Credit ratings and credit risk: Is one measure enough?

Jens Hilscher and Mungo Wilson[*]

Abstract

This paper investigates the information in corporate credit ratings from a positive and normative perspective. If ratings are to be informative indicators of credit risk they must reflect what a risk-averse investor cares about: both raw default probability and systematic risk. We find that ratings are inaccurate measures of raw default probability - they are dominated as predictors of failure by a simple model based on publicly available financial information. However, ratings do contain relevant information since they are related to a measure of exposure to common (and undiversifiable) variation in default probability, exposure that is related to CDS risk premia. Given the multidimensional nature of credit risk, it is not possible for one measure to capture all the relevant information. In consequence, ratings may be prone to misinterpretation.

JEL Classification: G12, G24, G33

Keywords: credit rating, credit risk, default probability, forecast accuracy, systematic default risk

1 Introduction

Despite recent criticism, credit ratings remain the most common and widely used measure of corporate credit quality. Investors use credit ratings to make portfolio allocation decisions; in particular pension funds, banks, and insurance companies use credit ratings as investment screens and to allocate regulatory capital. Central banks use credit ratings as proxies for the quality of collateral. Corporate executives evaluate corporate policies partly on the basis of how their credit rating may be affected. The recent financial crisis has resulted in renewed debate to understand if ratings are appropriate for these purposes. Regulators have called for alternatives and the U.S. government has sued S&P over pre-crisis fraud.[1]

Before we can assess the suitability of credit ratings or embark on a search for alternatives, it is important first to understand (a) what credit ratings *should* measure, (b) what credit ratings *actually* measure, and (c) if a single measure can capture all the relevant information. A diversified and risk-averse investor will care about both raw default probability and systematic risk, just as a corporate bond's price depends not only on its expected payoff (which depends on its raw default probability) but also on its discount rate or risk premium (which depends on its systematic default risk). Credit ratings, if they are indeed suitable measures of credit risk, therefore ought to contain information about at least one and ideally both of these important attributes.[2]

Our analysis proceeds in two steps. First, we analyze the extent to which credit ratings reflect information about raw default probability. Using U.S. data from 1986 to 2008 we compare prediction accuracy of S&P credit ratings[3] and a simple alternative based on publicly

---

[1]Section 939A of the 2010 Dodd-Frank act calls for federal agencies to review regulations containing "any references to or requirements ... regarding credit ratings." In February of 2013 the U.S. Department of Justice sued S&P.

[2]Interestingly, rating agencies themselves appear to be aware of this distinction: On the one hand, Standard & Poor's website states that a AA rating means that a bond is, in the agency's opinion, "less likely to default than the BBB bond." ("... [A] corporate bond that is rated 'AA' is viewed by the rating agency as having a higher credit quality than a corporate bond with a 'BBB' rating. But the 'AA' rating isn't a guarantee that it will not default, only that, in the agency's opinion, it is less likely to default than a 'BBB' bond.") However, on the same web-page, the agency states that a speculative-grade rating "factors in greater vulnerability to down business cycles."

[3]In unreported results we check that our results are qualitatively unchanged when using Moody's credit ratings.

available information. We also consider the ability of credit rating to explain variation in our benchmark measure of raw default probability. Second, we measure variation in systematic (and therefore undiversifiable) default risk over the business cycle and propose a simple measure of exposure to this risk. We then ask if systematic default risk varies across credit rating.

We find that ratings are a poor predictor of corporate failure. Following Shumway (2001), Chava and Jarrow (2004), and Campbell et al. (2008)[4] we use a straightforward direct measure of raw default probability based on accounting data and stock market prices. We find that this measure, which we refer to as 'failure score,' is substantially more accurate than rating at predicting failure at horizons of 1 to 10 years. The higher accuracy in predicting the cumulative failure probability is driven by a much higher ability of failure score at predicting marginal default probabilities at horizons of up to 2 years and the fact that credit rating adds little information to marginal default prediction at horizons up to 5 years. The conventional view that credit ratings provide accurate information about the likelihood of default and other forms of corporate failure is thus largely incorrect.[5]

It might seem possible that some specific features of credit ratings, such as their ordinal ranking and infrequent updating, are responsible for their poor performance as optimal predictors of default. We find that this is not the case: Our results are robust to using a discretized measure of failure score with the same number of categories as ratings, using recent ratings changes and outlook measures, and allowing predicted average default rates to vary over time.

We provide additional evidence that fitted failure probability – constructed as an optimal predictor of default – is indeed an accurate benchmark predictor of default: failure probability explains variation in CDS spreads within identically rated firms (i.e. the market views within-rating variation in failure probabilities as important) and failure probability is a significant predictor of a deterioration in credit quality as measured by rating downgrades.

---

[4]These papers build on the seminal earlier studies of Beaver (1966), Altman (1968), and Ohlsen (1982). More recent contributions to the long and rich literature on using accounting and market-based measures to forecast failure include Beaver, McNichols, and Rhie (2005), and Duffie, Saita, and Wang (2007).

[5]We note that credit ratings are often used as proxies for default probability. See, for example, West (1970), Blume, Lim, and MacKinlay (1998), Krahnen and Weber (2001), Löffler (2004b), Molina (2005), and Avramov, Chordia, Jostova, and Philippov (2009).

Using fitted default probabilities we next explore the ability of ratings to explain variation in default probabilities. Contrary to the interpretation that credit rating reflects raw default probability we find considerable overlap of default probability distributions across investment grade ratings; many firms with investment grade ratings have the same or very similar default probabilities even though their ratings are quite different. This means that variation in rating explains only very little variation in raw default probability. Furthermore, there is important time-variation in failure probabilities not captured by ratings.

