A_t(i) = A_t \equiv \int A_t(h)dh. \quad (3)$$

The beginning-of-period wealth of households who do not have access to the insurance agency is instead given by (1), with $T_t(i)$ set equal to zero.

If we let d_t denote aggregate real deposits with financial intermediaries at the end of period t ,²¹ and b_t aggregate real borrowing from intermediaries, then we must have

$$P_t b_t = - \int_{\mathcal{B}_t} A_t(i)di, \quad p_t [b_t^g + d_t] = \int_{\mathcal{S}_t} A_t(i)di,$$

where \mathcal{B}_t is the set of households i for which $A_t(i) < 0$, \mathcal{S}_t is the (complementary) set of households for which $A_t(i) \geq 0$, and b_t^g is real government debt at the end of period t . We assume that government debt is held directly by savers, rather than by financial intermediaries, so that the rate of return that must be paid on government debt is i_t^d , the rate paid on deposits at the intermediaries. (For simplicity, we assume here that all government debt also consists of riskless, one-period nominal bonds, so that deposits and government debt are perfect substitutes.) The aggregate beginning-of-period assets A_t of households referred to in (3) are then given by

$$A_t = [(d_{t-1} + b_{t-1}^g)(1 + i_{t-1}^d) - b_{t-1}(1 + i_{t-1}^b)]P_{t-1} + D_t^{int}, \quad (4)$$

integrating (1) over all households i .

The supply of government debt evolves in accordance with the government's flow budget constraint

$$b_t^g = b_{t-1}^g(1 + i_{t-1}^d)/\Pi_t + G_t + T_t^g/P_t - \tau_t Y_t, \quad (5)$$

where $\Pi_t \equiv P_t/P_{t-1}$ is the gross rate of inflation, G_t is government purchases of the composite good, τ_t is a proportional tax on sales of goods,²² and Y_t is the quantity of the composite good produced by firms. Given the sales tax, the distributed profits of firms are equal to

$$D_t = (1 - \tau_t)P_t Y_t - \int W_t(j)h_t(j)dj, \quad (6)$$

where $h_t(j) \equiv \int h_t(j; i)di$ is aggregate labor hired of type j .

We assume an *intermediation technology* in which real lending in the amount b_t requires an intermediary to obtain real deposits of a quantity

$$d_t = b_t + \Xi_t(b_t), \quad (7)$$

²¹ Here "real" deposits and other real variables are measured in units of the Dixit-Stiglitz composite consumption good, the price of which is P_t . Deposit contracts, loan contracts, and government debt are actually all assumed to be non-state-contingent *nominal* contracts. We introduce *real* measures of the volume of financial intermediation because we assume that the intermediation technology specifies real costs of a given volume of *real* lending.

²² Note that there are two potential sources of government revenue in our model: variation in the size of the net lump-sum transfers T_t^g , and variation in the tax rate τ_t . We introduce the process $\{\tau_t\}$ as an additional source of time-varying supply-side distortions.

where $\Xi_t(b)$ is a (possibly time-varying) function satisfying $\Xi_t(0) = 0$ and $\Xi_t(b) \geq 0$, $\Xi'_t(b) \geq 0$, $\Xi''_t(b) \geq 0$ for all $b \geq 0$. The first term on the right-hand side represents the funds that the intermediary lends to its borrowers, while $\Xi_t(b_t)$ represents a real resource cost of loan origination and monitoring.²³ (The quantities in (7) should be interpreted as referring to the deposits and loans of an individual intermediary; however, in equilibrium, all intermediaries operate on the same scale, so that in our eventual characterisation of equilibrium, we can identify per-intermediary and aggregate or per-capita quantities.) These costs of intermediation are one of the sources of the financial friction in our model. Like Goodfriend and McCallum (2007), we simply posit an intermediation technology, rather than seeking to provide a behavioral justification for the spread between the interest rate available to savers and the one at which it is possible to borrow. This means that we are unable to consider possible effects of central-bank policy on the efficiency of the banking system.²⁴ We can, however, consider the consequences for the effects of monetary policy, and for the optimal conduct of monetary policy, of the existence of, and of exogenous variation in, obstacles to fully efficient financial intermediation.

Given this technology, a perfectly competitive banking sector will result in an equilibrium spread ω_t between deposit rates and lending rates, such that

$$1 + i_t^b = (1 + i_t^d)(1 + \omega_t), \quad (8)$$

where $\omega_t = \Xi'_t(b_t)$. We shall allow, however, for additional sources of credit spreads that are associated with increased resource utilisation by intermediaries. Specifically, we shall assume that the equilibrium spread is given by

$$1 + \omega_t = \mu_t^b(b_t)(1 + \Xi'_t(b_t)), \quad (9)$$

where $\mu_t^b \geq 1$ is a (possibly time-varying) *markup* in the intermediary sector, assumed here to vary either for exogenous reasons, or perhaps as a consequence of variation in the total volume of lending. (Our allowance for an exogenously varying markup function is analogous to our allowance for a possibly time-varying “wage markup” in the treatment below of labor supply.) In allowing for a markup in the loan rates charged by intermediaries – and in particular, in considering a “financial shock” in which banking markups increase for reasons treated as exogenous – we follow Gerali *et al.* (2008).²⁵ However, we need not view the markup μ_t^b as

²³ This real resource cost can be interpreted in either of two ways: either as a quantity of the composite produced good that is used in the activity of banking, or as a quantity of a distinct type of labor that happens to be a perfect substitute for consumption in the utility of households (so that the value of this labor requirement in units of the composite good is exogenously given). The interpretation that is chosen does not affect the validity of the equations given here, though it affects the interpretation of variables such as “ c_t ” in terms of the quantities measured in national income accounts. See the Appendix for further discussion.

²⁴ Certainly we do not deny that at least at certain times, central banks do seek to affect the efficiency of the banking system; this is true most obviously in the case of actions taken in a central bank’s capacity as “lender of last resort” during a financial crisis. However, we regard such actions as representing a largely *independent* dimension of policy from *monetary* policy, by which we mean control of the supply of central-bank balances to the payments system, and of the overnight interest rate paid for such balances in the interbank market. (Additional lending to intermediaries through the discount window or similar facilities need not imply any increase in the total supply of central-bank deposits, as the actions of the Federal Reserve during the most recent crisis have demonstrated.) Here we are concerned solely with the analysis of the central bank’s monetary policy decisions, taking as given the evolution of the intermediation frictions (that may reflect other dimensions of central-bank policy, as well as developments elsewhere in the economy).

²⁵ Imperfectly competitive banking is also a feature of the theoretical models of Teranishi (2008) and Sudo and Teranishi (2008), and the empirical model of Hulsewig *et al.* (2007).

necessarily reflecting market power on the part of intermediaries; for example, it might stand in for a time-varying risk premium (though we do not explicitly model any source of risk²⁶), or for variation in the fraction of loans made to fraudulent borrowers.²⁷ What matters is that the sources of spreads between deposit rates and lending rates may or may not correspond increased real consumption of resources by the activity of the intermediaries; and we consider the consequences of variations in the efficiency of financial intermediation of both types. Using this general notation, market-clearing in the goods market requires that

$$Y_t = \int c_t(i)di + G_t + \Xi_t(b_t) \quad (10)$$

each period, and the distributed profits of intermediaries are given by

$$D_{t+1}^{int} = [(1 + i_t^b)b_t - (1 + i_t^d)d_t]P_t = \{[\mu_t^b(1 + \Xi_t') - 1]b_t - \Xi_t(b_t)\}P_t(1 + i_t^d). \quad (11)$$

This completes our description of the flows of both income and goods among households, intermediaries, and goods-producing firms. We turn now to the implications of optimal household decisions with regard to consumption, saving, and borrowing. A household for which $A_t(i) > 0$ (ie a saver) must satisfy a first-order condition

$$\lambda_t(i) = \beta(1 + i_t^d)E_t[\lambda_{t+1}(i)/\Pi_{t+1}] \quad (12)$$

in period t , where $\lambda_t(i) = u_c(c_t(i); \xi_t)$ is the household's marginal utility of (real) income in period t , while a household for which $A_t(i) < 0$ (a borrower) must instead satisfy

$$\lambda_t(i) = \beta(1 + i_t^b)E_t[\lambda_{t+1}(i)/\Pi_{t+1}]. \quad (13)$$

We need not discuss the corresponding first-order condition for a household that chooses $A_t(i) = 0$ exactly (though this is certainly possible, given the kink in households' budget sets at this point), as no households are in this situation in the equilibria that we describe here.

Under conditions specified in the Appendix, one can show that there is an equilibrium in which every household of type s has positive savings, while every household of type b borrows, in every period. Hence the interest rate that is relevant for a given household's intertemporal tradeoff turns out to be perfectly correlated with the household's type (though this is not due to participation constraints). Moreover, because in equilibrium, households that access the insurance agency in a given period t have the same marginal utility of income at the beginning of that period (before learning their new types), regardless of their past histories, it follows that in any period, all households of a given type have the same marginal utility of income, regardless of their histories. Hence we can write λ_t^T for the marginal utility of (real) income of any household

²⁶ In the technology for financial intermediation specified here, there is no risk, since loans and deposits are assumed to be perfectly matched, both in maturity and in currency denomination, and the intermediary's costs are determined by the value of the loans at origination, not by the real value of required repayment.

²⁷ Under the latter interpretation, b_t is the real value of loans to legitimate borrowers, who intend to repay, but χ_t dollars must be lent for every dollar of legitimate loans, so that total costs of the banks are $\chi_t b_t + \Xi_t(b_t)$. This leads to a marginal cost of lending given by $\chi_t + \Xi_t'(b_t)$, which can be written in the same form as the right-hand side of (9), under a suitable definition of the function $\mu_t^b(b_t)$. If these additional costs $(\chi_t - 1)b_t$ to the banks are windfall income to the fraudulent borrowers, and all households share equally in the opportunities for income from fraud, then these are not real resource costs of banking, and the consequences for household budgets are the same as if the additional charges were pure profits of the banks (and so distributed equally to households as part of D_{t+1}^{int}).

of type τ in period, where $\tau \in \{b, s\}$. Thus the equilibrium evolution of the marginal utility of income for all households can be described by just two stochastic processes, $\{\lambda_t^b, \lambda_t^s\}$.

These two processes satisfy the two Euler equations

$$\lambda_t^b = \beta E_t \left[\frac{1 + i_t^b}{\Pi_{t+1}} \{ [\delta + (1 - \delta) \pi_b] \lambda_{t+1}^b + (1 - \delta) \pi_s \lambda_{t+1}^s \} \right], \quad (14)$$

$$\lambda_t^s = \beta E_t \left[\frac{1 + i_t^d}{\Pi_{t+1}} \{ (1 - \delta) \pi_b \lambda_{t+1}^b + [\delta + (1 - \delta) \pi_s] \lambda_{t+1}^s \} \right] \quad (15)$$

in each period. (These follow from (12) – (13), taking into account the probability of switching type from one period to the next.) It follows that all households of a given type must also choose the same consumption in any period and, assuming an interior choice for consumption by households of each type, these common consumption levels must satisfy

$$\lambda_t^b = u^{b'}(c_t^b), \quad \lambda_t^s = u^{s'}(c_t^s),$$

which relations can be inverted to yield demand functions

$$c_t^b = c^b(\lambda_t^b; \xi_t), \quad c_t^s = c^s(\lambda_t^s; \xi_t). \quad (16)$$

Substituting these into (10) yields an equilibrium relation

$$Y_t = \pi_b c^b(\lambda_t^b; \xi_t) + \pi_s c^s(\lambda_t^s; \xi_t) + G_t + \Xi_t(b_t) \quad (17)$$

linking aggregate demand to the two marginal utilities of income and aggregate borrowing.

The three relations (14)–(17) generalise the “intertemporal IS relation” of the basic NK model, which can be expressed by an equation relating aggregate demand to the marginal utility of income of the representative household (analogous to (17)) and a single equation relating that marginal utility of income to the expected real rate of return implied by the model’s single interest rate. The present model implies a similar relation between interest rates and the timing of expenditure as in the basic model. The main differences are (i) that now there are *two different* interest rates that each affect aggregate demand (though with the same sign), by affecting the expenditure decisions of different economic units, and (ii) that the resources used by the banking sector can also affect aggregate demand.

The presence of two interest rates relevant to aggregate demand determination does not mean there are two independent dimensions of monetary policy. Instead, the two rates must be linked by equations (8)–(9), determining the equilibrium credit spread.²⁸ If we introduce no further frictions, the policy rate (which is a rate at which banks are willing to lend short-term funds to one another) corresponds to the deposit rate i_t^d ,²⁹ and we may suppose that the central bank

²⁸ Of course, there *is* an additional, independent dimension of central-bank policy if the central bank has measures, independent of its control of the policy rate, that can influence the financial frictions represented by the functions $\Xi_t(b_t)$ or $\mu_t^b(b_t)$. Since we do not here model the underlying foundations of these frictions, we cannot comment on the nature of such independent dimensions of policy using the present model.

²⁹ We could introduce a distinction between the rate that banks pay depositors and the rate banks pay one another for overnight funds, by supposing, as Goodfriend and McCallum (2007) do, that banks must hold unremunerated reserves in proportion to their deposits, while required reserves are not increased by borrowing funds in the interbank market. We abstract from reserve requirements here.

directly controls this rate.³⁰ In the case that banking uses no real resources (so that $\Xi_t(b_t) = 0$ regardless of the volume of lending) and the markup μ_t^b is independent of the volume of lending as well, the system consisting of equations (8)–(9) and (14)–(17) gives a complete account of how real aggregate demand is determined by the expected path of the policy rate i_t^d relative to expected inflation.³¹ This predicted relation between aggregate demand and the expected path of future interest rates is of essentially the same kind as in the basic NK model. Hence the introduction of financial frictions, of a kind capable of accounting for the observed average size and variability of spreads between deposit rates and lending rates, need not imply any substantial change in our understanding of the way in which central bank control of short-term interest rates determines aggregate expenditure.

Indeed, the basic NK model remains nested as a special case of the model proposed here. In the case that both types of households have identical preferences ($u^b(c; \xi) = u^s(c; \xi)$), and the wedge between the deposit rate and lending rate is always zero ($\Xi_t(b) = 0$, $\mu_t^b(b) = 1$, so that $\omega_t = 0$ at all times), our model is equivalent to the basic NK model. For in this case $i_t^b = i_t^d$ at all times, so that there is a single interest rate; equations (14)–(15) then imply that $\lambda_t^b = \lambda_t^s$ at all times;³² and since the functions $c^b(\lambda; \xi)$ and $c^s(\lambda; \xi)$ must be identical in this case, equilibrium must involve $c_t^b = c_t^s$ at all times. Equation (17) then reduces simply to the standard relation $Y_t = c_t + G_t$, while equations (14)–(15) imply that the common marginal utility of income of all households satisfies the usual Euler equation. Of course, this parameterisation is not the one we regard as most empirically realistic (in particular, it would not account for observed spreads, as discussed below); but since the model has *exactly* the implications of the basic NK model for *some* parameter values, it becomes merely a quantitative issue to determine how different its predictions are for other parameter values. In fact, our results reported below suggest that for many questions, a reasonably parameterised version of this model yields predictions quite similar to those of an appropriately parameterised version of the basic NK model.

1.2 The Dynamics of Private Indebtedness

We allow in general for the possibility that aggregate real borrowing b_t from financial intermediaries may affect aggregate demand, by affecting the real resources used by the banking sector (the term $\Xi_t(b_t)$ in (17)), by affecting the equilibrium spread between the deposit rate and the lending rate (equation (9)), or both. Hence in general a complete model of how interest-rate policy affects aggregate demand requires that we model the evolution of aggregate bank credit, or alternatively, of aggregate household indebtedness.

Integrating (1) over all those borrowers in period t who did not have access to the insurance agency in the current period, one finds aggregate net beginning-of-period assets for these households of

$$-\delta P_{t-1} b_{t-1} (1 + i_{t-1}^b) + \delta \pi_b D_t^{int}.$$

³⁰ The issues involved in discussing how the central bank actually controls the policy rate are no different here than in the case of the standard NK model. See, for example, Woodford (2003, chap. 2).

³¹ To be more precise, the expected path of real interest rates determines only desired current expenditure relative to expected future expenditure, so that current aggregate demand also depends on expected long-run output, just as in the basic NK model (see, eg Woodford, 2003, chap. 4). The expected long-run level of output is determined by supply-side factors and by the long-run inflation target.

³² See the Appendix for demonstration of this.

Adding to this quantity the beginning-of-period assets (A_t per household) of those households who did receive insurance transfers at the beginning period t and then learned that they are of type b , one obtains

$$\int_{\mathcal{B}_t} A_t(i) di = (1 - \delta)\pi_b A_t - \delta P_{t-1} b_{t-1} (1 + i_{t-1}^b) + \delta \pi_b D_t^{int} \quad (18)$$

for the aggregate beginning-of-period net assets of borrowers in period t . Moreover, integrating (2) over all period t borrowers, one obtains

$$P_t b_t = - \int_{\mathcal{B}_t} A_t(i) di + \pi_b [P_t c_t^b - w_t^b - D_t - T_t^g],$$

where w_t^τ denotes the real wage income of each household of type τ .³³ Finally, using (18) to substitute for aggregate beginning-of-period assets, and then using (4) to substitute for A_t , using (5) to substitute for T_t^g , using (6) to substitute for D_t , using (7) to substitute for d_t , using (8) to substitute for i_t^b , using (11) to substitute for D_t^{int} , and using (17) to substitute for Y_t , one obtains

$$\begin{aligned} b_t = & \delta [b_{t-1} + \pi_s \omega_{t-1}(b_{t-1}) b_{t-1} + \pi_b \Xi_{t-1}(b_{t-1})] (1 + i_{t-1}^d) / \Pi_t - \pi_b \Xi_t(b_t) \\ & + \pi_b [\delta b_{t-1}^g (1 + i_{t-1}^d) / \Pi_t - b_t^g] + \pi_b \pi_s [(c_t^b - c_t^s) - (w_t^b - w_t^s)], \end{aligned} \quad (19)$$

using the notation $\omega_t(b_t)$ for the function defined in (9).