In the second part of the paper, we investigate the relationship between credit ratings and systematic risk. We begin by identifying a measure of systematic risk. We assume a single factor structure for default probability and measure a firm's systematic risk by its 'failure beta', the sensitivity of its default probability to the common factor. We find that median default probability is highly correlated with the first principal component (which explains the majority of the variation in default probability across ratings) and therefore use median default probability as our measure of the common factor.

For risk averse investors to be concerned about failure beta it must be the case that a bond's failure beta affects the undiversifiable component of its risk. It is straightforward to show that failure betas are monotonically related to joint default probability for any pair of firms, so that higher failure beta is equivalent to higher undiversifiable default risk. Furthermore, times of high default probabilities (high levels of the common factor) are bad times: the realized default rate varies countercyclically, being much higher during and immediately after recessions and financial crises (e.g. Campbell et al. (2008), Duffie et al. (2009)).[6] Risk averse investors will demand a higher risk premium as compensation for higher exposure to bad times.

We find that credit rating strongly reflects variation in systematic risk and that exposure to bad times is compensated by higher CDS risk premia. We estimate failure betas for each rating and find that failure beta is strongly related to rating: there is in fact a monotonic

---

[6]The recent recession is no exception: An important consequence of the recent financial crisis and recession has been the ongoing wave of major corporate failures and near-failures. In the first eight months of 2009 216 corporate issuers defaulted affecting $523 billion of debt (September 2009 S&P report). High default rates in recessions may be the result of low fundamentals during these times (Campbell et al. (2008)), they may be driven by credit cycles (Sharpe (1994), Kiyotaki and Moore (1997), Geanakoplos (2009)), or by unobservable factors (Duffie et al. (2009)).

relationship between rating and failure beta, and failure beta explains 95% of variation in rating. The increase in default probability during recessions and financial crises ('bad times') is more pronounced for lower rated (high failure beta) firms. Investors demand compensation for the exposure to this risk – we find that variation in failure beta explains 93% of the variation in CDS risk premia across ratings.

The relationship between credit rating (and CDS risk premia) and systematic risk is robust to using more conventional measures of systematic risk such as CAPM beta and down beta, the sensitivity of stock returns to negative market returns. The relationship is stronger for down beta and strongest for failure beta, suggesting that credit ratings are capturing primarily exposure to bad times, something corporate bond investors are particularly concerned about.

Taken together, our results indicate that in the case of corporate credit risk, even though credit ratings are inaccurate predictors of default, they contain important information about systematic risk. We are now able to assess the third question posed above – can a single measure, e.g. credit rating, accurately reflect all relevant dimensions of credit risk? Given that credit risk contains at least two dimensions that investors care about, it follows that a single measure cannot accurately capture all aspects of credit risk. Indeed, we show that a firm's default risk and its systematic risk are distinct: multiplying failure beta by the common component of default probability is an inferior predictor of default probability, both at short and long horizons, when compared to failure score. Decomposing default probability into a systematic and an idiosyncratic component, we show that both are needed to forecast default. Furthermore, credit rating is primarily related to the systematic component of default probability; the idiosyncratic component does not help explain variation in rating. Imposing the restriction of using only one measure will thus necessarily result in a substantial loss of information about credit risk.

Our results can explain a number of otherwise puzzling aspects of ratings: (1) why ratings are not as good as a simple alternative at forecasting default: to do so may not be their sole purpose; (2) why ratings do not distinguish well between firms with different default probabilities: default probability and systematic default risk are economically different attributes; (3) why agencies 'rate through the cycle': if systematic risk equals "vulnerability to down business

4

cycles," (the measurement of which is a stated objective) it cannot vary over the business cycle, so neither can rating to the extent rating reflects systematic risk; (4) why risk-averse investors are interested in ratings and why variation in borrowing cost is strongly related to rating: investors care both about expected payoff and about risk premia.

This paper adds to a growing literature that evaluates the ability of ratings to predict default, beginning with Hickman (1958). Some studies consider the information about default in credit ratings and single measures such as leverage (Galil (2003)), or distance to default (Kealhofer (2003), Cantor and Mann (2003)), propose transformations of such measures (Blöchlinger, Leippold, and Maire (2012)), or consider alternative ratings (Cornaggia and Cornaggia (2012)).[7] Van Deventer, Li, and Wang (2005) evaluate Basel II implementations and compare accuracy ratios of S&P credit ratings to a reduced-form measure of default probability.

We advance this line of work since we provide a comprehensive comparison of the marginal and cumulative ability of credit ratings to predict failure when compared to a simple alternative, use the most recent reduced-form models, document that default probabilities can explain variation in CDS spreads and predict downgrades, and measure differences in default probability within rating and over time.

Furthermore, all of these studies take as given the premise that credit risk is one-dimensional and do not consider optimal measures of credit risk that reflect all the information relevant to risk-averse investors. Instead, we decompose default probability into systematic and idiosyncratic components and relate credit ratings to measures of systematic risk, which, to the best of our knowledge, has received virtually no attention in the literature.[8]

Our findings are also related to several studies that investigate the determinants of corporate bond prices. The idea that both default probabilities and risk premia affect bond prices and CDS spreads is well understood (see e.g. Elton, Gruber, Agarwal, and Mann (2001)). Equivalently, studies have shown that prices depend on both objective and risk-neutral proba-

---

[7]Bharath and Shumway (2008) and Campbell et al. (2008) document that distance to default, essentially leverage scaled by volatility and based on the seminal insights by Merton (1974), is easily dominated by a multivariate default prediction model of the variety which we employ in our empirical analysis.

[8]One exception is Schwendiman and Pinches (1975) who show that lower-rated issuers have higher CAPM beta.

bilities (Chen (2009), Bhamra, Kuehn, and Strebulaev (2010)). However, these papers do not relate their findings to credit ratings, other than using ratings as a control.