The dynamics of private indebtedness thus depend, among other things, on the distribution of wage income across households of the two types. We assume labor supply behavior of exactly the same kind for both types of households (as a consequence of their identical disutility of working), except for the fact that the marginal utilities of income for the two types of households differ. Any household i , if acting as a wage-taker in the market for labor of type j , will supply hours $h_t(j; i)$ to the point at which

$$v_h(h_t(j; i); \xi_t) = \lambda_t(i) W_t(j) / P_t. \quad (20)$$

Aggregation of the labor supply behavior of the two types is facilitated if, as in Benigno and Woodford (2005), we assume the isoelastic functional form

$$v(h; \xi_t) \equiv \frac{1}{1 + \nu} h^{1 + \nu} \bar{H}_t^{-\nu},$$

where $\{\bar{H}_t\}$ is an exogenous labor-supply disturbance process. Solving (20) for the competitive labor supply of each type and aggregating, we obtain

$$h_t(j) = \bar{H}_t [\tilde{\lambda}_t W_t(j) / P_t]^{1/\nu}$$

for the aggregate supply of labor of type j , where

$$\tilde{\lambda}_t \equiv [\pi_b (\lambda_t^b)^{1/\nu} + \pi_s (\lambda_t^s)^{1/\nu}]^\nu, \quad (21)$$

³³ The fact that each household of a given type has the same labor supply and same wage income follows from the fact that in equilibrium each has the same marginal utility of income; see the further discussion of labor supply below.

or alternatively

$$W_t(j)/P_t = \tilde{\lambda}_t^{-1} (h_t(j)/\bar{H}_t)^\nu \quad (22)$$

for the real wage required if firms are to be able to hire a quantity $h_t(j)$ of labor of type j . More generally (and also as in Benigno and Woodford), we allow for the possibility of imperfect competition in the labor market, and suppose that the real wage required to hire a given aggregate quantity of labor of type j is given by

$$W_t(j)/P_t = \mu_t^w \tilde{\lambda}_t^{-1} (h_t(j)/\bar{H}_t)^\nu, \quad (23)$$

where $\mu_t^w \geq 1$ is an exogenous, possibly time-varying markup factor, indicating variations in the market power of labor.

The above theory of labor supply implies that households of type τ supply fraction $(\lambda_t^\tau/\tilde{\lambda}_t)^{1/\nu}$ of all labor of each type j , and hence receive that same fraction of aggregate labor income. However, in order to solve for the dynamics of private indebtedness, we must also determine the distribution of national income between labor and capital (since profits are distributed equally to all households, unlike wage income). Once again, aggregation is facilitated by assuming (as in Benigno and Woodford) an isoelastic production function

$$y_t(i) = A_t h_t(i)^{1/\phi}$$

for each differentiated good i , where $\phi \geq 1$ and A_t is an exogenous, possibly time-varying productivity factor, common to all goods. Dixit-Stiglitz preferences (on the part of government as well as households³⁴) imply that the demand for each differentiated good i is given by

$$y_t(i) = Y_t \left(\frac{p_t(i)}{P_t} \right)^{-\theta},$$

where Y_t is demand for the composite good, $p_t(i)$ is the price of good i , P_t is the price of the composite good, and $\theta > 1$ is the elasticity of substitution across differentiated goods.

Using these relations to solve for the labor demand $h_t(i)$ of each firm i as a function of its price, integrating over the firms in each industry j to find the total demand for labor of type j ,³⁵ solving for the implied real wage for labor of type j , and finally integrating over all types of labor, we obtain a total wage bill

$$\int W_t(j) h_t(j) dj = \mu_t^w \frac{P_t}{\tilde{\lambda}_t \bar{H}_t^\nu} \left(\frac{Y_t}{A_t} \right)^{1+\omega_y} \Delta_t, \quad (24)$$

³⁴ Dixit-Stiglitz preferences imply that household utility depends only on the quantity purchased of a certain composite good, a CES aggregate of the purchases of the individual goods. We assume that government purchases quantity G_t of this same composite good, and that the composition of government purchases minimise the cost of obtaining that quantity of the composite good. We similarly assume that the resources Ξ_t used in intermediation are in units of the composite good, and that intermediaries obtain these resources at minimum cost.

³⁵ Note that we assume, as in Woodford (2003, chap. 3), that all firms in a given industry re-evaluate their prices at the same time, so that the price $p_t(i)$ is at each time the same for all firms i in industry j .

where $\omega_y \equiv \phi(1 + \nu) - 1 \geq 0$ and

$$\Delta_t \equiv \int \left(\frac{p_t(i)}{P_t} \right)^{-\theta(1+\omega_y)} di \geq 1$$

is a measure of the dispersion of goods prices (taking its minimum possible value, 1, if and only if all prices are identical). In the Calvo model of price adjustment, this dispersion measure evolves according to a law of motion

$$\Delta_t = h(\Delta_{t-1}, \Pi_t), \quad (25)$$

where the function $h(\Delta, \Pi)$ is defined in the Appendix.

Using (24) for the total wage bill and our conclusion regarding the distribution of the wage bill between households of the two types, we can solve for the wage income of households of each type. This solution, together with the consumption functions (16), allows us to write the last term in square brackets in (19) as a function of the form $B(Y_t, \lambda_t^b, \lambda_t^s, \Delta_t; \tilde{\xi}_t)$, defined in the Appendix, where the vector $\tilde{\xi}_t$ of exogenous disturbances includes both the vector of preference shocks ξ_t and the additional exogenous disturbances A_t and μ_t^w . The law of motion for private indebtedness b_t can then be written

$$\begin{aligned} b_t = & \delta[b_{t-1} + \pi_s \omega_{t-1}(b_{t-1})b_{t-1} + \pi_b \Xi_{t-1}(b_{t-1})](1 + i_{t-1}^d)/\Pi_t - \pi_b \Xi_t(b_t) \\ & + \pi_b [\delta b_{t-1}^g (1 + i_{t-1}^d)/\Pi_t - b_t^g] + \pi_b \pi_s B(Y_t, \lambda_t^b, \lambda_t^s, \Delta_t; \tilde{\xi}_t). \end{aligned} \quad (26)$$

This allows us to describe the evolution of real private debt as a function of its own past level, disturbances to the financial sector (possible exogenous shifts in the functions $\Xi_t(b)$ and $\omega_t(b)$), the evolution of the policy rate i_t^d relative to inflation, the evolution of real government debt b_t^g , and the additional aggregate variables $(Y_t, \lambda_t^b, \lambda_t^s, \Delta_t; \tilde{\xi}_t)$ that determine the relative expenditure and the relative incomes of the two types of households.

The system of equations consisting of (8)–(9), (14)–(17), and (25)–(26), together with a monetary-policy reaction function (such as a Taylor rule) to specify i_t^d (as a function of variables such as inflation and real activity) and a fiscal rule to specify the real public debt b_t^g (also possibly as a function of variables such as inflation and real activity), then comprise a complete “aggregate demand block” for our model, that suffices to determine the evolution of the variables $\{\lambda_t^b, \lambda_t^s, i_t^b, i_t^d, \Pi_t, \Delta_t, b_t\}$ given the evolution of $\{Y_t\}$ and the exogenous disturbances. It remains to specify the model’s “aggregate supply block,” that determines aggregate output Y_t for any given evolution of inflation and other variables, in order to have a complete general-equilibrium model of the monetary transmission mechanism.

A noteworthy property of this system is that when credit frictions matter, Ricardian equivalence generally does not obtain. Even if we consider alternative paths for $\{b_t^g\}$ while holding the path of distorting taxes $\{\tau_t\}$ constant, so that contemplated changes in the path of government debt are achieved entirely through changes in the size of lump-sum transfers, a change in the path of the public debt *will* generally require a different equilibrium evolution of real activity, interest rates and inflation, contrary to the implication of the basic NK model.³⁶ For

³⁶ Crucial to this result is our assumption here that the government can borrow from the private sector at a rate more favorable than that available to private non-financial borrowers: the rate i_t^d at which intermediaries are able to obtain funding, rather than the rate i_t^b paid by households that must borrow from intermediaries. In effect, when the public debt is increased the government is (among other things) borrowing at this lower rate on behalf of households that would like to borrow at this rate but are assumed to be unable to do so on their own account. This increases aggregate demand in somewhat the same way as a reduction in credit spreads does.

(26) implies that in the absence of any offsetting changes in the paths of other endogenous variables, a change in the path of $\{b_t^g\}$ will require an offsetting change in the path of $\{b_t\}$; essentially, government borrowing crowds out private borrowing, in the absence of changes in macroeconomic conditions that increase aggregate private saving.³⁷ In the special case considered at the end of the previous section (when $\Xi_t = 0$ and ω_t is independent of the level of private debt), this change in the path of private indebtedness still has no consequences for the determination of aggregate output, interest rates or inflation, or for the allocation of consumption or labor effort between the two types of households, and so Ricardian equivalence still obtains. However, *except* in this special case, a change in the path of private indebtedness has consequences for aggregate demand determination, by changing the spread between the lending rate and the deposit rate, by changing the resources used by intermediaries, or both.

1.3 Aggregate Supply

It remains to specify the aggregate supply side of the model. This part of the model remains the same as the basic NK model (as expounded, for example, in Benigno and Woodford, 2005), except that in modelling the cost of supplying a given quantity of output (and hence the incentives of price-setters) we must take account of the differing labor supply behavior of savers and borrowers. The model of labor supply explained above implies that the equilibrium real marginal cost of supplying output in any industry j is equal to

$$s_t(j) = \frac{\phi \mu_t^w}{A_t^{1+\omega_y} \bar{H}_t^\nu} \frac{y_t(j)^{\omega_y}}{\tilde{\lambda}_t}.$$

This differs from the expression in Benigno and Woodford only in that the factor $\tilde{\lambda}_t$ in the denominator is no longer the marginal utility of income of a representative household, and so is no longer so simply related to aggregate real expenditure.

As in the basic NK model, we assume staggered price adjustment of the kind first hypothesised by Calvo (1983). This implies an inflation equation of the form

$$\Pi_t = \Pi(Z_t), \tag{27}$$

where Z_t is a vector of two forward-looking variables, recursively defined by a pair of relations of the form

$$Z_t = G(Y_t, \lambda_t^b, \lambda_t^s; \tilde{\xi}_t) + E_t[g(\Pi_{t+1}, Z_{t+1})], \tag{28}$$

where the vector-valued functions G and g are defined in the Appendix. (Among the arguments of G , the vector of exogenous disturbances $\tilde{\xi}_t$ now includes the sales tax rate τ_t , in addition to the disturbances already mentioned; this is relevant to firms' pricing decisions, as they balance *after-tax* marginal revenue with the marginal cost of supplying more.)

These relations are of exactly the same form as in the basic NK model, except that two distinct marginal utilities of income are here arguments of G ; in the case that $\lambda_t^b = \lambda_t^s = \lambda_t$, the relations

³⁷ In the simple case in which $\omega_t(b_t) = \Xi_t(b_t) = 0$, (26) determines the evolution of an aggregate credit variable, $b_t + \pi_b b_t^g$, in a way that is independent of the composition of that variable, so that a unit increase in b_t^g requires a reduction of b_t by precisely π_b units, so that each borrowing household must borrow exactly one unit less for each unit that is borrowed (per capita) by the government. The relation between the evolution of the two variables is more complex when private indebtedness increases credit frictions while government debt does not, but the most important effect of government borrowing remains the "crowding out" of private borrowing.

(28) reduce to exactly the ones in Benigno and Woodford (2005). The system (27)–(28) indicates the nature of the short-run aggregate-supply trade-off between inflation and real activity at a point in time, given expectations regarding the future evolution of inflation and of the variables $\{Z_t\}$. (The precise nature of the implied aggregate-supply relation is discussed further in section 2.1.) Equations (8)–(9), (14)–(17), (25)–(26), and (27)–(28), together with equations specifying interest-rate policy and the evolution of the public debt, then comprise a complete system of equations for determination of the endogenous variables $\{Y_t, \lambda_t^b, \lambda_t^s, i_t^b, i_t^d, Z_t, \Pi_t, \Delta_t, b_t\}$, given the evolution of the exogenous disturbances.

2. Credit Frictions and the Propagation of Disturbances

We have shown that it is possible to generalise the basic NK model in a fairly straightforward way to incorporate credit frictions – more specifically, a spread between the deposit rate and the lending rate, that may be large or small, constant or variable, and exogenous or endogenous, depending how we choose to parameterise the model. This shows, at the very least, that the inherent structure of NK models does not in some way require one to ignore the existence of such frictions. But how much does this generalisation change the implications of the resulting model?

In this section, we consider the effects on the economy of a variety of types of exogenous disturbances, including monetary policy shocks, under simple specifications of monetary policy. Our goal is not yet to compare monetary policies, but rather to compare the predictions of alternative model specifications; we wish to determine to what extent our conclusions about the consequences of a given monetary policy are affected by the introduction of heterogeneity and credit frictions.

2.1 Log-linearised structural relations

To approach this question, we log-linearise the structural relations of our model around steady-state values of the various endogenous variables that represent a perfect foresight equilibrium in the case of no random variation in any of the exogenous disturbance processes, as discussed further in the Appendix. The solution to these linear equations under a correspondingly log-linear specification of monetary policy provides a linear approximation to the equilibrium responses to the various types of disturbances, in the case that these random variations are small enough. The linearity of the solution allows us to discuss the equilibrium responses to individual shocks independently of whether other exogenous variables change concurrently, and to discuss the size of the responses relative to the size of the shock without caring about the size of the shock that is considered.

We first summarise the structure of the log-linearised model, as these equations themselves provide considerable insight into the model's implications, and the similarities and differences between the predictions of the generalised model and those of the basic NK model (which is itself most familiar in its log-linearised form). We log-linearise the structural relations of the previous section around a steady state with zero inflation ($\bar{\Pi} = 1$). This means that in our analysis, we shall restrict attention to monetary policy rules that imply an inflation rate of zero, or one not far from zero, in the absence of stochastic disturbances. This simplification is familiar in the standard NK literature, and we follow it here in order to focus solely on the new complications introduced by heterogeneity and credit frictions. Moreover, we show in section 3 that according to the present model, optimal monetary policy has this property; hence the approximation adopted

here suffices for the study of monetary policies that are close enough to optimal policy.

We turn first to the model's "aggregate demand" block. Log-linearisation of equations (14)–(15) yields

$$\hat{\lambda}_t^b = \hat{a}_t^b - E_t \pi_{t+1} + (\delta + (1 - \delta)\pi_b)E_t \hat{\lambda}_{t+1}^b + (1 - \delta)\pi_s E_t \hat{\lambda}_{t+1}^s, \quad (29)$$

$$\hat{\lambda}_t^s = \hat{a}_t^d - E_t \pi_{t+1} + (\delta + (1 - \delta)\pi_s)E_t \hat{\lambda}_{t+1}^s + (1 - \delta)\pi_b E_t \hat{\lambda}_{t+1}^b, \quad (30)$$

introducing the notation $\hat{\lambda}_t^\tau \equiv \log(\lambda_t^\tau/\bar{\lambda}^\tau)$ for $\tau = b, s$; $\hat{a}_t^m \equiv \log(1 + i_t^m/1 + \bar{i}^m)$ for $m = b, d$; and $\pi_t \equiv \log \Pi_t$ for the rate of inflation. (In each case, a variable with a bar indicates the steady-state value of the corresponding variable, discussed in the Appendix.) Log-linearisation of (8) similarly yields

$$\hat{a}_t^b = \hat{a}_t^d + \hat{\omega}_t, \quad (31)$$

where $\hat{\omega}_t \equiv \log(1 + \omega_t/1 + \bar{\omega})$. We can similarly log-linearise (9) to obtain $\hat{\omega}_t$ as a linear function of \hat{b}_t , where we define $\hat{b}_t \equiv \log(b_t/\bar{b})$.