In contrast to our focus on corporate credit ratings – arguably the core competency of credit rating agencies – credit ratings of structured products have been the topic of several studies (for example, Benmelech and Dlugosz (2009), Bolton, Freixas, and Shapiro (2012), Griffin and Tang (2012)). In this context the distinction between default probability and systematic risk has been made by Coval, Jurek, and Stafford (2009) and Brennan, Hein, and Poon (2009). However, both papers assume that ratings relate only to default probability or expected loss and proceed to show how this can lead to mis-pricing. In our study we propose an explicit measure of systematic risk and find that credit ratings contain information not only about default probability but also about systematic risk.

The rest of the paper is organized as follows: the next section describes our data and failure prediction methodology; section 3 presents our main results on credit rating and default probability and then investigates further the information in credit ratings and failure score relevant to default; section 4 relates ratings to systematic default risk; the last section concludes.

2 Measuring corporate default probability

In the first part of the paper we explore the information about raw default probability in corporate credit ratings. To do this we perform two empirical exercises. We first propose a direct measure of raw default probability, an empirical measure based on publicly available accounting and market-based information. We examine the ability both of our measure and of ratings to forecast default. We then analyze further the relationship between our measure of default probability and ratings.

We begin by introducing and discussing our measure of default probability. Our method for predicting default follows Campbell et al. (2008) and builds on the earlier work of Shumway (2001) and Chava and Jarrow (2004). Specifically, we use the same failure indicator and explanatory variables as Campbell et al. All of the variables, the specification, and the estimation procedure (described in more detail in section 2.2) are discussed in Campbell et al., who also

show that this specification outperforms other standard methods of default prediction. The model is more accurate than Shumway and Chava and Jarrow, who use a smaller set of explanatory variables, and is also more accurate than using distance-to-default, a measure based on the Merton (1974) model (e.g. Vassalou and Xing (2004)).[9]

2.1 Corporate failures and explanatory variables

Following Campbell, Hilscher, and Szilagyi (2008 and 2011) our failure indicator includes bankruptcy filing (chapter 7 or chapter 11), de-listing for performance-related reasons, D (default) or SD (selective default) rating, and government-led bailout. The data was provided to us by Kamakura Risk Information Services (KRIS) and covers the period 1963 to 2008.[10]

Table 1 panel A reports the number of firms and failure events in our data set. The second column counts the number of active firms, which we define to be those firms with some available accounting or equity market data. We report the number of failures over time and the percentage of active firms that failed each year (failure rate) in columns 3 and 4. We repeat this information for those firms with an S&P credit rating in columns 5 through 7. Since our data on credit ratings begin in 1986 we mainly focus on reporting statistics for the period from 1986 to 2008. The universe of rated firms is much smaller; only 18% of active firms are rated on average. However, rated firms tend to be much larger which means that the average share of liabilities that is rated is equal to 76%.

The failure rate exhibits strong variation over time. This variation is at least partly related to recessions and financial crises (table 1 panel B). The average failure rate during and in the 12 months after NBER recessions is equal to 1.4%. In the 12 months after the October 1987 stock market crash and the September 1998 Russian and LTCM crisis the failure rate is equal to 2%. Both of these are higher than the 0.8% failure rate outside of recessions and crises. The pattern for rated firms is very similar. The failure rate for rated firms is almost three times

---

[9]Bharath and Shumway (2008) also document that a simple hazard model performs better than distance-to-default.

[10]The broad definition of failure captures at least some cases in which firms avoid bankruptcy through out-of-court renegotiations or restructurings (Gilson, John, and Lang (1990) and Gilson (1997)), or cases in which firms perform so poorly that they delist, often before subsequently defaulting.

higher during and immediately after recessions (2.4%) and crises (2.3%) than it is outside of these times (0.9%).

To our history of failure events we add measures of financial distress. We construct explanatory variables using accounting and equity market data from daily and monthly CRSP files and quarterly data from Compustat. The explanatory variables we use measure profitability, leverage, past returns, volatility of past returns, firm size, firm cash holdings, and firm valuation. Together, these variables, and a constant, make up the vector x_{it}, which we use to predict failure at different horizons. The variables are the same as those used in Campbell et al. (2008 and 2011) and are described in more detail in the table note.

2.2 Predicting failure in a logit model

We assume the month-t marginal probability of failure in month $t + s$ follows a logistic distribution. We allow the coefficients, the relative weights of the different predictor variables, to depend on the horizon over which we are predicting failure. The conditional probability of failure is given by:

$$P_t(Y_{i,t+s} = 1|x_{it}) = (1 + \exp(-\delta'_s x_{it}))^{-1} \tag{1}$$

where $Y_{i,t+s}$ is an indicator variable that equals one if firm i fails in month $t + s$ conditional on not failing earlier, x_{it} is a vector of our explanatory variables, including a constant, observed at the end of month t, and $\delta'_s x_{it}$ is a linear combination of these explanatory variables. We estimate the vector $\hat{\delta}$ and refer to the linear combination $\hat{\delta}'_s x_{it}$ as the 'failure score' of firm i in month t. Failure score and failure probability are then (positively) related by equation (1).[11]

Table 2 reports results from estimating a logit model using data from 1963 to 2008.[12] Columns 1 and 2 report results from predicting failure over the next month and in 12 months

---

[11]Assuming independence of default in each month, the probability that a firm defaults between month t and month $t + s$ is then one minus the probability of survival for s months:

$$P_t(Z_{i,t,t+s} = 1) = 1 - \Pi_{j=1}^s (1 - P_t(Y_{i,t+j}))$$

where $Z_{i,t,t+s}$ equals one if firm i defaults between month t and month $t + s$.