This system can be alternatively expressed in a way that makes the model's implications more transparent. If we take a weighted average of equations (29) and (30), weighting the two equations by π_b and π_s respectively, we obtain

$$\hat{\lambda}_t = \hat{a}_t^{avg} - E_t \pi_{t+1} + E_t \hat{\lambda}_{t+1}, \quad (32)$$

where we now define $\hat{\lambda}_t \equiv \pi_b \hat{\lambda}_t^b + \pi_s \hat{\lambda}_t^s$ as the average (log) marginal utility of income and

$$\hat{a}_t^{avg} \equiv \pi_b \hat{a}_t^b + \pi_s \hat{a}_t^d \quad (33)$$

as the average of the interest rates that are relevant (at the margin) for all of the savers and borrowers in the economy. Subtracting (30) from (29) instead yields

$$\hat{\Omega}_t = \hat{\omega}_t + \delta E_t \hat{\Omega}_{t+1}, \quad (34)$$

where $\hat{\Omega}_t \equiv \hat{\lambda}_t^b - \hat{\lambda}_t^s$ is a measure of the inefficiency of financial intermediation, insofar as the marginal utilities of the two (ex ante identical) types would be equated if financial markets were frictionless. Equations (32) and (34) are equivalent to the system (29)–(30), but highlight the fact that the (appropriately defined) *average* marginal utility of income is still related to the expected path of real interest rates – once an appropriate average interest rate is defined – in exactly the same way as in the basic NK model, while the *dispersion* of marginal utilities of income across differently situated members of the population depends only the evolution of the credit spread $\{\omega_t\}$ (which is in turn a function of exogenous conditions affecting the banking sector, and of the total volume of lending) and not the absolute level of real or nominal interest rates.

Log-linearisation of (17) yields

$$\hat{Y}_t = s_c \bar{c}_t - \bar{\sigma}(\hat{\lambda}_t + s_\Omega \hat{\Omega}_t) + \hat{G}_t + \hat{\Xi}_t, \quad (35)$$

where we define $\hat{Y}_t \equiv \log(Y_t/\bar{Y})$, $\hat{G}_t \equiv (G_t - \bar{G})/\bar{Y}$, and $\hat{\Xi}_t \equiv (\Xi_t - \bar{\Xi})/\bar{Y}$,³⁸ and the exogenous disturbance \bar{c}_t is a weighted average of changes in the impatience to consume of the two types

of households. The coefficient $\bar{\sigma}$ measures the (appropriately weighted) average³⁹ sensitivity of households' expenditure decisions to variations in the marginal utility of income (or equivalently, their interest-sensitivity);

$$\bar{\sigma} \equiv \pi_b s_b \sigma_b + \pi_s s_s \sigma_s > 0, \quad (36)$$

where σ_τ is each type's intertemporal elasticity of substitution and $s_\tau \equiv \bar{c}^\tau / \bar{Y}$ is the steady-state share of each type's purchases in aggregate national expenditure. The coefficient

$$s_\Omega \equiv \pi_b \pi_s \frac{s_b \sigma_b - s_s \sigma_s}{\bar{\sigma}} \quad (37)$$

indicates the degree to which aggregate demand is affected by heterogeneity in the marginal utility of income, given the *average* marginal utility of income; this depends on the degree to which the expenditure decisions of borrowers are more interest-elastic than those of savers. (More precisely, what matters is how much the aggregate reduction in borrowing by borrowers, per percentage point increase in the interest rate that they face, exceeds the aggregate increase in saving by savers in response to an interest-rate increase of the same size.)

Solving (35) for $\hat{\lambda}_t$ as a function of aggregate expenditure, and substituting for $\hat{\lambda}_t$ in (32), we obtain an "intertemporal IS relation"

$$\dot{Y}_t = -\bar{\sigma}(\hat{\lambda}_t^{avg} - E_t \pi_{t+1}) + E_t \dot{Y}_{t+1} - E_t [\Delta g_{t+1} + \Delta \hat{\Xi}_{t+1} - \bar{\sigma} s_\Omega \Delta \hat{\Omega}_{t+1}], \quad (38)$$

where $g_t \equiv \hat{G}_t + s_c \bar{c}_t$ is a composite disturbance as in Woodford (2003, pp. 80, 249), and Δ indicates a first difference. Note that the first four terms on the right-hand side of (38) are exactly as in the basic NK model (with appropriate generalisations of the definitions of variables and coefficients to allow for heterogeneity), while the final two terms exist only in the case of credit frictions. An important difference between this relation and the standard "IS relation" is that the interest rate appearing in it is no longer the policy rate. Instead, (31) together with (33) imply that the policy rate \hat{r}_t^{d} and the rate that is relevant for the IS relation are linked by the equilibrium relation

$$\hat{r}_t^{avg} = \hat{r}_t^{d} + \pi_b \hat{\omega}_t, \quad (39)$$

indicating that the spread between them increases when credit spreads increase.

The complete aggregate demand block developed in section 1.1 can then be summarised (in our log-linear approximation) by the intertemporal IS relation (38), together with (39) connecting the average interest rate with the policy rate, the log-linear version of (9) for the determination of the credit spread, and (34) for the determination of the marginal-utility gap $\hat{\Omega}_t$. In the case that either $\hat{\omega}_t$ or $\hat{\Xi}_t$ depends (to first order) on the evolution of \hat{b}_t , completion of the system of equilibrium relations requires a law of motion for aggregate private indebtedness. Log-linearising (26), and using the same method as above to substitute for $\hat{\lambda}_t^b$ and $\hat{\lambda}_t^s$, we obtain an equation for \hat{b}_t as

³⁸ We do not define these last two hat variables as log deviations from the steady-state value, so that we can discuss calibrations in which \bar{G} or $\bar{\Xi}$ may equal zero, though we still consider small non-zero values of the corresponding disturbances.

³⁹ Definition (36) implies that $\bar{\sigma}$ is only actually an average of σ_b and σ_s in the case that $\bar{G} = \bar{\Xi} = 0$. More generally, $\bar{\sigma}$ is s_c times the average household intertemporal elasticity of substitution, where $s_c \equiv \pi_b s_b + \pi_s s_s$ is the share of private expenditure in aggregate expenditure. In terms of the notation used in Woodford (2003, pp. 80, 243), $\bar{\sigma}$ is the coefficient analogous to σ in the representative-household model, while the coefficients σ_τ are analogous to the intertemporal elasticity of substitution σ_c .

a linear function of \hat{b}_{t-1} , $\hat{a}_{t-1}^d - \pi_t$, \hat{Y}_t , $\hat{\Omega}_t$, \hat{b}_t^g , \hat{b}_{t-1}^g , and the exogenous disturbances. (See the Appendix for details.)

Log-linearisation of the aggregate-supply block consisting of equations (27)–(28) yields the log-linear aggregate-supply relation

$$\pi_t = \xi[\omega_y \hat{Y}_t - \hat{\lambda}_t - \nu \bar{h}_t - (1 + \omega_y)a_t + \hat{\mu}_t^w + \hat{\tau}_t] + \beta E_t \pi_{t+1}, \quad (40)$$

through calculations explained in the Appendix, where we define $\hat{\lambda}_t \equiv \log(\tilde{\lambda}_t/\bar{\lambda})$, $\bar{h}_t \equiv \log(\bar{H}_t/\bar{H})$, $a_t \equiv \log(A_t/\bar{A})$, $\hat{\mu}_t^w \equiv \log(\mu_t^w/\bar{\mu}^w)$, $\hat{\tau}_t \equiv -\log(1 - \tau_t/1 - \bar{\tau})$, and

$$\xi \equiv \frac{1 - \alpha}{\alpha} \frac{1 - \alpha\beta}{1 + \omega_y\theta} > 0$$

(where $0 < \alpha < 1$ is the fraction of prices that remain unchanged from one period to the next) determines the sensitivity of the inflation rate to variation in average marginal costs. Note that (40) takes exactly the same form as in the basic NK model, except that here $\hat{\lambda}_t$ replaces the marginal utility of income of the representative household.

It is also important to note that the “average” marginal utility of income $\hat{\lambda}_t$ that enters the aggregate-supply relation is in general not exactly the same as the one that enters the aggregate-demand relation (35), or the one that is most directly related to the expected path of real interest rates in (32). The two are related through the identity

$$\hat{\lambda}_t = \hat{\lambda}_t + (\gamma_b - \pi_b)\hat{\Omega}_t,$$

where

$$\gamma_b \equiv \pi_b \left(\frac{\bar{\lambda}^b}{\bar{\lambda}} \right)^{1/\nu}.$$

Using this to substitute for $\hat{\lambda}_t$ in (40), and then using (35) to substitute for $\hat{\lambda}_t$ as in the derivation of (38), we obtain an aggregate-supply relation

$$\pi_t = \kappa(\hat{Y}_t - \hat{Y}_t^n) + u_t + \xi(s_\Omega + \pi_b - \gamma_b)\hat{\Omega}_t - \xi\bar{\sigma}^{-1}\hat{\Xi}_t + \beta E_t \pi_{t+1}, \quad (41)$$

with a slope

$$\kappa \equiv \xi(\omega_y + \bar{\sigma}^{-1}) > 0.$$

Here the composite exogenous disturbance term \hat{Y}_t^n (the “natural rate of output”) is a linear combination of the disturbances \bar{c}_t , \hat{G}_t , \bar{h}_t , and a_t (sources of variation in the flexible-price equilibrium level of output that, in the absence of steady-state distortions or financial frictions, correspond to variations in the *efficient* level of output, as discussed further in section 3); the additional exogenous term u_t (the “cost-push shock”) is instead a linear combination of the disturbances $\hat{\mu}_t^w$ and $\hat{\tau}_t$ (sources of variation in the flexible-price equilibrium level of output that do *not* correspond to any change in the efficient level of output). This is identical to the “new Keynesian Phillips curve” of the basic NK model, with the exception of the terms proportional to $\hat{\Omega}_t$ and $\hat{\Xi}_t$, indicating “cost-push” effects of the credit frictions in our extended model.

Equations (38) and (41) are thus direct analogs of two of the equations of the canonical “three-equation model”; the third equation (a central-bank reaction function, such as a Taylor rule, for

the policy rate as a function of inflation and output) is unchanged by the existence of credit frictions. In the case that both $\{\hat{\omega}_t\}$ and $\{\hat{\xi}_t\}$ can be treated as exogenous processes (so that $\{\hat{\Omega}_t\}$ is exogenous as well), these same three equations again provide a complete system for the determination of equilibrium inflation, output and interest rates, *except* that one must adjoin equation (39) to connect the interest rate that appears in the IS relation to the policy rate. If one substitutes the central-bank reaction function for \hat{r}_t^d in (39), in order to derive the implied response of the average interest rate – or if one supposes that the central bank uses the average interest rate as its operating target, a policy proposal that we analyse further in section 3 – then one again obtains a three-equation model directly analogous to the basic NK model. For example, if the central bank follows a Taylor rule of the form

$$\hat{r}_t^d = \phi_\pi \pi_t + \phi_y \hat{Y}_t + \epsilon_t^m, \quad (42)$$

then the complete model would consist of (38), (41), and

$$\hat{r}_t^{avg} = \phi_\pi \pi_t + \phi_y \hat{Y}_t + \pi_b \hat{\omega}_t + \epsilon_t^m. \quad (43)$$

The only differences relative to the basic NK model are that the interest rate appearing in this three-equation system is not the only relevant interest rate and may not correspond to the policy rate; that the numerical values of the coefficients $\bar{\sigma}$ and κ must take appropriate account of the different degrees of interest-sensitivity of expenditure of different units in the economy; and that time-varying financial frictions are an additional source of disturbance terms in all three equations.

It follows that at least in this case, inflation and output determination can be understood in exactly the same way as in the basic NK model, *regardless of the average size of credit frictions, or their degree of variability*. For example, in the case that the monetary policy equation involves no response to lagged variables (or to any endogenous variables other than inflation, output, or forecasts of these), and the policy implies a determinate rational-expectations equilibrium, that equilibrium will make inflation, output and interest rates all a function solely of the economy's *current state* – to be precise, the current values of \hat{Y}_t^n , g_t , u_t , $\hat{\omega}_t$, $\hat{\xi}_t$, and the monetary policy disturbance, and current information about the expected future evolution of these variables. (As has often been remarked of the basic NK model, the model is thus “purely forward-looking,” and cannot explain inflation persistence other than as a consequence of persistence in the exogenous disturbances just mentioned.)

In the simple case of a monetary policy described by (42), the conditions for determinacy of equilibrium remain exactly the same as in the basic NK model; in the case that $\phi_\pi, \phi_y \geq 0$, these amount simply to the requirement that the policy rule conform to the “Taylor Principle” (Woodford, 2003, p. 254), ie that the response coefficients satisfy

$$\phi_\pi + \frac{1 - \beta}{\kappa} \phi_y > 1.$$

If this condition is satisfied, one can solve for inflation as a function of current and expected future values of the disturbance processes in exactly the same way as is explained in Woodford (2003, chap. 4, secs. 2.2, 2.4), and the coefficients on current and expected future values of the disturbances \bar{c}_t , \hat{G}_t , \bar{h}_t , a_t , $\hat{\mu}_t^w$, $\hat{\tau}_t$, or ϵ_t^m at all horizons are *identical* to the predictions of the basic NK model, if the latter model is calibrated to have the same values for the coefficients β , ξ , $\bar{\sigma}$, and ω_y .⁴⁰ The only difference in the solution is that shocks to the current or expected

⁴⁰ Of course, the numerical values of some of these coefficients may be different, owing to the existence of credit frictions, than they would be in an economy without such frictions, owing, for example, to an effect of steady-state

future values of the financial disturbances $\hat{\omega}_t$ and $\hat{\xi}_t$ will affect equilibrium inflation as well.

Moreover, not only does the model predict the same numerical responses to non-financial disturbances, under given monetary-policy coefficients (ϕ_π, ϕ_y) – so that one’s conclusions about the desirability of a particular choice of those coefficients, from the point of view of how they effect the economy’s response to non-financial disturbances, will be unchanged – but the predicted responses to financial disturbances do not really involve any new considerations (beyond the mere fact that such disturbances can occur and ought to be measured in order to properly conduct policy). The effects of variations in the processes $\{\hat{\omega}_t, \hat{\xi}_t\}$ on inflation and output are predicted to be the same as the effects that *other* kinds of disturbances have, when they shift the three equations to a similar extent and with a similar expected degree of persistence. Thus the effects of financial shocks on inflation can be decomposed into three types of effects that are already present in the basic NK model: the effects of a disturbance to the “natural rate of interest” (a shift in the real average interest rate consistent with a zero output gap), the effects of a “cost-push shock” (a shift in the size of output gap required for price stability), and the effects of a “monetary policy shock” (a change in the average interest rate relative to what would ordinarily follow from the current inflation rate and output gap, in this case due to a change in the credit spread rather than a change in the policy rate). Financial disturbances typically have effects of all three types; but their consequences can be easily understood if the consequences of those three general types of disturbances are already understood.

The case in which $\{\hat{\omega}_t, \hat{\xi}_t\}$ are both completely exogenous processes is, of course, a fairly special one. If one or both of them depends on the volume of bank lending, as allowed for in our exposition above, a larger system of equations, including the law of motion for private debt, is needed in order to predict the evolution of inflation, output and interest rates. We do not seek to present analytical results for this more complex case, but instead offer some illustrative numerical results.

2.2 Model Calibration

The numerical values for parameters that are used in our calculations are explained in the Appendix. Many of the model’s parameters are also parameters of the basic NK model, and in the case of these parameters we assume similar numerical values as in the numerical analysis of the basic NK model in Woodford (2003). The new parameters that are also needed for the present model are those relating to heterogeneity or to the specification of the credit frictions. The parameters relating to heterogeneity are the fraction π_b of households that are borrowers, the degree of persistence δ of a household’s “type”, the steady-state expenditure level of borrowers relative to savers, s_b/s_s , and the interest-elasticity of expenditure of borrowers relative to that of savers, σ_b/σ_s .⁴¹

In the calculations reported here, we assume that $\pi_b = \pi_s = 0.5$, so that there are an equal number of borrowers and savers. We assume that $\delta = 0.975$, so that the expected time until a

distortions resulting from credit spreads on the steady-state level of output, and hence the point at which various elasticities are evaluated. This would not, however, affect the accuracy of predictions made by the NK model if it were correctly parameterised to match the elasticities observed in an actual economy.

⁴¹ Another new parameter as a consequence of heterogeneity is the steady-state level of government debt relative to GDP, \bar{b}^g/\bar{Y} . This parameter need not be specified in the representative-household basic NK model, since changes in it simply imply a different steady-state level of net transfers, and the size of these does not affect any of the equilibrium relations. In the model with heterogeneity, it does matter, because of the failure of Ricardian equivalence noted above. But in our baseline calculations, we assume that $\bar{b}^g = 0$.

household has access to the insurance agency (and its type is drawn again) is 10 years. This means that the expected path of the spread between lending and deposit rates for 10 years or so into the future affects current spending decisions, but that expectations regarding the spread several decades in the future are nearly irrelevant.

We calibrate the values of s_b and s_s to equal 1.1 and 0.3 respectively, so that the steady-state share of private expenditure in output is 0.7 (the mean of those two values).⁴² This degree of heterogeneity is chosen arbitrarily for purposes of illustration; it is important, however, that $s_b > s_s$, as this is required in order for the steady state to involve borrowing by the type b households. The degree of heterogeneity assumed in our calibrated examples implies steady-state debt \bar{b} between 0.5 and 0.6 of steady-state output (with the exact fraction depending on the intermediation technology).