[12]We note that this analysis uses the same sample period as Campbell et al. (2011) and thus results are identical to those in table 2 of their paper.

respectively. The explanatory variables are related to failure as we would expect. Firms are more likely to fail if they are less profitable, have higher leverage, lower and more volatile past returns, and lower cash holdings. The market-to-book ratio enters with a positive sign. Firms with lower price per share are more likely to fail and size enters with a counterintuitive positive coefficient, which is most likely driven by the high correlation of size and price. At the 12-month horizon, the results are similar, except that size and price are insignificant.

As measures of fit we report McFadden's pseudo R^2 which is equal to 31.6% and 11.8% for the 1-month and 12-month models. For comparison, Campbell et al. (2008) report a pseudo R^2 of 31.2% for their 'best model,' 27% for Shumway's (2001) model, and 15.9% when using distance-to-default. We also report the accuracy ratio which measures the tendency for the default predictor to be higher when default actually subsequently occurs (true positive) and lower when default subsequently does not occur (true negative). It is a useful non-parametric measure of model performance and varies from 50% (random model) to 100% (perfect model). It is a commonly used measure when evaluating a binary response model. For the 1-month and 12-month models reported in table 2 the accuracy ratios are equal to 95.5% and 86.2%.

3 Information about default probability in credit rating

Having constructed our measure of raw default probability we can now compare our failure score with S&P long-term general corporate credit rating as a predictor of default. Data on monthly S&P credit ratings are from Compustat.[13] To investigate the relative performance of credit rating and failure score, we add rating as an additional explanatory variable in our

---

[13]S&P also supply short-term ratings, but these cover a much smaller sample of issuers. We have checked that our results on prediction accuracy are robust to the inclusion of short-term credit ratings. As we discuss in Section 3.1.3, our results also are robust to using Moody's instead of S&P ratings. In addition to ratings provided by rating agencies, banks often develop internal ratings. Carey and Hrycay (2004) and Krahnen and Weber (2001) discuss that rating process.

hazard model. For our first set of results we estimate:

$$P_t(Y_{i,t+s} = 1) = (1 + \exp(-\alpha_s - \gamma_s \left(\delta'_s x_{it} \right) - \phi_s Rating_{it}))^{-1} \tag{2}$$

We restrict the coefficients δ'_s to equal their estimates obtained when including data for all listed firms, as opposed to only those that are rated. This means that the coefficient vector δ_1 contains coefficients based on estimating the same model as in table 2, column 1 (except that we use recursively-estimated coefficients, see below). For longer horizons we use the equivalent longer-range estimates. In other words, we estimate a failure score for all listed firms and then estimate how much additional information is contained in rating regarding the failure prospects of rated firms. This sets the bar for failure score a little higher than just estimating an unrestricted regression with rating as an additional firm characteristic.[14] To control for look-ahead bias we estimate the coefficients recursively: We re-estimate the model each year from 1986 to 2007, update the estimates of δ_s, and then use those coefficients to predict failure during the following year. Thus, our estimates of default probability have no more information available to them as a contemporaneous ratings agency would have had.

S&P credit ratings for firms that are not in default run from AAA to C. Ratings from AA to CCC are further divided into 3 subgroups each with a '+' or a '−' added to the rating (e.g. A+, A, A−). We assign a score of 1 to AAA and each reduction in rating receives an additional score of 1 so that BBB (the lowest investment grade rating) is assigned a score of 9 and C (one notch above default) receives a score of 21. Thus our ratings variable, like failure score, is positively related to default risk. We note at this point that, first, the assumption of linearity does not affect our results of relative forecast accuracy; we discuss robustness checks in more detail in section 3.1.3. Second, patterns in model prediction accuracy are qualitatively and quantitatively very similar when employing the accuracy ratio instead of pseudo R^2. Since the accuracy ratio is entirely based on ranking observations, it is invariant to any monotonic transformation of credit rating.

---

[14]If we instead estimate the unrestricted regression, failure score performs better at all horizons.

3.1 Relative forecast accuracy of credit rating and failure score

3.1.1 Marginal forecast accuracy

Table 3 reports the results from our estimation of the baseline model in equation (2). Panel A reports pseudo R^2 and accuracy ratios. We report results for specifications with only failure score, only rating, and both failure score and rating. We focus specifically on the ability of different measures to forecast failure at different horizons and consider 1, 3, 6, and 12-month horizons, as well as 2, 3, 4, and 5-year horizons. We are estimating the probability of default at these horizons conditional on no previous default. This means that we are intuitively estimating forecast accuracies of marginal default probabilities at different points in time. We consider cumulative forecast accuracies in section 3.1.2.

Failure score predicts default at horizons of one month with a pseudo R^2 of 39.1% versus 29.2% for rating alone, which means that failure score outperforms rating by 9.9 points. Adding rating to failure score increases the pseudo R^2 from 39.1% to 42%. Thus, rating appears to contain little additional information about the probability of failure in the immediate future, while failure score significantly outperforms rating.

Figure 1 plots the pseudo R^2 for all horizons from our baseline model for failure score only, rating only, and both together. Since we expect a large increase in uncertainty at longer horizons we expect marginal forecast accuracies to diminish with the forecast horizon. This is indeed what we find; the ability of either failure score, rating, or both to forecast failure declines monotonically with the forecast horizon. Using both measures, the pseudo R^2 declines from 42% at the 1-month horizon to 5.5% at the 60-month horizon. Failure score continues to outperform rating in the medium term, at horizons of 3, 6, and 12 months. Failure score outperforms rating by 13.1, 11.2, and 6.8 points at the 3, 6, and 12 month horizons. At 24 months pseudo R^2s are equal, though the accuracy ratio of failure score only is 0.9 points higher than for rating only.[15] For the 3 to 5-year horizons rating only is a slightly more accurate predictor than failure score only (we discuss shortly that this small advantage cannot

---

[15]Also, when using discretized failure score (see section 3.1.3), the 24-month pseudo R^2 is 1 point ahead of the rating-only R^2.

make up for the lower accuracy of rating at short horizons). Nevertheless, using both measures is always better in terms of accuracy than using only one of the measures. Table 3 also reports accuracy ratios and we find that using them results in the same pattern across the different prediction horizons as the pseudo R^2.

Table 3 panel B reports the coefficient estimates and their associated z-statistics for the specifications including both failure score and rating. The significance levels of credit rating and failure score, when both are included, reflect the relative performance of the individual measures. The pattern in z-statistics reflects the pattern in pseudo R^2 – failure score is more significant up to 3 years, and rating is more significant at 4 and 5 years. The significance levels of the coefficients also reflect the incremental information of the two measures.

3.1.2 Cumulative forecast accuracy

We also consider the ability of ratings and failure score to predict cumulative failure probabilities at longer horizons. We expect that the slightly superior performance of rating at predicting the marginal probability of failure at horizons of more than 3 years, conditional on no earlier failure, is not enough to make up for the much greater predictive power of failure score at shorter horizons. The area under each line in figure 1 can be thought of as an estimate of the ability to forecast default over time (cumulative probability), rather than at some future point (marginal probability). The area under the 'both' line is only slightly greater than under the line for failure score alone, while it is clearly substantially larger than the area under the line for rating alone.

To consider the relative accuracy more formally each January we construct cumulative failure events for the following 1, 2, 3, 4, 5, 7 and 10 years. We then use rating and 12-month failure score as predictors of default. Panel C of table 3 reports the pseudo R^2 measures which decline monotonically with the horizon but are always higher for failure score only than for rating only. At horizons of one year, failure score's forecast accuracy is 40% compared to 24.1% for rating. Adding rating to failure score increases the pseudo R^2 from 40% to 41.6%. At the 5-year horizon, failure score predicts correctly cumulative failure events 20.9% of the time versus 18.0% for rating only, and failure score outperforms rating at all intervening horizons. Adding

12

rating to failure score increases the pseudo R^2 from 20.9% to 25.2% at 5-year horizons.[16]

At horizons above 5 years failure score still dominates credit rating as a default predictor: the pseudo-R^2s are respectively 18.4% versus 16.5% at 7 years and 17% versus 14.8% at 10 years, although credit ratings are still useful additional default predictors even at long horizons. Thus failure score is a better predictor of long-run cumulative default predictability than credit rating, even at a horizon of 10 years.

It may not be too surprising that failure score is a good forecast of default at short and medium horizons: most investors should presumably be aware of impending disaster at such short horizons and equity market data, such as past returns and volatility, will likely reflect this awareness. Yet all the information available to the market is also available to the rating agencies,[17] which means that by ignoring or not responding to publicly available early warning signals of default at horizons of up to 2 years, ratings fail as an optimal forecast of default. However, what may be more surprising is that credit ratings are not optimal forecasts of default even at 10-year horizons. We conclude that, whatever else ratings may measure, they are not optimal forecasts of default.

3.1.3 Robustness of relative forecast accuracy

We now investigate the robustness of our conclusions to a range of other possibilities in investigating relative forecast accuracy. We briefly discuss the reason for each robustness test as well as the results of performing it.[18]

First, we perform an additional check if our results are driven by a subtle form of look-ahead bias that could result from variable choice being based on data up to and including 2003 (the same period in Campbell et al.). We thus estimate coefficients on failure score from 1963 to 2003 and then test relative out-of-sample performance using data on failure events from 2004 to 2008. In doing so the data used to choose the variables in the model and the data used for

---

[16]The (unreported) pattern in accuracy ratios is similar.

[17]In fact, it may be that rating agencies have additional information, that is not available to the public (see, for example, Jorion, Liu, and Shi (2005)). If they do have such information, and if this information is reflected in the rating, it does not seem to make up for their seemingly slow response to market data.

[18]Results from the various tests are available upon request.

the dependent variable (the failure indicator) do not overlap. This is a genuine out-of-sample test (as opposed to the pseudo out-of-sample test performed previously). We find that the relative difference between failure score and rating is larger during the 2004-2008 period than for the full sample used in table 3. We conclude that failure score is a superior predictor of corporate failure out-of-sample.

Second, the superior performance of failure score could be due to the discrete nature of credit rating, and our comparing it, perhaps unfairly, to a continuous failure score. To address this possibility we discretize our recursively-estimated failure score measure and compare its performance with rating using the same procedure as we used for the continuous version. We choose our discretization so that the size of a group with a common (discrete) failure score accounts for the same proportion of the rated sample as the group with a common rating. For example, the number of observations of firms rated AAA corresponds to the size of the group with the lowest failure score. We then assign scores of 1 to 21 to these groups. We find that the discretized failure score predicts default at a similar level of accuracy as continuous failure score which means that it performs as well relative to ratings. In fact, at horizons equal to and above 1 year, discretized failure score performs better than continuous failure score.

Third, one might be concerned that our results are driven by the inability of ratings to capture variation in aggregate default rates. From the results in table 1 we know that there are significant differences in the failure rate over time. However, there is no corresponding change in ratings, given that ratings 'rate through the cycle' (Amato and Furfine (2004), Löffler (2004a)). It is possible, therefore, that the forecast accuracy of ratings would improve if we were to allow predicted average default rates to vary over time. We investigate this hypothesis in three ways: (a) we include separate dummy variables for recessions and financial crises and compare relative performance. (b) We include median failure score together with rating. If failure score reflects time variation but ratings do not, adding median failure score to rating should reduce this disadvantage. (c) We include time dummies together with ratings and failure score. Since there are several years with only very few events, we include two-year dummies for estimation purposes. We find that none of these alternative specifications significantly affects the results in table 3.