Finally, we calibrate the value of σ_b/σ_s to equal 5. This is again an arbitrary choice, though the fact that borrowers are assumed to have a greater willingness to substitute intertemporally is important, as this results in the prediction that an exogenous tightening of monetary policy (a positive value of the residual ϵ_t^m in (42)) results in a reduction in the equilibrium volume of credit b_t (see Figures 2 and 5 below). In fact, the degree of asymmetry assumed here results in a predicted contraction of credit in response to a monetary policy shock of roughly the magnitude indicated by VAR estimates using recent US data in the case of an exogenous credit spread (Figure 2),⁴³ though the predicted credit contraction is smaller (while still positive) when we assume that credit spreads increase with the volume of credit. (In the results reported here, we hold constant our parameterisation of preferences when we change the assumed intermediation technology, in order to clarify how the intermediation technology affects the results obtained.⁴⁴)

It is also necessary to specify the steady-state values of the functions $\omega(b)$ and $\Xi(b)$ that describe the financial frictions, in addition to making clear what kinds of random perturbations of these functions we wish to consider when analysing the effects of “financial shocks.” We here mainly present results for two cases. In each case, we assume that there is no steady-state financial markup ($\bar{\mu}^b = 1$), so that the steady-state credit spread is due entirely to the marginal resource cost of intermediation; but we do allow for exogenous shocks to the markup μ_t^b (which then becomes slightly greater than 1), and this is what we mean by the “financial shock” in Figures 16 and 17 below.⁴⁵ In treating the “financial shock” as involving an increase in markups but no increase in the real resources used in banking, we follow Gerali *et al.* (2008).⁴⁶

⁴² The implied share of government purchases in total output is then 0.3, minus the small part of output that is consumed by intermediaries. The implied steady-state level of government purchases therefore varies slightly, depending on our calibration of the intermediation technology.

⁴³ As discussed in the Appendix, our estimated elasticities range from values in the range from -0.2 to -0.4 for samples using only data since the 1990s, though we obtain larger responses, on the order of -0.9, using samples including data from the 1980s. See also Lown and Morgan (2002) for evidence similarly supporting the association of credit contraction with a monetary policy tightening.

⁴⁴ To be precise, we hold constant across specifications of the financial frictions the numerical values assumed for the total share of private expenditure in aggregate output, as well as for the relative shares s_b/s_s of the two types; and for the aggregate elasticity of intertemporal substitution $\bar{\sigma}$, as well as for the relative elasticities σ_b/σ_s of the two types. This does not quite mean that the utility functions $u^b(c; \xi)$ and $u^s(c; \xi)$ are invariant; see the Appendix for details.

⁴⁵ Note that our conclusions regarding both equilibrium and optimal responses to shocks *other* than the “financial shock” are the same as in an economy in which the banking system is perfectly competitive (and there are no risk premia), up to the linear approximation used in the numerical results reported below.

The two cases considered differ in the specification of the (time-invariant) intermediation technology $\Xi(b)$. In the case of a *linear intermediation technology*, we suppose that $\Xi(b) = \bar{\omega}b$, while in the case of a *convex intermediation technology*, we assume that

$$\Xi(b) = \tilde{\Xi}b^\eta \tag{44}$$

for some $\eta > 1$.⁴⁷ In both cases, in our numerical analyses we assume a steady-state credit spread $\bar{\omega}$ equal to 2.0 percentage points per annum,⁴⁸ corresponding to the median spread between the FRB index of commercial and industrial loan rates and the federal funds rate, over the period 1986-2007. (Combined with our assumption that “types” persist for 10 years on average, this implies a steady-state “marginal utility gap” $\bar{\Omega} \equiv \bar{\lambda}^b/\bar{\lambda}^s = 1.22$, so that there would be a non-trivial welfare gain from transferring further resources from savers to borrowers.) In the case of the convex technology, we set η so that a one-percent increase in the volume of credit increases the credit spread by 10 basis points (per annum).⁴⁹ The assumption that $\eta > 1$ allows our model to match the prediction of VAR estimates that an unexpected tightening of monetary policy is associated with a slight reduction in credit spreads (see, eg Lown and Morgan, 2002); and the elasticity assumed in our calibration is roughly of the magnitude implied by the relative size of our estimates of the respective declines in the volume of credit and of the average credit spread.⁵⁰

As a first exercise, we consider the implied equilibrium responses of the model’s endogenous variables to the various kinds of exogenous disturbances, under the assumption that monetary policy is described by a Taylor rule of the form (42). The coefficients of the monetary policy rule are assigned the values $\phi_\pi = 2$ and $\phi_y = 0.25$ as in Woodford (2003, chap. 4), allowing comparison between our quantitative results here and those presented there for a calibrated representative-household model. Among other disturbances, we consider the effects of random disturbances to the error term ϵ_t^m in the monetary policy rule. Later, we consider the predicted dynamics under a variety of other monetary policy specifications as well.

2.3 Numerical results

We begin by considering the predicted responses to aggregate disturbances of a kind that also exist in the basic NK model, in order to determine how accurate that model’s answers are about the questions to which it *gives* answers. We first consider the case of a linear

⁴⁶ These authors cite the Eurosystem’s quarterly Bank Lending Survey as showing that since October 2007, banks in the euro area had “strongly increased the margins charged on average and riskier loans” (p. 24).

⁴⁷ One interpretation of this function is in terms of a monitoring technology of the kind assumed in Goodfriend and McCallum (2007). Suppose that a bank produces monitoring according to a Cobb-Douglas production function, $k^{1-\eta^{-1}}\Xi_t^{\eta^{-1}}$, where k is a fixed factor (“bank capital”), and must produce a unit of monitoring for each unit of loans that it manages. Then the produced goods Ξ_t required as inputs to the monitoring technology in order to manage a quantity b of loans will be given by a function of the form (44), where $\tilde{\Xi} = k^{1-\eta}$. A sudden impairment of bank capital, treated as an exogenous disturbance, can then be represented as a random increase in the multiplicative factor $\tilde{\Xi}$. This is another form of “financial shock”, with similar, though not identical, effects as the financial markup shock considered here; see the Appendix for further discussion.

⁴⁸ In our quarterly numerical model, this means that we choose a value such that $(1 + \bar{\omega})^4 = 1.02$.

⁴⁹ This requires that $\eta = 6.06$.

⁵⁰ See the Appendix for further details.

intermediation technology. In this case, the credit spread ω_t evolves exogenously, as assumed in the discussion at the end of section 1.1, but Ξ_t is no longer independent of b_t . Nonetheless, in this case we continue to find that for a reasonable parameterisation of the quantity of resources used in intermediation, the existence of credit frictions makes virtually no difference for the predicted equilibrium responses to shocks.

This is illustrated in Figures 2-4 for three particular types of exogenous disturbances. In Figure 2 we consider the equilibrium responses to a contractionary monetary policy shock, represented by a unit (one percentage point, annualised) increase in ϵ_t^m . We furthermore assume that the policy disturbance is persistent; specifically, ϵ_t^m is assumed to follow an AR(1) process with coefficient of autocorrelation $\rho = 0.75$. The separate panels of the figure indicate the impulse responses of output, inflation,⁵¹ the deposit rate, the lending rate,⁵² and aggregate private debt respectively. Figure 3 illustrates the equilibrium responses of the same variables to a unit positive innovation in the productivity factor, where the disturbance is again assumed to have an autocorrelation of 0.75, and monetary policy is conducted in accordance with (42) with no random term. Figure 4 shows the corresponding equilibrium responses in response to an increase in government purchases by an amount equal to one percent of total output.

In each figure, the predicted impulse responses under our model with financial frictions (the case labeled 'FF' in each figure) are contrasted with those under two variant parameterisations of the model. The case labeled 'NoFF' corresponds to an otherwise identical model in which $\omega_t(b) \equiv 0$ and $\Xi_t(b) \equiv 0$, but we retain the heterogeneity in preferences, parameterised in the same way as in the 'FF' model. The case labeled 'RepHH' is one in which in addition to assuming zero credit frictions, we assume identical preferences for the two types; this model is equivalent to a representative-household model (specifically, to the basic NK model as presented in Woodford, 2003, chap. 4). Comparison of these three cases allows us to separately consider the degree to which credit frictions as opposed to heterogeneity make a difference.

In each of Figures 2 through 4, we observe that the impulse responses of output, inflation, and the two interest rates are virtually identical under all three parameterisations of the model. (The same is true for the other aggregate disturbances that have analogs in the representative-household model – a common disturbance to the impatience to consume of all households, a disturbance to the disutility of work, a shock to government purchases, a shock to the tax rate, or a shock to the wage markup – though we do not include these figures here.) We have already explained in section 2.1 why this would be true in the case that the resources used in intermediation are independent of the volume of lending. Our numerical results indicate that even when we assume that intermediation uses resources (and indeed that credit spreads are entirely due to the marginal resource cost of making additional loans), and that the required resources are proportional to the volume of lending, heterogeneity and the existence of a steady-state credit spread (of a realistic magnitude) still make only a negligible difference. This is because the contribution of the banking sector to the overall variation in the aggregate demand for produced goods and services is still quite small.⁵³

Financial frictions matter somewhat more for equilibrium dynamics if we also assume that

⁵¹ In the plots, both the inflation rate and the interest rates are reported as annualised rates, so that 0.10 means an increase in the inflation rate of 10 basis points per annum. In terms of our quarterly model, what is plotted is not the response of π_t , but rather the response of $4\pi_t$.

⁵² In the present model, the spread between the deposit rate and the lending rate is exogenously fixed, and so these two variables necessarily respond by exactly the same amount, except in the case of a shock to the exogenous credit spread itself. However, we include both panels as we use the same format for the figures to follow, when inclusion of both is no longer redundant.

credit spreads vary endogenously with the volume of lending. Figures 5-10 show equilibrium responses of the same aggregate variables to a variety of types of exogenous disturbances, in the case of the “convex intermediation technology” calibration discussed in section 2.2. Figures 5, 6 and 8 show responses to the same three kinds of shocks as in Figures 2-4 respectively, but for the alternative intermediation technology. Figure 7 shows responses to an exogenous 1 percent increase in the wage markup μ_t^w ; Figure 9 shows responses to an exogenous increase in the impatience to consume of savers; and Figure 10 shows responses to an exogenous increase in real government debt by an amount equal to 1 percent of GDP. In each case, the disturbance is modeled as an AR(1) process with autoregressive coefficient 0.75.

In the case of the monetary policy shock (Figure 5), we again find that the equilibrium responses of output and inflation are nearly the same in all three models, though the ‘FF model’ is no longer quite so indistinguishable from the ‘NoFF’ model. The most important effect of allowing for endogeneity of the credit spread is on the implied responses of interest rates to the shock. Because credit contracts in response to this shock (as noted earlier, though now by less than in Figure 2), the spread between the lending rate and the deposit rate decreases, in accordance with the empirical finding of Lown and Morgan (2002). This means that the deposit rate need no longer decline as much as does the lending rate. Moreover, because the reduced spread has an expansionary effect on aggregate demand, both output and inflation decline slightly less in response to the shock than in the ‘NoFF’ model; this is also a reason for the deposit rate to decline less, and in fact the reduction in its decline is sufficient that the lending rate also declines slightly less than in the ‘NoFF’ model, despite the reduction in the spread. Thus the most visible effect is on the predicted response of the deposit rate, which is visibly smaller in the ‘FF model’. The effects of financial frictions are similarly mainly on the path of the deposit rate in the case of a shock to the sales tax rate τ_t (not shown).

The effects of financial frictions are somewhat less trivial in the case of the technology shock (Figure 6) and the shock to the wage markup (Figure 7). Though again the largest effect is on the path of the deposit rate, in these cases the endogeneity of the markup also has non-negligible effects on the equilibrium responses of output and inflation. (The reason for the difference is that these are now shocks that have larger effects on the path of credit, and so larger effects on the equilibrium spread in the case of the convex technology.) Because an increase in productivity leads to an expansion of credit, credit spreads now increase in the ‘FF model’; this has a contractionary effect on aggregate demand, so that output increases less, while inflation declines slightly more than in the ‘NoFF model’. Similar effects of financial frictions are observed in the case of a disturbance to the disutility of working (an exogenous increase in the multiplicative factor \bar{H}_t in (22), not shown). The effects of an increase in the wage markup (Figure 7) are likewise similar, but with opposite signs.

The effects of financial frictions are even more significant in the case of a shock to government purchases (Figure 8) or to the consumption demand of savers (Figure 9).⁵⁴ These are both disturbances that crowd out the expenditure of private borrowers (as the most interest-sensitive category of expenditure) to a significant extent, and so substantially reduce equilibrium borrowing and credit spreads. In each case, the reduction in spreads has a further expansionary effect on aggregate demand, so that output increases by more than in the ‘NoFF’ model, while inflation rises slightly instead of falling.

⁵³ Note that in each of Figures 2-4, the existence of the credit frictions in the ‘FF’ model makes a substantial difference for the equilibrium evolution of credit b_t relative to the prediction of the ‘NoFF’ model. However, this change in the size of the banking sector does not have substantial consequences for aggregate output, employment, or inflationary pressure.

⁵⁴ The shock considered here increases the value of $c^s(\lambda)$ by one percent for each possible value of λ .

Note that the effect would be quite different in the case of a shock to the consumption demand of *borrowers* rather than savers (not shown). In this case, private credit would increase rather than decrease, and by less than in Figure 9, because of the greater interest-elasticity of the demand of borrowers; this would imply a small increase in spreads, making the disturbance slightly less expansionary, but with a less dramatic effect than in Figure 9.⁵⁵ The aggregate effects of financial frictions are even smaller in the case of a uniform increase in the consumption demand of *both* types of households, since in this case the effects of the two types of expenditure on equilibrium credit spreads partially offset one another.

Finally, the consequences of financial frictions are of particular qualitative significance in the case of a disturbance to the path of government debt (Figure 10). Here we consider a disturbance to fiscal policy that temporarily increases the level of government debt, through a lump-sum transfer to households, which is then gradually taken back over a period of time, so that the path of real government debt is eventually the same as it would have been in the absence of the shock. In the case of the 'NoFF model', *Ricardian equivalence* holds, as in the representative household model; and so in these cases, the fiscal shock has *no effect* on output, inflation, or interest rates. However, an increase in government borrowing crowds out private borrowing, and in the case of the convex intermediation technology, the reduced private borrowing implies a reduction in spreads. This has an expansionary effect on aggregate demand, with the consequence that both output and inflation increase, as shown in the figure.⁵⁶

We obtain similar conclusions in the case of other simple specifications of monetary policy. For example, instead of a Taylor rule, we may assume that the central bank adheres to a *strict inflation target*, adjusting the policy rate as necessary in order to ensure that the inflation rate is unaffected by any exogenous disturbances. Once again, we find that neither heterogeneity nor financial frictions make much difference for the equilibrium responses in the case of the linear intermediation technology (we suppress these figures). In the case of the convex intermediation technology, equilibrium responses under the 'FF model' are slightly different in the case of shocks that cause substantial endogenous variation in credit spreads. For example, Figure 11 shows the equilibrium responses under this kind of policy in the case of a shock to the demand of savers (the same shock as in Figure 9), for the same three alternative models as in Figures 5-10. Again, the policy rate is increased substantially more in the 'FF model' than in the 'NoFF model', because of the reduction in the spread. And again the increase in output in response to the shock is somewhat greater in the 'FF model'; however, this effect is much less dramatic than in Figure 9. While the reduction in credit spreads has a small effect on the aggregate-supply relation – the output level consistent with price stability is slightly increased – the primary effect is on the IS relation (the average real interest rate consistent with a zero output gap is increased) and on the relation between the policy rate and the average interest rate that is relevant for aggregate-demand determination (the lower spread means that a higher policy rate is needed to achieve a given average interest rate). The latter two effects make an unadjusted Taylor rule a substantially more expansionary policy in response to this kind of shock (as shown in Figure 9), but they are automatically canceled under a (correctly implemented) inflation targeting policy,

⁵⁵ The effect of financial frictions in this case is somewhat similar to the case of the technology shock shown in Figure 5. See the Appendix for the corresponding figure.

⁵⁶ Ricardian equivalence does not hold precisely in the 'FF model' even in the case of the linear intermediation technology. However, in this case (not shown) there is no reduction in credit spreads in response to the shock, and the only consequence for aggregate demand comes from the reduction in the resources used by the banking sector, so that shock is actually (very slightly) *contractionary* in this case. (See the Appendix for the corresponding figure.) But there is very little difference in the predictions of the 'NoFF' and 'FF' models in the case of that technology, so that we omit the figure here.

so that equilibrium outcomes are not so different in the economies with and without financial frictions. The consequences of financial frictions are even more modest in the case of the other kinds of disturbances previously discussed (figures not shown here).

To sum up, we find that under an empirically realistic calibration of the average size of credit spreads, the mere existence of a positive credit spread does *not* imply any substantial quantitative difference for our model's predictions, either about the effects of a monetary policy shock or about the effects of other kinds of exogenous disturbances under a given systematic monetary policy. What matters somewhat more is the degree to which there is *variation* in credit spreads. If spreads vary endogenously (as in our model with a convex intermediation technology), then the effects of disturbances are somewhat different, especially in the case of types of disturbances – such as variations in government borrowing, or changes in the relative spending opportunities available to savers as opposed to borrowers – that particularly affect the evolution of the equilibrium volume of private credit.

Another important difference of the model with credit frictions is the possibility of exogenous disturbances to the banking sector itself, represented by exogenous variation in either the intermediation technology $\Xi_t(b)$ or the intermediation markup $\mu_t^b(b)$. Again, these disturbances matter to the determination of aggregate output, inflation and interest rates primarily to the extent that they imply variation in credit spreads. The equilibrium effects of disturbances of this kind under alternative monetary policies are considered further below (see Figures 16-17).

3. Optimal monetary stabilisation policy

We turn now to the implications of credit frictions for optimal monetary policy. We shall suppose that the objective of policy is to maximise the average ex ante expected utility of the households. This implies an objective of the form

$$E_0 \sum_{t=0}^{\infty} \beta U(Y_t, \lambda_t^b, \lambda_t^s, \Delta_t; \tilde{\xi}_t) \quad (45)$$

where

$$U(Y_t, \lambda_t^b, \lambda_t^s, \Delta_t; \tilde{\xi}_t) \equiv \pi_b u^b(c^b(\lambda_t^b; \xi_t); \xi_t) + \pi_s u^s(c^s(\lambda_t^s; \xi_t); \xi_t) - \frac{1}{1+\nu} \left(\frac{\tilde{\lambda}_t}{\tilde{\Lambda}_t} \right)^{-\frac{1+\nu}{\nu}} \bar{H}_t^{-\nu} \left(\frac{Y_t}{A_t} \right)^{1+\omega} \Delta_t, \quad (46)$$

and

$$\tilde{\Lambda}_t \equiv \left[\pi_b (\lambda_t^b)^{\frac{1+\nu}{\nu}} + \pi_s (\lambda_t^s)^{\frac{1+\nu}{\nu}} \right]^{\frac{\nu}{1+\nu}}.$$

Again, the derivation is provided in the Appendix. Note that the final term in (46) represents the average disutility of working, averaging both over the entire continuum of types of labor j and over the two types of households, using the model of equilibrium labor supply discussed in section 1.2.

While one might reasonably consider the optimal use of fiscal policy for stabilisation purposes as well, we shall here consider only the optimal conduct of monetary policy, taking as given the state-contingent evolution of the fiscal variables $\{\tau_t, b_t^g\}$. The problem with which we are concerned is thus the choice of state-contingent paths for the endogenous variables

$\{ Y_t, \lambda_t^b, \lambda_t^s, i_t^b, i_t^d, Z_t, \Pi_t, \Delta_t, b_t \}$, consistent with the structural relations (8)–(9), (14)–(17), (25)–(26), and (27)–(28), so as to maximise (45). Note that there is one fewer structural relation per period than endogenous variables, so that there is one dimension of variation of monetary policy each period, which may be thought of as the central bank’s choice of the policy rate i_t^d .

We can analyse the solution to this optimisation problem, by differentiating a Lagrangian to obtain a system of first-order conditions, that take the form of nonlinear (expectational) stochastic difference equations. (Details are given in the Appendix.) A first important conclusion, demonstrated in the Appendix, is that when there are no stochastic disturbances (ie each of the exogenous variables in $\tilde{\xi}_t$ takes a constant value), the first-order conditions for optimality admit a *stationary* (or steady state) solution, in which the rate of inflation is *zero*. Hence under an optimal policy commitment, in the absence of stochastic disturbances the inflation rate will eventually converge to zero;⁵⁷ and in the case of small enough stochastic disturbances, the optimal policy commitment will involve an inflation rate that fluctuates asymptotically around zero. To the extent that the disturbances are small enough for a linear approximation to the equilibrium relations to provide an adequate approximation to the equilibrium dynamics, optimal policy involves a *long-run average* inflation rate of zero, even in the stochastic case.

This result generalises the one obtained by Benigno and Woodford (2005) for the representative-household case, and implies that the optimal inflation target is independent of the (average) severity of the distortions resulting from credit frictions, just as it is independent of the severity of the steady-state distortions resulting from market power in the goods or labor markets or from distorting taxes. This indicates a first important respect in which conclusions about optimal policy derived from a model that abstracts from financial frictions continue to apply when one allows for such frictions. The result also justifies our attention here only to the consequences of alternative policies that imply a long-run average inflation rate near zero (as in our analysis of the consequences of a Taylor rule in section 2); since we know that the optimal policy commitment involves inflation fluctuations around zero, we can restrict our analysis to policies with that property, both when seeking to further characterise optimal policy, and when investigating the desirability of simple policy rules that are intended to approximate optimal policy.

3.1 Linear-quadratic analysis

Under certain simplifying assumptions, we can obtain an analytical solution for the optimal state-contingent policy – or more precisely, for a linear approximation to optimal policy, in the case of small enough fluctuations around the optimal (zero-inflation) long-run steady state – using the method of linear-quadratic approximation introduced in Rotemberg and Woodford (1997) and further expounded by Benigno and Woodford (2007).⁵⁸ Under these assumptions, we can derive

⁵⁷ Under a once-and-for-all commitment chosen to maximise the objective (45) at some initial date, under no constraints other than those required for a perfect foresight equilibrium from the time of adoption of the policy commitment onward – the “Ramsey” policy problem – a higher inflation rate will be chosen initially, in order to exploit the short-run aggregate-supply trade-off without having to take account of any consequences of anticipation of such inflation in the period prior to adoption of the policy; but the policy will involve a commitment to eventually reduce the inflation rate to zero, since the long-run inflation commitment internalises the consequences of anticipation of the inflation rate in prior periods. (See Woodford, 2003, chap. 7, for discussion of this in the context of the basic NK model.) Optimal policy “from a timeless perspective,” in the sense defined in Woodford (2003, chap. 7) and Benigno and Woodford (2005), instead involves zero inflation at all times, in the absence of stochastic disturbances.

⁵⁸ These simplifying assumptions are not required in order to compute a valid LQ approximation to our policy problem, as explained in Benigno and Woodford (2007). However, in general, the algebraic expression of the solution to the LQ problem will be complex, so we discuss it here only in a special case allowing a solution of

a quadratic loss function for monetary stabilisation policy with the property that minimisation of the loss function is equivalent (in the case of small enough disturbances) to maximisation of the utility-based objective (45). The linear policy rule that minimises the quadratic loss function subject to the linear constraints obtained by log-linearising the model structural relations (as in section 2.1) then provides a linear approximation to optimal policy.

We begin by using structural relation (17) together with the definition $\Omega_t \equiv \lambda_t^b/\lambda_t^s$ to solve for λ_t^b and λ_t^s as functions of Y_t, Ω_t, Ξ_t , and the exogenous disturbances. Substituting these solutions into (46), we obtain a period utility function $\tilde{U}(Y_t, \Omega_t, \Xi_t, \Delta_t; \tilde{\xi}_t)$ to replace the function U defined in (46). We then compute a quadratic (Taylor-series) approximation to the function \tilde{U} around the values of its arguments in the zero-inflation steady state, $(\bar{Y}, \bar{\Omega}, \bar{\Xi}, 1; 0)$. This takes an especially simple form under the following special assumptions: (i) the steady-state tax distortion $\bar{\tau}$ exactly cancels the distortion resulting from market power in the goods markets ($1 - \tau = \mu^p \equiv \theta/(\theta - 1)$), so that in the zero-inflation steady state, price is equal to marginal cost; (ii) there is no steady-state wage markup ($\bar{\mu}^w = 1$); (iii) the steady-state credit spread $\bar{\omega} = 0$ (which, because of relation (34), implies that $\bar{\Omega} = 1$ as well); and (iv) there are no resources consumed by the intermediary sector in steady state ($\bar{\Xi} = 0$). Note that the assumed absence of *steady-state* distortions of any of these kinds does not mean that we cannot consider the effects of these distortions; as with the other exogenous disturbances, we consider the effects of small departures from the steady-state values. But in the special case considered in this section, each of these distortions is assumed to be of order $\mathcal{O}(\|\xi\|)$ in the notation of Woodford (2003, chap. 6). Finally, we also assume (v) that the gradient $\bar{\Xi}_b = 0$ in steady state as well, so that any *endogenous* variation in the resources used by the banking sector is of, at most, second order, though we allow for variations in the intercept $\Xi_t(\bar{b})$ that are of order $\mathcal{O}(\|\xi\|)$.⁵⁹

In this special case, the Taylor series approximation to the period utility function takes the simple form

$$\tilde{U}_t = -\frac{\bar{\lambda}\bar{Y}}{2} \{(\bar{\sigma}^{-1} + \omega_y)(\hat{Y}_t - \hat{Y}_t^n)^2 + \psi_\Omega \hat{\Omega}_t^2 + (2/1 + \omega_y)\hat{\Delta}_t\} - \bar{\lambda}\bar{\Xi}_t + \text{t.i.p.} + \mathcal{O}(\|\xi\|^3), \quad (47)$$

where the term “t.i.p.” collects terms that are independent of monetary policy (because they depend only on exogenous disturbances) and the residual is of, at most, third order in the amplitude of the disturbances. Here $\bar{\lambda}$ is the common steady-state marginal utility of income of all households (under a calibration in which $\bar{\Omega} = 0$); $\bar{\sigma}$ is the “aggregate” intertemporal elasticity of substitution defined in (36) above; the coefficient $\psi_\Omega > 0$ is defined in the Appendix; and hats denote percentage deviations from the steady-state values of the various variables, as in section 2.1. As in equation (41), \hat{Y}_t^n denotes the percentage deviation of the “natural rate of output” – here equivalent to both the efficient level of output, given preferences and technology, and to the flexible-price equilibrium level of output in the absence of time-varying tax distortions, wage markups, or financial frictions – from the steady-state level of output. This variable is a function purely of the exogenous disturbances (described further in the Appendix); and it is exactly the *same* function of the exogenous disturbances as in the basic NK model (as expounded in Woodford, 2003, chap. 3), with the exception that we must in general take a weighted

a simple form. The same general method is used, however, to approximately characterise optimal policy in the numerical results presented below, that do not rely upon the simplifying assumptions introduced in this section.

⁵⁹ This last assumption is not necessary in order for the approximation (47) to average utility to be valid, but it is necessary in order for the terms in (47) that depend on policy to be *purely quadratic*, ie for them to include no linear terms. This last condition is necessary in order for the loss function to be evaluated to second order under alternative policies using only linear approximations to the model’s structural relations, as discussed in Woodford (2003, chap. 6) and Benigno and Woodford (2007).

average of the preference shocks of the two types of households, rather than assuming that their preferences always shift in exactly the same way, and use $\bar{\sigma}$ in place of the elasticity of intertemporal substitution of the representative household.

Taking a discounted sum of these terms, and using a second-order Taylor series approximation to ((25)) to substitute for the $\hat{\Delta}_t$ terms in terms of inflation, we obtain a quadratic objective

$$\sum_{t=0}^{\infty} \beta^t U_t = -K \sum_{t=0}^{\infty} \beta^t L_t + \text{t.i.p.} + \mathcal{O}(\|\xi\|^3), \quad (48)$$

where $K > 0$ and the period loss function is of the form

$$L_t = \pi_t^2 + \lambda_y (\hat{Y}_t - \hat{Y}_t^n)^2 + \lambda_\Omega \hat{\Omega}_t^2 + \lambda_\Xi \Xi_{bt} \hat{b}_t, \quad (49)$$

for certain weights $\lambda_y, \lambda_\Omega, \lambda_\Xi > 0$ defined in the Appendix. Maximisation of average expected utility is thus equivalent (to the order of approximation required here) to minimisation of the expected discounted value of the loss function ((49)). And because the terms in ((49)) are purely quadratic, the loss function can be evaluated to second order using only a log-linear approximation to the equilibrium dynamics of the endogenous variables under a given policy. Hence it is possible to use the log-linearised structural relations (derived in section 2.1) as the constraints in our (approximate) optimal policy problem. We thus obtain a linear-quadratic (LQ) problem, the solution to which provides a log-linear (approximate) characterisation of optimal policy.

It is noteworthy that in (49), both the form of the output-gap stabilisation objective (ie the definition of \hat{Y}_t^n) and the relative weight λ_y placed on this objective are *identical* (as functions of the model parameters) to those in the corresponding derivation for the basic NK model, modulo the need to “average” the preferences of the two types of households, as discussed above. In particular, not only is the output gap appearing here the same one that appears in the aggregate-supply relation (41) – when that relation is written in such a way that the trade-off between inflation variations and output-gap variations, given inflation expectations, shifts only in response to variations in distorting taxes, wage markups, or financial frictions – just as in the basic NK model; but in addition the weight is given by $\lambda_y = \kappa/\theta$, where κ is the slope of the inflation/output-gap tradeoff in (41), again as in the basic NK model. Thus in the special case that *there are no financial frictions* (ie $\omega_t = 0, \Xi_t = 0$ at all times), so that the last two terms in (49) vanish, along with the non-standard terms in (41), both the welfare-based loss function and the aggregate-supply relation (that defines the available trade-off between dynamic paths for the two variables in the loss function) are of *exactly the same form* as in the basic NK model, once one defines “average” variables appropriately. The existence of preference heterogeneity of the kind assumed in the present model – heterogeneity both with respect to the interest-sensitivity of different units’ expenditure decisions and with respect to the time variation in their opportunities for productive expenditure – does not in itself require any substantial modification of the theory of optimal monetary stabilisation policy.

If we instead allow for time-varying financial frictions (though no steady-state distortions, as explained above), but assume that there is no *endogenous* variation in these frictions – ie that $\{\omega_t, \Xi_t\}$ are exogenous processes, independent of the evolution of private indebtedness⁶⁰ – we continue to obtain a very simple characterisation of optimal policy. In this case, the final

⁶⁰ For example, we may assume that (i) no real resources are used in intermediation, so that $\Xi_t(b) = 0$, and the credit spread ω_t is a pure financial markup; and (ii) the markup μ_t^b (and hence the spread ω_t) evolves exogenously, and is unaffected by the volume of bank lending.

term in (49) is zero, and the penultimate term is independent of policy (to second order), since the log-linear approximate structural relation (34) implies that if $\{\omega_t\}$ is an exogenous process, $\{\Omega_t\}$ is also an exogenous process, at least up to a residual that is at most of second order, so that $\hat{\Omega}_t^2$ is exogenous, at least up to a residual of order $\mathcal{O}(\|\xi\|^3)$. Hence the loss function can be written (ignoring terms independent of policy) in the standard New Keynesian form, which is to say, as

$$E_0 \sum_{t=0}^{\infty} \beta^t [\pi_t^2 + \lambda_y x_t^2], \quad (50)$$

where $x_t \equiv \hat{Y}_t - \hat{Y}_t^n$ is the welfare-relevant output gap. In this case, the appropriate *objectives* of stabilisation policy remain as in the basic NK model; the only differences made by financial frictions relate to the feasible paths for inflation and the output gap, and to the path for the policy rate required to implement given paths for inflation and the output gap.

Time-variation in financial frictions does matter for the optimal conduct of monetary policy, because they shift both the IS relation (38) and the aggregate-supply relation (41)). However, only the latter relation represents a constraint upon the set of achievable outcomes for the target variables, inflation and the output gap. And the effect of financial frictions on this relation is purely to add an additional additive disturbance term. The first-order conditions that characterise the solution to the LQ problem of minimising (50) subject to the constraint that (41) hold each period are unaffected by these disturbances, and so is the optimal *target criterion* that expresses the linear relation that must exist between the evolution of inflation and of the output gap in order for the first-order conditions for optimality to be satisfied. Just as in the basic NK model, the optimal target criterion is of the form⁶¹

$$\pi_t + (\lambda_y/\kappa)(x_t - x_{t-1}) = 0. \quad (51)$$

While the state-contingent paths for inflation and the output gap that *satisfy* this criterion are different in the case of a time-varying credit spread, the criterion that the central bank should use at each point in time to determine if policy remains on track is unchanged. Not only can optimal policy still be characterised as “flexible inflation targeting,” but the optimal target criterion is of an identical form to what is optimal in the absence of credit frictions.

The implementation of an optimal policy does require the central bank to monitor the varying size of the credit frictions – more precisely, the varying size of credit spreads – in order to determine how it must act in order to ensure fulfillment of the target criterion (51). These matter for two reasons. First, the paths of inflation and the output gap consistent with (51) depend in general on the evolution of credit spreads, because of the effect of those spreads on the aggregate-supply trade-off (41). And second, the path of policy rates required to implement given (feasible) paths for inflation and output depends on the path of credit spreads, because of their effects on both the relation (38) between average interest rates and expenditure and the relation (39) between the policy rate and the relevant “average” interest rate.

The required adjustment of the policy rate follows from standard treatments (eg Clarida *et al.*, 1999; Woodford, 2003, chap. 7) of the optimal interest-rate response to “cost-push shocks” and variations in the natural rate of interest in the context of the basic NK model. Variations in credit

⁶¹ See Woodford (2003, chap. 7) for derivation of this characterisation of optimal policy in the case of the basic NK model, and for further discussion of the implementation of optimal policy using a target criterion.

spreads result in a total cost-push term in the aggregate-supply relation equal to⁶²

$$u_t^{FF} = u_t + \xi s_\Omega \hat{\Omega}_t,$$

where $u_t \equiv \xi(\hat{\mu}_t^w + \hat{\tau}_t)$ is the cost-push term in the absence of financial frictions (but taking account of preference heterogeneity), and the coefficient s_Ω is defined as in (37); and they similarly result in a natural rate of interest (understood to mean the real value of the relevant *average* rate of interest that would be required to maintain a zero output gap at all times) equal to

$$r_t^{n,FF} = r_t^n - s_\Omega(\hat{\Omega}_t - E_t \hat{\Omega}_{t+1}),$$

where r_t^n is similarly the natural rate of interest in the absence of financial frictions (but taking account of preference heterogeneity). The standard theory of how “the interest rate” should be adjusted in response to exogenous variations in the processes $\{u_t, r_t^n\}$ continues to apply under this extension of the basic NK model, but it now should be understood to determine the optimal operating target for the *average* interest rate i_t^{avg} . The required adjustment of the central bank’s *policy* rate i_t^d is then given by (39), and this relation is also shifted when credit spreads change.