Fourth, another concern could be that our results are driven by not accounting for possible non-linearities in the relationship between rating and observed failures. We include rating linearly in the logit model and using a different functional form may lead to an increase in forecast accuracy. Although such a change may increase the pseudo R^2, it will not affect the accuracy ratio of the predictor since any monotonic transformation of rating will lead to the same classification of predicted failures and therefore have the same accuracy ratio. To investigate whether or not the pseudo R^2 is affected we include rating dummies instead of rating score. We group firms into 10 groups by rating and estimate a logit model allowing the coefficient on the dummy variables to vary freely.[19] Again, we find that failure score outperforms rating by a substantial margin in predicting default.

Fifth, it is possible that ratings do a poor job at predicting failure because a typical rating is stale, but that ratings changes or ratings that have recently changed are much better at predicting default.[20] We address this concern in two ways: (a) We add the interaction of rating change and rating to our standard specification. If ratings that recently changed contain more information this change should lead to an increase in forecast accuracy. (b) We include a downgrade indicator as an additional variable. Downgrades may contain important information about the possibility of future default and allowing for an additional effect may increase accuracy. This check also addresses the concern that ratings changes are asymmetrically informative and that only downgrades really matter. Neither change to our main specification affects our results materially. We also include outlook (negative, positive) and watch (downgrade, upgrade) as additional variables and find that our results are unchanged. We perform this check using Moody's data, since S&P outlook and watch data are not available in COMPUSTAT.

Finally, we run all the tests (not just those in the preceding section) using Moody's ratings

---

[19]From an estimation point of view it is not possible to include a different dummy variable for each rating. Some ratings have very low frequencies of failures, and some have no observed events. It is therefore necessary to group observations together. Grouping ratings also helps with the possibility that the relationship between rating and failure may not be monotonic. For example, it may be that in the data B- rated firms are more likely to default than CCC+ rated firms.

[20]Such an interpretation would be consistent with Hand, Holthausen, and Leftwich (1992) who document bond price effects in response to rating changes, implying that such changes are viewed as news.

instead of S&P ratings. Our findings about the relative strength of failure score grow slightly firmer if we use Moody's instead, and none of our other findings are materially altered. For brevity, we include only our results using S&P ratings. Our results using Moody's ratings are available on request.

We conclude that our results are robust to out-of-sample evaluation, discretization, time effects, non-linearities, vintage effects, asymmetries in the effect of rating, and choice of rating agency.

3.2   The relationship between default probability and rating

The fact that a simple model, combining accounting and market-based variables, dominates ratings as a default predictor provides evidence that ratings are not primarily an optimal estimate of raw default probability. We now explore this hypothesis further by analyzing the extent to which rating reflects information related to default probability. We first provide additional evidence that the fitted values of our model may be regarded as benchmark estimates of default probability and then present evidence on how ratings relate to these estimates.

3.2.1   Further motivation for failure score as a benchmark measure of default probability

If variation in default probability is viewed by market participants as being informative it should be reflected in market prices.[21] To check this we consider the ability of our estimates of default probability to explain variation in credit default swap (CDS) spreads. CDS spreads can be thought of as the spread over a default-free bond of equivalent maturity that a given issuer must pay. Intuitively, the spread should reflect both compensation for a high default probability (expected loss) as well as the asset's risk premium. At this point we consider only if variation in spreads across issuers and over time can be attributed to raw default probability.

---

[21]The idea that default probability is related to yield spreads on risky debt was suggested as early as Fisher (1959). Specifically, Fisher motivates his approach by an earlier quote that "No person of sound mind would lend on the personal security of an individual of doubtful character and solvency." More recently, Duffie et al. (2008) and Huang and Huang (2012) have explored this idea.

We return to the effect of systematic risk in section 4. We use monthly 5-year CDS spreads from 2001 to 2007, obtained from Markit. Our sample consists of all rated firms for which we are able to construct a failure probability resulting in a sample of over 38,000 firm-months.

Table 4 panel A presents results of regressions of log spreads on log 12-month failure probability based on the model reported in table 2.[22] We assume a linear relationship[23] and include rating fixed effects (columns (1) and (2)), rating and year fixed effects (columns (3) and (4)), and firm fixed effects (columns (5) and (6)). For each set of fixed effects we then run a regression with and without failure probability. In all specifications failure probability is a highly economically and statistically significant determinant of CDS spreads. A 1% increase in failure probability is associated with a 0.44% to 0.71% increase in spreads. Failure probability explains 30% of within rating variation and 30.5% of within firm variation in CDS spreads. The information in failure probability is also reflected in overall R^2: adding failure probability to a model containing only rating fixed effects results in an increase of overall R^2 from 64.5% to 75.2%; adding failure probability to rating and year fixed effects increases overall R^2 from 77.7% to 82.6%.[24] We conclude that our estimates of default probability contain important information reflected in market prices. In related work, Campbell and Taksler (2003) show that equity return volatility helps explain variation in credit spreads after controlling for credit rating. Indeed, volatility is an important component of failure score.

We also present evidence that failure probabilities predict downgrades. In panel B of table 4 we estimate logit regressions of an indicator variable that is equal to one if a firm is downgraded during the next month and use failure score as our explanatory variable. We control for rating effects (columns (1) and (2)) and rating and year effects (columns (3) and (4)). For each set of dummies we estimate models with and without failure score. We find that the coefficient on failure score is highly statistically significant and that failure score adds

---

[22]Standard errors are clustered by year to take into account the possibility of cross-sectional correlation.

[23]The assumption of linearity is consistent with an earlier study by Berndt, Douglas, Duffie, Ferguson, and Schranz (2008). In addition, in unreported results, we find strong evidence for a linear relationship, with coefficients stable when running regressions separately for different rating groups.