The precise consequences of these several factors for the proper adjustment of the policy rate can be given a simple answer if we make still more special assumptions. In the “symmetric” case in which $s_b \sigma_b = s_s \sigma_s$, $s_\Omega = 0$, and as a result variation in credit spreads has neither a cost-push effect nor any effect on the natural rate of interest. In this case, the optimal state-contingent evolution of inflation and the output gap depend only on the evolution of the exogenous disturbances $\{\hat{\mu}_t^w, \hat{\tau}_t\}$; the implied optimal evolution of aggregate output depends also on the evolution of preferences and technology, but is similarly independent of the time variation in credit spreads. The required evolution of the average interest rate i_t^{avg} in order to support these paths is also independent of the evolution of credit spreads. Time-variation in credit spreads matters for the optimal conduct of monetary policy only because the policy rate associated with a given average interest rate changes, as indicated by (39). We obtain a simple conclusion: an increase in the credit spread ω_t reduces the optimal policy rate i_t^d , *by an amount precisely equal to fraction π_b of the increase in the credit spread.*

In this simple case, at least, we confirm the appropriateness of the kind of rule of thumb suggested by McCulley and Toloui (2008) and Taylor (2008): an increase in credit spreads justifies a reduction in the policy rate (ie the federal funds rate operating target, in the case of the U.S. Federal Reserve), below what would otherwise be justified by current aggregate conditions, by an amount that is proportional to the increase in credit spreads. However, the appropriate adjustment is not by the *full amount* of the increase in credit spreads, as these authors suggest. That would be appropriate only if it were optimal for the rate faced by *borrowers* to be unaffected by the increased credit frictions, regardless of the consequences for the interest rate obtained by *savers*. In fact, a change in the interest rate obtained by savers creates distortions, just as a change in the interest rate faced by borrowers does; and when it is necessary to increase the spread between these two interest rates, necessarily increasing distortions of one kind or the other, it is optimal to *share* the adjustment burden by increasing each kind of distortion to some extent. If there are equal numbers of savers and borrowers, the optimal rule in the present special case would be to “split the difference,” and reduce the policy rate by *half* the increase in the spread.

⁶² The cost-push effect of variations in $\hat{\Omega}_t$ here has a simpler expression than in (41), because of the assumption in this section that $\bar{\Omega} = 1$, which implies that $\gamma_b = \pi_b$.

Matters are more complicated, of course, if we assume that either the resources used in financial intermediation, the size of credit spreads, or both depend on the volume of bank lending. Rather than seek analytical results in the more general case, we present some illustrative numerical calculations of optimal policy in calibrated examples, and investigate the degree to which the insights suggested by the analysis of this simple case continue to apply.

3.2 Numerical analysis

In order to check the degree to which the results obtained above for a special case continue to hold, at least approximately, under more general assumptions, we numerically analyse optimal policy in the calibrated economies for which we have already analysed the consequences of two simple policy rule in section 2. Under assumptions more general than those used in the previous section, we can characterise the optimal responses to exogenous disturbances of various sorts by deriving the first-order conditions that characterise optimal (Ramsey) policy – the problem of maximising (45) subject to constraints (8)–(9), (14)–(17), (25)–(26), and (27)–(28) – and then log-linearising them around the zero-inflation optimal steady state. The resulting log-linear equations can be solved for log-linear optimal dynamic responses of the various endogenous variables to (small enough) random shocks to each of the exogenous disturbance processes.

A useful question about these optimal responses is the degree to which they can be achieved through one or another rule for the conduct of monetary policy. Given our results for the special case treated in the previous section, one obvious candidate for a rule is *flexible inflation targeting*, here understood to mean a commitment to adjust the policy rate as necessary to ensure that the target criterion (51) holds at all times.⁶³ Other simple proposals that we shall consider include the two policies considered for illustrative purposes in section 2, namely, the Taylor rule (42) with the coefficients assumed in section 2.2, and strict inflation targeting.

The equilibrium responses of the endogenous variables to a technology shock (of exactly the same kind previously considered in Figures 3 and 6) under each of these alternative monetary policies are shown in Figure 12. (The model parameterisation is again the one with a convex intermediation technology, as in Figures 5-11.) The solid line (labeled ‘Optimal’) indicates the equilibrium responses to the increase in productivity under the optimal policy. The dashed line (labeled ‘PiStab’) instead indicates responses under a policy that fully stabilises inflation (ie strict inflation targeting); the line marked with + signs (labeled ‘Taylor’) indicates responses under policy conducted in accordance with the Taylor rule; and the line marked with x’s (labeled ‘FlexTarget’) indicates responses under the flexible inflation targeting policy.

In the case of this kind of shock, the aggregate-supply relation (41) implies that there is little inconsistency between inflation stabilisation and output-gap stabilisation; and as a consequence strict inflation targeting and flexible inflation targeting are barely distinguishable policies.⁶⁴ They are also both very close to the optimal policy, confirming that in this respect the analytical results of the previous section continue to provide a good approximation. The Taylor rule is instead

⁶³ More precisely, the target criterion that we assume is the one that characterises optimal policy in the representative-household model. The target criterion discussed in the previous section corresponded to optimal policy in a representative household model *in which the steady-state level of output is efficient*, which required that $1 - \tau = \mu^p \equiv \theta/(\theta - 1)$. More generally, the optimal target criterion for the representative-household model continues to be of the form (51), but the definition of the output gap x_t and the relative weight λ_y are slightly different, as explained in Benigno and Woodford (2005).

⁶⁴ In fact, if we did not allow for endogeneity of the credit spread, as in the model with a linear intermediation technology, they would not differ at all.

much less close to an optimal policy, because it requires policy to be tightened in response to the output increase, even when this does not represent high output relative to the natural rate (which is increased by the technology shock). Similar results are obtained in the case of exogenous shocks to the disutility of labor, the demand of borrowers, or to the path of government debt (none of which are shown here): in each case, there is sufficiently little tension between the requirements of inflation stabilisation and of output-gap stabilisation that flexible inflation targeting and strict inflation targeting are similar policies, and both are fairly close to optimal policy (while the Taylor rule is much less close).

Figure 13 shows the corresponding equilibrium responses in the case of a shock to the wage markup (of the kind previously assumed in Figure 7), under the same four alternative policies. This case is interesting because it is one in which strict inflation targeting is clearly not an optimal policy, even in the representative-household model, owing to the substantial “cost-push” effect of such a shock. (However, even in this case, strict inflation targeting is still more similar to optimal policy than is adherence to the Taylor rule.) The figure shows that in the case of this kind of shock, as with the other “supply shocks” discussed above, *flexible* inflation targeting is nonetheless quite a close approximation to optimal policy. A similar result is obtained in the case of a shock to the sales tax rate (not shown): strict and flexible inflation targeting are no longer nearly identical policies, but flexible inflation targeting closely approximates optimal policy.

Figure 14 shows the corresponding equilibrium responses to a shock to the level of government purchases (of the kind previously assumed in Figures 4 and 8); and Figure 15 shows the responses to a shock to the demand of savers (of the kind previously assumed in Figures 9 and 11). In the case of a shock to government purchases, strict inflation targeting is again not optimal,⁶⁵ and in at least some respects the Taylor rule is in this case closer to the optimal policy than would be strict inflation targeting. Nonetheless, once again flexible inflation targeting is the closest to optimal policy of the set of simple policy rules considered here, though optimal policy would be slightly tighter in the period of the shock. In the case of a shock to the demand of savers as well, flexible inflation targeting is the closest to optimal policy, though again optimal policy would be slightly tighter in the period of the shock. Flexible inflation targeting is nonetheless a slightly tighter policy in response to the expansionary shock than strict inflation targeting would be, and in particular it prevents the persistent increase in inflation that would be allowed by the Taylor rule.

Finally, Figure 16 shows the corresponding equilibrium responses in the case of a shock to the financial markup μ_t^b , of a size sufficient to increase the credit spread ω_t by one percentage point (annualised). This kind of shock (not discussed in section 2.3 because there is no analogous shock in the models without financial frictions) would be quite contractionary if monetary policy were conducted in accordance with an unadjusted Taylor rule.⁶⁶ But as in the case of a productivity shock (shown in Figure 12) or a shock to the disutility of labor supply, either kind of inflation targeting is much closer to optimal policy. Yet even in this case, flexible inflation targeting is not quite an equivalent policy to strict inflation targeting, and is closer to the optimal policy.

Overall, our conclusion is that while the additional distortions that were omitted in the special case for which we were able to give an analytical characterisation of optimal policy in section 3.1 are of at least some significance in our calibrated model, the flexible inflation targeting rule

⁶⁵ This would be true even in the representative-household model, given the existence of steady-state distortions, as discussed by Benigno and Woodford (2005).

⁶⁶ This effect could be substantially mitigated in the case of a spread-adjusted Taylor rule, as discussed in section 3.3 below.

(51) continues to provide a fairly good approximation to optimal policy, in response to each of the variety of types of exogenous disturbances discussed above. Since this is also the rule that characterises optimal policy in the basic NK model, in at least this sense the basic NK model remains quite a good guide to policy in the kind of environment that we consider. Of course, it is important to remember that the policy prescription provided by (51) is not a complete description of the way in which the policy rate should be adjusted: it is still necessary to use a *model* of the transmission mechanism to determine what adjustments of the policy rate are needed to ensure that the target criterion is satisfied. And the model used for this latter purpose needs to be one that takes account of the credit frictions – in particular, that takes account of the variations over time in the size of credit spreads. But the target criterion around which monetary policy deliberations are structured may not need to be changed in response to the existence of credit frictions.

3.3 A spread-adjusted Taylor rule

The numerical results of the previous section show that a simple Taylor rule of the form (42) does not provide too close an approximation of optimal policy in the case of a number of different types of possible disturbances. But might an adjustment of the rule to take account of credit frictions cure some of the problems with the unadjusted Taylor rule? In particular, does the proposal of authors such as McCulley and Toloui (2008) or Taylor (2008), to adjust the federal funds rate operating target in response to changes in credit spreads, for any given level of inflation and output, represent an improvement upon the classic proposal of Taylor (1993)?

Let us consider a generalisation of (42) of the form

$$\hat{r}_t^d = \phi_\pi \pi_t + \phi_y \hat{Y}_t - \phi_\omega \hat{\omega}_t, \quad (52)$$

for some coefficient $0 \leq \phi_\omega \leq 1$. (We now omit the random term ϵ_t^m , as there is clearly nothing *desirable* about unnecessary randomisation of policy.) This kind of rule lowers the intercept of the Taylor rule by an amount equal to fraction ϕ_ω of the credit spread. In the case that $\phi_\omega = 1$, the rule is equivalent to having a conventional Taylor rule, but for the *lending rate* rather than the deposit rate (or interbank funding rate). The case $\phi_\omega = 1$ formalises the proposal of McCulley and Toloui (2008), and also captures the idea of proposals that the funds rate should be lowered when credit spreads increase, so as to prevent the increase in spreads from “effectively tightening monetary conditions” in the absence of any justification from inflation or high output relative to potential.

Figure 17 shows the responses of endogenous variables to a “financial shock” of the same kind as in Figure 16, but for variant monetary policy rules of the form (52). The response labeled ‘Taylor’ (the dashed line) again corresponds to the standard Taylor rule (the case $\phi_\omega = 0$), and is the same as in Figure 16. The response labeled ‘Taylor+25’ corresponds to the case $\phi_\omega = 0.25$, and so on up to ‘Taylor+100,’ corresponding to the case $\phi_\omega = 1$. The figure also again plots the responses under optimal policy, shown by the solid line.

We observe that adjusting the intercept of the Taylor rule in response to changes in the credit spread can indeed largely remedy the defects of the simple Taylor rule, in the case of a shock to the economy of this kind. And the optimal degree of adjustment is close to 100 percent, as proposed by McCulley and Toloui and by Taylor.⁶⁷ Figure 18 shows that the same is true in the

⁶⁷ This last conclusion is somewhat sensitive to the parameterisation of our model, even in the case of this particular type of disturbance. See the Appendix for further discussion.

case of a shock to the level of government debt (of the kind considered in Figure 10). In the case of the “financial shock”, the unadjusted Taylor rule is too contractionary, while in the case of the fiscal shock it is too expansionary; but in both cases, the spread adjustment corrects the Taylor rule in the right direction and even (for the parameter values assumed here) by almost exactly the right amount.

This is not true, however, more generally. Figure 19 shows the corresponding equilibrium responses to a shock to the demand of savers (of the kind considered in Figures 9, 11, and 15). In the case of this kind of shock, the unadjusted Taylor rule is too expansionary, and (since the shock decreases credit spreads) a spread adjustment modifies policy in the right direction, just as in Figure 18. But in this case, a 100 percent spread adjustment would be *too* contractionary; instead, a 50 percent spread adjustment most closely approximates optimal policy. Similar conclusions apply in the case of a shock to government purchases, shown in Figure 20. Again the spread adjustment is in the right direction, but a 100 percent adjustment would be far too much; in this case, the 25 percent spread adjustment leads to responses most similar to optimal policy.

In other cases, even a 100 percent spread adjustment may not be *enough* to eliminate the defects of the simple Taylor rule. Figure 21 shows the corresponding equilibrium responses to a shock to the demand of borrowers. (As with the shock to the demand of savers, we here assume a preference shock that increases $c^b(\lambda)$ by one percent for each possible value of λ .) In this case, a spread adjustment modifies policy in the right direction (ie it loosens policy), but even a 100 percent spread adjustment is not nearly enough to produce responses similar to those under optimal policy.⁶⁸ The unadjusted Taylor rule tightens policy too much in response to this kind of disturbance, but this is *not* primarily a consequence of the increase in credit spreads resulting from the shock; indeed, the Taylor rule would tighten too much in response to this shock even in an economy in which the credit spread is exogenous (as in the case of the linear intermediation technology discussed above). Indeed, the increase in credit spreads is fairly modest in this case, under our parameterisation of the model, so even a full offset for the increase in the credit spread does not correct policy by nearly enough.

This is true to an even greater extent in the case of a technology shock, as shown in Figure 22. Though the spread adjustment again modifies the Taylor rule in the right direction (making it less excessively contractionary in response to the surge in output that is justified by increased productivity), it has relatively little effect on equilibrium outcomes, given the modest increase in spreads. A similar comment applies in the case of shocks to the disutility of working, to the tax rate, or to the wage markup (not shown).

It is interesting to observe that in *all* of these cases, the spread adjustment modifies the simple Taylor rule in the right direction. There is thus some generality to the conclusion that the Taylor rule is too tight in the case of shocks that increase credit spreads (in most of the above cases, because credit increases) and too loose in the case of shocks that reduce credit spreads. However, this does not mean that the change in credit spreads, even if accurately observed by the central bank, would be an ideal indicator of the degree to which a simple Taylor rule is likely to be biased as a guide to welfare-maximising policy. For the adjustment of the Taylor-rule intercept in response to the shock that would best approximate optimal policy is not *the same multiple* of the change in the credit spread in all cases – indeed, the optimal factor of proportionality varies widely in the cases considered above.⁶⁹ Thus simply tracking credit

⁶⁸ We do not attempt to calculate the size of spread adjustment that would best approximate optimal policy in this case; it would clearly be a spread adjustment that would be excessive in the case of the other types of shocks already discussed, and so not an interesting policy proposal.

spreads would not provide enough information to make the correct adjustment: a central bank would also need to determine which kind of disturbance is responsible for an observed change in credit spreads.

Can one usefully summarise the way in which such information about the particular disturbances currently affecting the economy should be used to determine the appropriate adjustment of the policy rate? Here it is worth noting that the flexible inflation targeting rule appears superior as a general rule of thumb to any member of the family of spread-adjusted Taylor rules. The targeting rule naturally implies a certain degree of adjustment for changes in spreads. This is because the targeting rule requires the central bank to determine the path for its policy rate consistent with projected paths of inflation and output with a certain desirable property; this requires it to take account of (and to offset, to the extent that it can with a single instrument) the effects of changes in credit spreads on the structural relations discussed in section 2. As a simple example, an increase in the credit spread increases the gap between i_t^{avg} (the interest rate that is relevant to aggregate demand determination) and the policy rate i_t^d , and given any desired degree of adjustment of i_t^{avg} in response to an economic disturbance, the policy rate will instead be raised less (or lowered more) in the case of an increase in credit spreads, in order to achieve the desired effect on i_t^{avg} . This effect alone would justify a credit spread adjustment of 50 percent (in our calibrated model), as a result of equation (39). However, this is not the only adjustment that a forecast-targeting central bank should take into account; credit spreads also shift the “IS” and aggregate-supply relations as well, as discussed in section 2. Nor are adjustments for those affects the only ones that differentiate a properly implemented targeting regime from a simple Taylor rule; forecast targeting also requires that the central bank take account of shifts in the natural rate of output, shifts in the natural rate of interest, and shifts in the aggregate-supply relation due to “cost-push” disturbances, as discussed in Woodford (2003, chaps. 4, 7). Sometimes the adjustments of the policy rate required by considerations of the latter types will happen to be in the same direction as would be implied by a “spread adjustment”, but this is fortuitous, and the targeting rule provides a better way of thinking about the nature and magnitude of the appropriate adjustment of policy.⁷⁰ While implementation of such a rule requires a greater degree of sophistication (and a greater degree of accurate real-time assessment of current conditions) on the part of the central bank, a rule of this kind provides a better guide to what the central bank should be seeking to do at each point in time.