[24]These results are consistent with Ederington, Yawitz, and Roberts (1987), who find that accounting measures such as coverage and leverage contain information about spreads on industrial bonds that are not reflected by rating.

substantial explanatory power. When including failure score together with rating dummies the pseudo-R^2 increases from 1.3% to 10.6%; when adding failure score to rating and year dummies the pseudo-R^2 increases from 2.4% to 11.4%. The accuracy ratios reflect the same pattern: including failure score increases the accuracy ratios by 17.3 and 13.7 points respectively. These results are consistent with Delianedis and Geske (2003) who find that distance-to-default contains information about rating migrations.

The evidence in table 4 indicates that variation in our estimates of default probability are reflected in market prices and contain information about ratings downgrades. In addition, tables 2 and 3 show that our estimates of default probability predict default well and better than ratings at horizons of up to ten years. We conclude that failure score is an accurate measure of raw default probability.

3.2.2 How credit ratings relate to failure probabilities

We now treat our estimates of default probability as observations of actual raw default probability and continue to explore the information in rating relevant for predicting default.

Ratings do not clearly separate firms by default probability, though the ranking of average default probabilities is correct. If rating measures raw default probability then variation in rating should explain variation in default probability. To explore the information about default probability in rating we therefore compare fitted failure probabilities across credit ratings. Figure 2 presents box plots of failure probability by rating. Each box plot is a vertical line showing the 10th percentile, median, and 90th percentiles as horizontal bars, with the interquartile range as a grey box. The highest-rated firms are closest to the origin and have the lowest failure probabilities. Specifically, we plot the base-ten logarithm of the annualized 12-month failure probability for firm-months with a given rating. To facilitate comparison across time, we subtract from every failure probability the annual median across all rated firms. This way the variation in default probability by rating is not driven by common variation in default probability over time, which we discuss shortly.

Three obvious inferences can be made from figure 2. First, the ranking of distributions by

18

rating is broadly correct: all points of the distribution, more or less, increase monotonically as rating declines from AAA to CC. Second, there is considerable overlap across ratings. For example, the 75th percentile default probability for any rating is always higher than the median for the next lower rating, or even for that two notches lower. Third, the overlap in distributions is much more obvious for investment grade issuers: there appears to be almost total overlap for issuers rated between AA and BBB-. There is so much overlap that for some adjacent ratings or even ratings two notches apart, we are unable to reject the hypothesis that their mean default probabilities are the same. In fact, the 75th percentile AA-rated issuer (two notches below AAA) is more likely to default than the median issuer rated BBB-, the last rating before reaching junk status. Therefore, the decline in distribution is mainly for non-investment grade issuers.

It appears that, especially for investment grade issuers, credit ratings are not strongly related to raw default probability. In a regression of log default probability on rating, rating explains only 20% of the variation in default probability for non-investment grade issuers. For investment grade issuers, the relationship is even weaker: Credit rating only explains 3% of the variation in default probability. The large within-rating dispersion and the inability of rating to explain variation in default probability suggest that ratings do not clearly separate firms into categories by default probability. We note that, as we have previously shown, within-rating dispersion in default probability is reflected in CDS spreads and therefore does not represent only noise.

For a given rating, a firm's default probability varies over time. We now turn our attention to examining variation in default probability by rating over time. We know that average default rates are higher during recessions and financial crises (table 1); however, ratings do not appear to capture this variation in default probability over the business cycle. Figure 3 plots median annualized 12-month failure probabilities over time for the 5 rating categories AA, A, BBB, BB, and B (the 5 letter ratings with the most available observations). Although the ranking of median failure probability by rating is largely preserved over time, the probability of failure of a typical firm in a given rating class rises dramatically in recessions and financial crises. In addition to the overall increase in default probability during bad times,

differences across ratings become larger.[25] If rating corresponded to raw default probability, the lines in figure 3 would be roughly flat and parallel.[26]

The strong variation in default probabilities over time may be related to the rating agencies' stated practice to 'rate through the cycle' (Amato and Furfine (2004), Löffler (2004a)). This practice implies that ratings may do a poor job measuring time variation in default probability but leaves open the question of how large this underlying variation actually is. Figure 3 quantifies the inability of rating to reflect fluctuations in raw default probability and demonstrates that this variation is substantial.

We also confirm that, consistent with the practice of 'rating through the cycle,' the share of firms in a particular rating group does not vary directly with business conditions. Figure 4 plots the share of firms rated AA, A, BBB, BB, and B. Although there is a clear decline over time in the share of firms rated AA and A (also see Blume, Lim, and MacKinlay (1998)), there is no clear tendency of the share of lower-rated issuers to increase during and after recessions and financial crises.[27]

The results in this section present evidence that failure score, a simple linear combination of variables based on publicly available accounting magnitudes and equity prices, is a significantly better predictor of corporate default and failure than credit rating at horizons of up to ten years. Estimated default probabilities are strongly related to CDS spreads and also predict downgrades. Treating fitted failure probabilities as measures of actual raw default probabilities we find that although ratings rank firms correctly in terms of broad averages, they do not clearly separate firms by default probability. Furthermore, for a given rating, there is a strong tendency for default probabilities to vary over time, especially increasing in bad times. All of these results indicate that ratings, contrary to what is often assumed, are not primarily or exclusively a measure of firm-specific raw default probability.

---

[25]We explore this pattern further in section 4 when we relate rating to measures of systematic risk.

[26]Our results relate to several previous studies that also find that default probabilities vary countercyclically. See e.g. Fons (1991), Blume and Keim (1991), Jonsson and Fridson (1996), McDonald and Van de Gucht (1999), Hillegeist, Keating, Cram, and Lundstedt (2004), Chava and Jarrow (2004), and Vassalou and Xing (2004).