3.4 Should Policy Respond to Variations in Aggregate Credit?

Some have suggested that because of imperfections in financial intermediation, it is more important for central banks to monitor and respond to variations in the volume of bank lending than would be the case if the “frictionless” financial markets of Arrow-Debreu theory were more nearly descriptive of reality. A common recommendation in this vein is that monetary policy should be used to help to stabilise aggregate private credit, by tightening policy when credit is observed to grow unusually strongly and loosening policy when credit is observed to contract.

⁶⁹ And of course, no proportional adjustment would fully implement optimal policy in any of these cases. Ideally, the adjustment of the Taylor-rule intercept would have dynamics somewhat different from the dynamics of the equilibrium response of the credit spread. For example, one observes in Figures 19 and 20 that the optimal adjustment factor would be larger in the period of the shock than in subsequent periods, in each of these cases.

⁷⁰ For example, in the case of the technology shock in Figure 22, the main reasons why the simple Taylor rule calls for too tight a policy are that it ignores the increase in the natural rate of output and the reduction in the natural rate of interest; the fact that in the simulations shown in the figure there is also a modest increase in the credit spread is coincidental.

For example, Christiano *et al.* (2007a) propose that a Taylor rule that is adjusted in response to variations in aggregate credit may represent an improvement upon an unadjusted Taylor rule.

In order to consider the possible advantages of such an adjustment, we now propose to replace (42) by a rule of the form

$$\hat{\Delta}_t^d = \phi_\pi \pi_t + \phi_y \hat{Y}_t + \phi_b \hat{\Delta}_t, \quad (53)$$

for some coefficient ϕ_b , the sign of which we shall not prejudge. (Christiano *et al.*, like most proponents of credit-based policies, argue for the desirability of a positive coefficient.) Figures 23-26 present the equilibrium responses to four different kinds of exogenous disturbances in the case of five different rules of the form (53), corresponding to five different possible values of ϕ_b . The responses labeled “Taylor” are again those implied by the unadjusted Taylor rule (the case $\phi_b = 0$); “Taylor+025” and “Taylor+050” refer to rules in which ϕ_b is equal to .025 or .050 respectively; and “Taylor-025” and “Taylor-050” are rules in which ϕ_b is equal to -.025 or -.050 respectively. For purposes of comparison, the responses associated with optimal policy are again plotted as a solid line in each figure.

In the case of a financial markup shock (Figure 23), the unadjusted Taylor rule makes policy too tight, as previously shown in Figure 16: both output and inflation fall significantly in response to the shock, when they should not. Moreover, private credit contracts in response to this shock, and so one might suppose that a Taylor rule that responds to credit with a coefficient $\phi_b > 0$ would represent an improvement. However, Figure 23 shows that in our model, the dynamics of private credit in response to the shock do not match very well the dynamics of the adjustment of the Taylor rule needed to implement optimal policy. A value of ϕ_b between .025 and .050 will suffice to prevent the undesired initial decline in inflation at the time of the shock, but such a modification of the Taylor rule will then be *too inflationary* in subsequent quarters. Moreover, such an adjustment does little to prevent the contraction of output in response to the shock; any value of ϕ_b large enough to solve that problem to any substantial extent will be much too inflationary, and will eventually stimulate output too much in later quarters as well. The problem is that the contraction in private credit in response to the shock is *too persistent* for a simple contemporaneous response to the level of private credit to represent an improvement upon the unadjusted Taylor rule. (Because of the dynamics of private debt implied by (26), the effects upon aggregate credit are substantially more persistent than the shock to the credit spread may be.)

The idea of adjusting the Taylor rule to incorporate a positive response to credit makes even less sense in the case of other kinds of disturbances. For example, Figure 24 shows the equilibrium responses to a shock to government purchases under the same set of alternative policies as in Figure 23. In the case of this kind of shock, the unadjusted Taylor rule makes policy slightly too loose, as previously shown in Figure 14. But credit *contracts* in response to this shock, so a rule of the form (53) with $\phi_b > 0$ would be even worse. One can in fact better approximate optimal policy in response to this shock if ϕ_b is slightly negative. However, the optimal value of ϕ_b is quite small, much less negative than -.025 (the smallest negative coefficient for which we plot the responses), so there is little gain from this kind of adjustment to the simple Taylor rule.

Similar remarks apply to the case of an increase in the demand of savers (not shown). Responding to credit is even less useful in the case of an increase in the demand of *borrowers* (Figure 25). In the case of this kind of shock, the unadjusted Taylor rule makes policy too *tight* (as shown in Figure 21), but credit *increases*, so again a negative value of ϕ_b would be needed to adjust policy in the right direction. Moreover, in this case there is a problem similar to the one demonstrated in Figure 23: a negative value of ϕ_b that is large enough to prevent the undesired initial decline in inflation at the time of the shock will then be *too stimulative* in later periods, and

will at the same time not stimulate output *enough* in the first year following the shock (unless it is so large as to be quite inflationary even initially). Again the problem is that credit responds in too delayed and too persistent a way to be an ideal indicator of the required adjustment, even when the sign is reversed from the conventional advice.

In other cases, responding to aggregate credit does little to improve the defects of the simple Taylor rule. Figure 26 shows the equilibrium responses to a technology shock under the same set of alternative policies. In this case, as in the one just discussed, the unadjusted Taylor rule prescribes policy that is too tight, while private credit grows strongly in response to the shock. Thus a negative value of ϕ_b is needed to improve upon the unadjusted rule. However, the modest negative values of ϕ_b considered in the figure are insufficient to prevent policy from continuing to be much too tight. (Similar results are obtained in the case of other types of “supply” disturbances – a shock to the disutility of working, a shock to the tax rate, or a wage markup shock – though these figures are not shown here.) We could consider much larger negative values of ϕ_b , but such a policy rule would be highly destabilising in the case of any of the “demand” disturbances considered in the previous two paragraphs. And even in the case of the technology shock, no value of ϕ_b would approximate optimal policy well, because the dynamics of the required adjustment of policy would not match the dynamics of credit, as in Figure 23.

Thus there seems little advantage in modifying the Taylor to include a response to aggregate credit of the kind proposed in (53). To the extent that there is any advantage to responding to credit, improvement of the equilibrium responses to “non-financial” disturbances would require a *negative* value of ϕ_b , rather than the positive value that would correspond to seeking to stabilise aggregate credit.⁷¹ Even such advantages as may be associated with a negative ϕ_b (as in the case illustrated in Figure 24) can be as well achieved by a spread-adjusted Taylor rule (recall Figure 20), and the spread-adjusted Taylor rule has the advantage of *also* prescribing the right direction of adjustment in the case of a “financial shock.” But the flexible inflation targeting rule better approximates optimal policy than any rule in either of these simple families of modified Taylor rules, since in the case of rules of the latter sorts, the optimal adjustment coefficient is quite different depending on the type of disturbance considered.

4. Provisional conclusions

The present analysis represents merely a first attempt at exploration of what is obviously a very rich terrain. Among other obvious limitations of the present analysis, we have allowed for only one, very simple form of possible endogeneity of credit spreads.⁷² Further analysis will be necessary before we can judge how robust the conclusions of the present analysis are to variations in this aspect of our model of the monetary transmission mechanism. Nonetheless, it

⁷¹ The fact that in each of these cases a somewhat negative value of ϕ_b would be better than any positive value is not accidental. It is an implication of our observation, in the previous section, that it is quite generally desirable to reduce the Taylor rule intercept in response to an increase in credit spreads. Since in the case of the convex intermediation technology (assumed again in this section), credit spreads increase if and only if credit increases (in the case of any of the non-financial disturbances), an adjustment equivalent to a “spread-adjusted Taylor rule” requires that $\phi_b < 0$. However, the required sign of the response to credit is reversed in the case of a “financial shock,” since in this case a shock that increases credit spreads reduces credit.

⁷² For example, we abstract from both from the possible dependence of loan rates on borrowers’ net worth stressed in the “financial accelerator” model of Bernanke *et al.* (1999) and from the stickiness of loan rates stressed by Hulsewig *et al.* (2007), Teranishi (2008), Sudo and Teranishi (2008), and Gerali *et al.* (2008).

may be useful to summarise some of the provisional conclusions suggested by our results.

4.1 Implications for models for policy analysis

With regard to the most general question raised in our introduction, our results suggest that the basic view of the way in which monetary policy influences aggregate expenditure and inflation presented in New Keynesian models need not be modified in any fundamental way as a consequence of the observation that substantial spreads exist on average between different interest rates in the economy, or that these spreads are not always constant over time. We have exhibited a simple extension of the basic NK model in which a time-varying positive spread exists between the interest rate available to savers and the interest rate at which borrowers can borrow. Yet in at least the simplest version of this model, the monetary transmission mechanism is virtually identical to that of the basic NK model: monetary policy can be viewed purely as central-bank control of a short-term nominal interest rate (the deposit rate i_t^d), and the ways in which aggregate expenditure and inflation are determined by the expected central-bank reaction function for the policy rate (e.g., a Taylor rule specification) are nearly identical to those in the basic NK model. Hence the fundamental lessons implied by that framework for monetary policy analysis continue to apply (for example, the conclusion that central banks influence the aggregate economy primarily by affecting the expected future path of short-run real rates of return, rather than through their control of the current short rate as such, the conclusion that optimal policy is history-dependent, and so on).

This does not mean that financial frictions are irrelevant to output and inflation determination. Even in the simplest case of the present model, time-variation in credit spreads affects both the “IS relation” between the expected path of the real policy rate and aggregate expenditure and the “AS relation” between aggregate output and inflation. However, in the simplest version of the model, these spreads simply contribute additional additive terms to these relations, corresponding to a new form of exogenous disturbance, in addition to the real sources of variation in the natural rate of interest and natural rate of output, and the “cost-push” disturbances allowed for in the basic NK model. The occurrence of such additional disturbances matters: successful monetary policy requires appropriate adjustment of the policy rate in response to disturbances, and this requires monitoring them in real time and correctly identifying their character as they occur. But the effects of “financial shocks” in the simplest version of our model with credit frictions are not fundamentally different than the effects of a certain linear combination of types of shocks that are already considered in the standard NK literature, and the appropriate response to them (from the point of view of stabilisation of inflation and/or real activity) is the same as would be appropriate in the case of that combination of familiar shocks.

Among other things, allowing for credit spreads does not in any way require one to reconsider the often-noted de-emphasis of measures of the money supply and sources of money demand in standard NK models.⁷³ We have shown that it is possible to extend the basic NK model to incorporate time-varying credit frictions, without making any reference to money or introducing a transactions role for money. This can be interpreted as a “cashless” model in which there actually are no transactions balances and no government liabilities that are held other than for

⁷³ Critics of the omission of a fundamental role for monetary aggregates in NK models (eg Issing, 2006; Goodhart, 2007) often point to the absence of multiple interest rates and of any role for financial intermediaries as a ground for suspecting the empirical relevance of such models. Goodhart, in particular, proposes that the absence of financial frictions in such models may account for the absence of an essential role for money: “by basing their model on [frictionless financial markets], the Neo-Keynesians are turning their model into an essentially *non-monetary* model. So it is no surprise that monetary variables are inessential in it” (p. 11).

their pecuniary returns. But as usual, the model can also be interpreted as one in which money does supply liquidity services and earns a correspondingly lower return than government debt, and in which the central bank implements its interest-rate target by adjusting the supply of money. It remains the case, under this latter interpretation, that what matters about monetary policy is the intended reaction function for interest rates, and not the adjustments of the supply of money that are required in order to achieve the interest-rate targets, and that, under a plausible calibration of the size of monetary frictions, the existence of such frictions is of negligible quantitative significance for the predicted evolution of aggregate activity and inflation.

In particular, there is no intrinsic connection between monetary statistics and the credit frictions in our model, so that a desire to track time variation in the credit frictions does not provide any new justification for particular attention to monetary aggregates. Of course, if we were to assume a mechanical proportionality between some monetary aggregate and the volume of intermediation through the banking sector – as, for example, in the model of Goodfriend and McCallum (2007), where deposits are always in strict proportion to base money, owing to an always-binding reserve requirement, the absence of uses for base money other than satisfaction of the reserve requirement, and the absence of sources of funding for banks that are not subject to the reserve requirement – then that measure of money could be useful for understanding aggregate conditions, to the extent that aggregate lending is an important determinant of aggregate demand. Even in the world modeled by Goodfriend and McCallum, however, it is unclear why anyone should prefer to monitor base money rather than bank credit (or aggregate bank liabilities) directly, unless more direct measures are for some reason unavailable. And in a more realistic model of banking under current conditions, the connection between the volume of financial intermediation and monetary aggregates is more tenuous. Indeed, there is no conceptual necessity of any connection between money and financial intermediation at all, as our model shows. Speaking of the importance of monitoring “money and credit” (in the same breath) because of the importance of financial intermediation to the economy appears to provide support for the traditional monetarist emphasis on measures of the money supply, but in fact there is no reason to equate credit with money. A proposal (as in the “monetary analysis” of the ECB) to track changes in bank credit to the extent that it belongs among the “components and counterparts” of a broad measure of the money supply might fortuitously result in attention to some useful information, but not due to a sound understanding of what one should be trying to measure.

There is a somewhat stronger case for attention to *credit* aggregates than monetary aggregates in the conduct of monetary policy. Nonetheless, the mere observation that credit frictions are important does not in itself make it obvious that policy should be conditioned on the observed evolution of the volume of lending. In our model, it is *credit spreads* that are of most direct significance as disturbance terms in the structural equations of our model of the transmission mechanism of monetary policy. In the simplest case, the part of the model that determines the evolution of aggregate credit actually decouples from the block of equations that are needed to determine the evolution of output and inflation. More generally, this is not true, but mainly because of the possibility that credit spreads are endogenously affected by changes in the volume of lending.⁷⁴ In such a case, it would still seem more important to monitor the endogenous variation in credit spreads in order to judge the appropriate level for the policy rate, rather than to monitor the volume of lending (which would be one among the several determinants of variation in those spreads).

⁷⁴ Technically, the volume of financial intermediation can also be relevant to aggregate demand determination owing to its implications for the resources consumed by the banking sector, but it is not obvious that this should be quantitatively important.

While our results suggest that in the case of many types of aggregate disturbances (both disturbances that are ordinarily thought of as “demand” disturbances, and others that are considered “supply” disturbances), the effects of shocks on the evolution of output, inflation and interest rates under a conventional specification of monetary policy are not too greatly changed by the introduction of credit frictions, this is not uniformly the case. One example is the effects of changes in the path of government debt owing to shifts in fiscal policy. While fiscal policy has *no* effects on inflation, output or interest-rate determination in the basic NK model (if distorting tax rates are assumed not to change, so that the changed path of government borrowing corresponds only to a change in the time path of net lump-sum transfers from the government) – that is, “Ricardian equivalence” obtains – in the presence of credit frictions of the kind modeled here, this is no longer the case (even under the special assumption about tax rates). This suggests that the integration of fiscal variables into models used in central banks for monetary policy analysis may deserve a higher place on the research agenda.

4.2 Implications for monetary policy

It is more difficult to draw definite conclusions about desirable monetary policies from our analysis, as conclusions of this kind are likely to be sensitive to details of model specification. We have nothing to say about the issue of how monetary policy decisions should take into account financial stability concerns – either possible consequences of interest-rate decisions for systemic risks to the financial sector, of the kind emphasised by the US Federal Reserve in some of its decisions this year, or possible consequences of interest-rate policy for risk-taking behavior, of the kind hypothesised by Borio and Zhu (2007) – since we simply abstract from such concerns in our reduced-form model of the financial sector. In principle, it should be possible to address concerns of these kinds within our framework, by introducing more complex hypotheses about the nature of endogenous variation in credit spreads, and we hope to pursue such an investigation in future work. Here we are able only to shed light on the way in which monetary policy should be affected by the magnitude of and time variation in credit spreads, taking the evolution of credit spreads as a given, that monetary policy (in the sense of interest-rate policy) is not expected to influence.

In posing this relatively limited question, we do not mean to deny the importance of central banks’ role as “lender of last resort.” However, contrary to some accounts, we do not see an intrinsic connection between this dimension of central banking and monetary policy (in the narrow sense of interest-rate control and control of the supply of central bank balances for use in payments). It seems to us that the most important way in which central banks reduce risks to financial stability is by extending credit to financial institutions in distress, as in the case of the US Federal Reserve’s traditional discount-window policy, or the new lending facilities created more recently; and lending of this kind need not imply either a reduction in the central bank’s interest-rate target or an expansion of its balance sheet (as has generally been true of the fairly aggressive lending by the Fed and ECB in recent months). While decisions about this aspect of central-bank policy are important and sometimes quite subtle, they can be considered in relative independence of a bank’s monetary policy objectives, and we do not seek to say anything about them here. Instead, we take this dimension of policy, with whatever consequences it may have for the evolution of credit spreads, as given, and consider the proper conduct of monetary policy given the lending capacity of the financial sector (represented by our assumptions about the “intermediation technology” and “financial markup”).

Of course, even our conclusions about optimal interest-rate policy may well have to be modified if one takes account of other possible sources of endogenous variation in credit spreads; only replication of our analyses under additional variant assumptions will be able to determine to

what extent this may be true. Nonetheless, we find some of the results from our analyses of alternative policies in the present simple model quite suggestive. At the very least, these should provide hypotheses deserving of further study in the context of more complex models. Probably the most interesting of these results relate to the way in which monetary policy should take account of variations in credit spreads.

It is often argued that widening credit spreads provide a *prima facie* case for the appropriateness of lowering the central bank's policy rate. The argument commonly given is that when spreads increase, the terms on which it is possible to borrow are tightened, even in the absence of any increase in the policy rate. If it was not desired to tighten monetary conditions, it is therefore necessary to lower the policy rate, to the extent required in order to preserve the original cost of borrowing. Authors such as McCulley and Toloui (2008) suggest a one-for-one reduction in the policy rate in response to increases in particular credit spreads.

In our model, it is certainly right that the policy rate is not the only interest rate that matters in assessing the degree to which financial conditions are expansionary. We can, to a useful approximation, define an "average" interest rate such that aggregate demand depends on the expected path of this average rate (relative to expected inflation); and when credit spreads increase, this average rate will be higher relative to the policy rate than under more ordinary circumstances. Hence it is necessary to lower the policy rate in order to prevent financial conditions from tightening, in the relevant sense. However, this argument alone would *not* justify lowering the policy rate by the full amount of the increased spread, nor would it justify lowering it to the extent necessary to keep *the rate at which it is possible to borrow* from rising. An increase in credit spreads also causes the lending rate to rise relative to the average rate, so that it is necessary for the lending rate to rise if financial conditions are not to be *loosened*, in the sense that matters for aggregate demand and the generation of inflationary pressure.

In the calibrated numerical examples considered in our paper, it is in some cases desirable to lower the policy rate by the full amount of the increase in the spread between the deposit rate and the lending rate; but in a number of cases a much smaller adjustment would lead to a more nearly optimal policy, while in other cases, even an adjustment several times as large as the increase in credit spreads would not suffice to correct the bias associated with a simple Taylor rule. While we find that a spread adjustment of the kind proposed by McCulley and Toloui would generally represent the right *direction* of adjustment of policy, relative to a simple Taylor rule, the simple adjustment that they suggest is not at all accurate as a guide to the *magnitude* of adjustment that would be appropriate.

Still less would our model justify the view, which sometimes appears to be assumed in popular discussions of the appropriate response to strains in credit markets, that the persistence of higher-than-average credit spreads means that *interest rates have not been cut enough*. (This is evidently what is assumed when commentators seek to judge whether policy rates have been cut by the right amount by looking at whether spreads remain unusually large, rather than asking whether borrowing rates are actually high.)

It is true that an increase in spreads is a source of deadweight loss in our model, so that a reduction of spreads to normal levels, if this could be done without changing anything else, would be desirable. But it is not necessarily true that monetary policy can do anything to undo an increase in credit spreads – this is certainly the case in our simplest model, where the credit spread is determined entirely by exogenous factors – and lowering interest rates will instead certainly have collateral effects. Even if monetary policy can influence spreads, it is not obvious that this will be beneficial. For example, in the case that spreads are endogenous because they depend on the volume of bank lending, monetary policy can lower spreads to the extent that it can lead to a contraction of bank lending; but *that* would not necessarily increase efficiency,

even if a reduction in the spread associated with a *given* volume of lending would enhance efficiency (by allowing more lending). A better principle may well be to use monetary policy to mitigate the distortions *caused* by an increase in credit spreads, to the extent that this is possible, rather than seeking to use policy to influence the level of spreads as such.

We have also briefly considered the view that a policy rule that responds to aggregate credit, in addition to inflation and real activity, will better stabilise the economy in the case that credit frictions are important. We have found little support for such a view, at least in the context of our model. In the case of “non-financial” disturbances of a variety of types, our analysis indicates that a more nearly optimal response to the disturbance than would result from a simple Taylor rule requires, if anything, that the intercept of the Taylor rule be *reduced* when aggregate credit increases – the opposite of the conventional advice, deriving from the idea that monetary policy should seek to stabilise aggregate credit, in addition to inflation and real activity. But in fact no rule that responds to aggregate credit has very desirable properties, especially if the same response coefficient is assumed regardless of the nature of the disturbance.

In fact, it is not obvious that one should expect to find any single variable (or even a small number of variables) that, when added to a standard Taylor rule, will provide a sufficient guideline for sound policy, regardless of the type of disturbances to which an economy may be subject. Instead, as has often been argued in other contexts, a policy prescription that specifies a *target criterion* that the central bank should seek to ensure is projected to be satisfied at all time is likely to provide a more robust description of good policy than a prescription for the bank’s reaction function. For example, our simulations show (consistently with previous literature) that a Taylor rule does not always lead to desirable policy responses to disturbances, even in the absence of financial frictions. It can hardly be expected, then, that modifying the Taylor rule to properly take account of variation in spreads can solve all of the problems with such a simple prescription.

A policy rule that directs the central bank to adjust its policy rate as necessary to satisfy a “flexible inflation target” will *automatically* require the central bank to adjust the policy rate to take account of changes in the severity of financial frictions, without any need to modify the target criterion that the bank aims to conform with. In our model of the transmission mechanism, it is the level and expected future path of the *average* interest rate, rather than the policy rate, that determines whether the evolution of output and inflation should satisfy the target criterion. When the relation between this average rate and the policy rate changes owing to a change in the size of interest-rate spreads, the level and expected path of the policy rate required for conformity with the target criterion will obviously change. The required policy rate will similarly change as a result of the effects of changing credit spreads on the “IS relation” and aggregate-supply relation discussed in section 2.

When the policy rule is specified in terms of a target criterion, it is not obvious that the target criterion that should be chosen depends much on the importance of credit frictions. In a particularly simple case of a model with time-varying credit frictions, we have shown that the optimal target criterion remains *exactly the same* as in the basic NK model: the central bank should seek to stabilise a weighted average of the inflation rate and the rate of growth of the output gap (or alternatively, to stabilise an output-gap-adjusted price level). Under more general assumptions, this exact equivalence does not obtain. Nonetheless, the target criterion that would be optimal in the case of the model without credit frictions seems still to provide a fairly good approximation to optimal policy in the model with credit frictions, when these are parameterised to be of an empirically realistic magnitude. Because of the advantages (for example, from the point of view of communication) of commitment to a simple criterion, and because of the degree to which any attempt to refine the rule would depend on fine details of the specification of the financial frictions, about which there is likely to be uncertainty in any

event, our results suggest that maintaining a commitment to the same target criterion as would be optimal in the absence of financial frictions is not a bad idea. This suggests that a central bank should *not change its target criterion* – what it regards as acceptable paths of inflation and real activity – at all in times of financial stress, but instead should take account of those developments *only* as a result of the changes that they imply for the links between the policy rate and the evolution of the target variables, and hence for the path of the policy rate that is required to satisfy the target criterion.

Comments on “Credit Frictions and Optimal Monetary Policy”, by Cúrdia and Woodford¹

Olivier Blanchard²

Cúrdia and Woodford (CW) have written a topical and important paper. There is no doubt in my mind that it will become a standard and much studied reference.

Let me first briefly place it in the broader context of current macroeconomic research. First-generation new-Keynesian models, of the type analysed by Woodford in his well-known book (2003), were based on a few central imperfections, namely monopolistic competition to allow for non-trivial market power and price setting, and nominal rigidities; their purpose was to show how shifts in demand could indeed affect output, and study the basic role of policy in that context. It was clear however that these models missed many of the imperfections central to macro. Thus, second-generation new-Keynesian models are focusing on the implications of additional imperfections, be it in labour markets, goods markets, financial markets, and credit markets. CW is likely to become one of the standard references for credit market imperfections.

The paper has all the hallmarks of the Woodford technology:

- The careful introduction of an additional imperfection in the benchmark NK model: Here, the imperfection is taken to be a wedge between borrowing and lending rates, which may come either from the use of resources in intermediation, or from the market power of intermediaries.
- A delicate choice of assumptions, to capture the essence while keeping tractability. A typical problem in introducing heterogeneity (here of lenders and borrowers) is the complexity of keeping track of distributions. Here, the choice by CW to allow for some insurance but only at the time when agents change type, elegantly cuts through the Gordian knot, and makes for a tractable analysis.
- A tough slog through the derivations, showing all the unpleasant terms in the equations, allowing one to assess whether they matter or not.
- At the end of the derivation tunnel, the emergence of a simple structure, based on the interaction of the heterogeneity of agents and the wedge, showing the effects of the wedge on both (consumption) demand, and (labour) supply.
- A set of strong positive and normative conclusions, and of practical policy conclusions.

Let me now turn to the specific issues. Observing the current financial crisis, many observers have two main worries. The first is that the deterioration of financial intermediation will have major adverse effects on activity. The second is that, in that environment, monetary policy may just not work. Taken at face value, the CW results are reassuring:

- The effects of a worsening of financial intermediation, they tell us, are likely to be limited. Changes in the wedge have important distribution effects, but small aggregate effects.

¹ Prepared for the BIS annual conference, June 2008.

² MIT and NBER.

- Monetary policy still works. Indeed, optimal monetary policy remains simple. When changes in the wedge are exogenous, then the optimal target criterion remains the same as in the model without a wedge. The key to a good policy is to focus not only on the rate controlled by the central bank (the lending rate in their model), but more so on the borrowing rate (the rate faced by borrowers in the economy).

Should we buy this reassuring message? Are these conclusions robust, or instead the result of specific assumptions? This is the question I shall take up in the rest of my comment. (There are many other results in the paper, which would all warrant further discussion: the effects of the existence of financial intermediation on the dynamic effects of other shocks; the effects of shocks to borrowers' or savers' behaviour; the characteristics of optimal monetary policy; the conditions under which a Taylor rule remains a good approximation; the use, if any, of credit aggregates. They are all important. Lack of time prevents me from taking them up.)

Let me start with an informal description of how CW reach their conclusions:

They focus on an economy where intermediation takes place between households — not between households and firms. Some households are lenders, some are borrowers. The difference between the two types comes primarily from a difference in effective discount rates. Savers discount the future less, borrowers discount the future more. (Households change types randomly, so there is a well defined steady state distribution of wealth.)

Intermediation is subject to a wedge, which makes the borrowing rate be higher than the lending rate. An increase in the wedge, at the same average interest rate, decreases the lending rate and increases the borrowing rate. As lending is less attractive, lenders save less. As borrowing is less attractive, borrowers borrow less. The result is strong distribution effects, with higher consumption by lenders, lower consumption by borrowers.

Can we sign the aggregate effect? Typically yes. As lenders tend to have lower consumption than borrowers, they account for a smaller fraction of the total demand for goods. Thus, their higher consumption is more than offset by the lower consumption of the borrowers. Aggregate demand goes down. (A more technical remark here: This aggregate effect is made stronger in the model by the assumption that the two groups differ in another way, namely in their elasticity of substitution. This seems rather unconvincing.)

A very similar mechanism operates on the labour supply side. In response to an increase in the wedge, for a given average rate, savers want to consume more and work less, borrowers want to consume less and work more. Thus, there is again a clear distribution effect, with a decrease in the labour supply of savers, an increase in the labour supply of borrowers. The aggregate effect is again likely to be small, but we can typically sign it: As savers work relatively more, they account for more of labour supply than borrowers, and thus their effect dominates: Labour supply decreases.

In short, an increase in the wedge leads to an adverse shift in aggregate demand, and an adverse shift in aggregate supply. It has potentially large distribution effects, but small aggregate effects. Monetary policy still works: The monetary authority can still affect the lending rate, and by implication, given the wedge, the borrowing rate. It just has to take into account that there are two rates. A policy such as that followed by the Fed over the last year, ie cutting the policy rate to maintain a roughly constant borrowing rate for prime loans or mortgages for example, is often, but not always (that depends on the underlying shocks) a good policy.

Are these conclusions likely to be robust? I am not sure.

CW focus on intermediation between households, rather than between households and firms. Thus, a failure of intermediation makes some households consume more and work less, others consume less and work more. There is no direct effect on production. It is clear, however, that much intermediation is between households and firms. Suppose that production takes time, and firms need to borrow in order to buy inputs. Then less

intermediation directly translates into less production. Or suppose, more conventionally, that financial intermediation is between saving and investment. Then, less intermediation implies less investment today, and thus less production in the future. In both cases, we are not talking about the net outcome of distribution effects, but with a direct effect on production. Can these effects be large? I suspect they can be.

Can we be sure that monetary policy continues to operate even under poor financial intermediation? Suppose again that intermediation is between saving and investment. And suppose, for the sake of argument, there is a complete breakdown of intermediation: Firms can no longer borrow, at any interest rate, and production/investment stops. It is clear that, if monetary policy can only affect the lending rate, it will have no effect on the outcome. Admittedly, I have looked at an extreme case, but it makes me think that non-linearities may be more relevant than the CW setup suggests. Other methods of intervention, such as direct liquidity provision, may work better than standard open-market operations.

Let me conclude. The paper represents a large methodological step. It shows how one can integrate financial intermediation in a general equilibrium model of fluctuations. It clarifies many technical and conceptual issues along the way. It suggests foundations for a recipe for central banks which smells right: Focus in large part on the rate at which the ultimate borrowers can borrow, rather than on the rate you control directly. It does not pretend to be the last word on the topic, but it provides the platform on which we can build.

Comments on “credit frictions and optimal monetary policy” by Cúrdia and Woodford

Charles Goodhart

Analyses and assessments of central bank activities have been unduly uni-dimensional in recent years, prior to 2007, focussing almost entirely on the role of their Monetary Policy Committees in setting interest rates, and virtually ignoring their other core purposes of maintaining financial stability and financial efficiency. By more, or less, exactly the same token the basic New-Keynesian DSGE macro-model is unidimensional in that it abstracts entirely from the key financial risk, that is default risk. The transversality condition, which embodies this risk-free assumption, allows the model to be made much simpler and more tractable, in particular by having representative agents. But it is nevertheless unsatisfactory. It is unrealistic; it is essentially non-monetary and non-financial, with no role for financial intermediation; academically it divides macro, with no proper role for default risk, from finance, where the relationship between risk and return and the probability of default are central.

I had hoped that a silver-lining to the financial turmoil of the last year would be that it would have demonstrated to the better macro-economists, and amongst these Michael is probably the best, of the fundamental error of their current approach. But so far I have been wrong. What Curdia and Woodford have done, building on the earlier Goodfriend and McCallum 2007 paper, is largely a botch job, to repair the outputs of the model without reworking the fundamental inputs. What they do, in effect, is to spatchcock a primarily exogenous and time-varying risk spread, a spread between rates offered to depositors and paid by borrowers, onto the model as before. Thus one has to adjust official policy rates, and expectations thereof, by taking account of the time-varying risk spread, and expectations thereof; but once that is done one largely, entirely in Goodfriend and McCallum, goes on as before.

I have to admit that for forecasting and descriptive purposes, it is a rather clever dodge. We all know that there are several features of the current credit crunch that are distinct and separate from measured spreads, for example denial of access to credit for sub-prime borrowers at any interest rate, tightening of credit conditions for those maintaining access to credit, etc., but these should be highly correlated with spreads, and thus for purely descriptive and forecasting purposes, the augmented model may well prove able to accommodate the events of 2007/8.

But this is because of the introduction of a ‘deus ex machina’, an exogeneously introduced time-varying interest rate spread. Where does this come from? Everybody knows that, in practice, this derives primarily from default risk; let me just cite Taylor and Williams, ‘A Black Swan in the Money Market’, NBER WP 13943, April 2008. Yet there is no mention of default in Goodfriend and McCallum, or at any rate in the early drafts of Curdia and Woodford. It is Hamlet without the Prince of Denmark. How can one sensibly discuss banking, or risk spreads, or money without treating default up front and centre?

There is, indeed, a debate whether the recent crisis was primarily driven by liquidity or default risk worries, but the two concepts are inextricably inter-twined. Concern with potential failure leads lenders to refuse to roll-over, and illiquidity can rapidly drive both individual banks and financial systems into solvency problems. The anticipation of potential defaults leads to contractions of credit, deleveraging, which latter does most of the damage, even without the necessity of formal default events. Neither Bear Stearns, nor Northern Rock, nor IKB formally defaulted, but the prospect that they, and others, might, (alongside sub-prime borrowers, various hedge funds and SIVs), exacerbated the recent turmoil.

One response, though I believe that it is an inadequate response, is that modelling a system with default is just too difficult. I do not believe that this is so. Martin Shubik and Dimitri Tsomocos, the latter with my support and encouragement, have done so. Moreover, a major reason why modelling default is difficult is that it forces one to abandon the representative agent formulation. In this respect Curdia and Woodford have taken a major step forward, which I commend and applaud. They have realised that the introduction of financial frictions logically requires agents to be heterogeneous. But then the authors require all their agents to save and borrow through banks. No reason for this constraint is given. Why does it happen in practice? As Diamond and Rajan have explained, it is because banks should be better able to screen credit risks (pace some recent events) and a combination of withdrawable deposits and the central bank safety net should make bank deposits safe for depositors.

But once we leave, as we should, the world of representative agents, the complexity of models increases sharply, as I think is well evidenced by the theoretical sections of the current paper. It should not be beyond the capacities of someone as gifted as Mike, and his associates, to go the extra step and to incorporate default risk at the heart of their analytical work. If I could only persuade him to do this, I would feel that my own work in this field had been justified.