[27]We note that the lack of a strong association of rating share and business conditions is also consistent with the inability of year dummies to explain variation in the downgrade rate in table 4.

4 Systematic risk and credit rating

We now ask if ratings instead measure systematic risk. When determining market prices a bondholder cares not only about default probability (expected payoff) but also about systematic risk (discount rate). In fact, S&P's website suggests that its rating reflects both things: AA is described as having a "very strong capacity to meet financial commitments" while BBB is described as having "[a]dequate capacity to meet financial commitments, but more subject to adverse economic conditions."

Figure 3 showed a strong tendency for median default probabilities of different ratings to spread out in recessions and crises so that the default probability of lower-rated firms increases by more during bad times. This suggests that rating reflects sensitivity of credit risk to bad times and, therefore, that rating may at least partly capture systematic risk of default. We now consider this hypothesis directly. In the next subsection, we introduce our measure of a firm's systematic default risk: failure beta. We then present evidence that ratings separate firms by failure beta and that failure beta is priced in the cross-section of CDS risk premia. Finally, we check that our claim that ratings capture systematic risk is robust to using alternative measures of systematic risk and show that systematic risk and default probability are economically different attributes.

4.1 Measuring systematic default risk: failure beta

We now identify a measure of systematic default risk, the extent to which a firm's default risk is exposed to common and therefore undiversifiable variation in default probability. To do this we must first construct a measure of such common variation. We assume that default probabilities have a single common factor, and estimate this common factor using principal component analysis. Extracting principal components in the standard way from the full panel of rated firms is problematic because the cross-section is much larger than the time series. We therefore first shrink the size of the cross-section by assigning each firm-month to a given rating-month and calculating equal-weighted average 12-month cumulative default probabilities (as used in figure 3). We perform the same exercise grouping the firms by industry instead of by

rating. This leaves us with two panels: the ratings panel consists of 18 ratings groups with 276 months of data; the industry panel consists of 29 Fama-French industries (30 industries excluding coal, for which we have insufficient data) again with 276 months. For each panel we extract principal components in the standard way.

We find clear evidence of common variation in default probabilities. For the ratings panel, we find that the first principal component explains 70.3% of variation in default probability, while the second principal component explains 9.5% and the third 5.8%. For the industry panel, the corresponding figures are 41.7%, 10.8% and 7.5%. In addition, both first principal components are capturing very similar variation: the correlation between the two is 0.954. Our assumption of a single factor is therefore a good approximation of the factor structure of default probabilities, however grouped. We also find that the first principal component is a measure of economy-wide variation in default probability: Both first principal components are close to equally-weighted across ratings and industry groups.

In order to gain more insight about the common component of default probability figure 5 plots the first principal component of the rating panel, the median default probability for the full panel of rated firms, as well as the mean default probability, weighted by book value of liabilities. The first principal component and the median default probability move closely together and have a correlation of 0.945.[28] We therefore use median default probability as our measure of the common component of default probability.

For the presence of a common factor to be relevant for asset prices it must be related to the stochastic discount factor. Median default probability is a good measure of bad times: it is noticeably higher during and immediately after recessions and financial crises, when economic theory suggests the stochastic discount factor is high (thin vertical lines show when financial crises occur, and grey bars show NBER recessions). The figure also plots the realized failure rate over the following 12 months for each January and reflects the correlation of 0.64 between median failure probability and failure rate.[29] We conclude that a diversified, risk-averse

---

[28]The correlation of the first principal component and the value-weighted mean default probability is 0.85. For the industry panel the correlation with the median is 0.913 and 0.811 for the mean. The first differences are also highly correlated for both measures.

[29]The one exception to this relationship is the spike in failure rates in 2001, after the end of the

investor will care about exposure to variation in median default probability.

Having identified the common factor and having interpreted it as correlated with the stochastic discount factor, we can estimate factor exposures: the sensitivity of a firm's default probability to the common factor. Specifically, for firm i, with cumulative failure probability P_{it}, and with credit rating CR we estimate:

$$P_{it} = \alpha_{CR} + \beta_{CR} P_t^{median} + \varepsilon_{it}. \tag{3}$$

P_{it} is the 12-month annualized default probability and P_t^{median} is its median across firms.[30] We use the 12-month measure since it will not be focused excessively on short-term determinants of failure. In addition, the 12-month measure is an important determinant of within-rating spread variation in the CDS market (table 4). To avoid worries of non-stationarity in default probability levels we estimate our regressions using changes in default probabilities rather than levels, although our results are robust to using default probability levels instead. This specification constrains all firms with the same rating to have the same failure beta, and the resulting estimate is the average firm failure beta, equal-weighted across all firm-months in the panel. Like stock market beta, failure beta must be estimated and such estimates are subject to error. Pooling the regression by rating, therefore, has the additional benefit of reducing measurement error of beta.[31] In order to ensure a sufficient number of observations for each rating, we combine all observations rated CCC and below together.[32]

The specification of (3) does not of itself constrain the dependent variable to lie between zero

technology bull market of the late 1990s, which is not associated with a large increase in default probabilities. The reason is visible in figure 3: most of the sharp increase in failures were accounted for by B-grade issuers (junk), whose median default probability did increase in advance. However, these issuers were not close to the overall median issuer and did not account for a large proportion of total rated corporate issuance.

[30] Or equivalently its first principal component. Our results are very similar if either the ratings or industry panel principal component is used instead.

[31] To control for outliers for each rating group we winsorize default probabilities at the 0.5% and 99.5% levels; to control for firm-specific variation in default probability we include firm fixed effects.

[32] As a robustness check, we also estimate failure betas firm-by-firm, sort into groups by failure beta, re-estimate the failure betas for each group, and compare with the mean rating for that group. Our results are not materially different if we use this alternative method, so we conclude that grouping the data by rating is not what drives our results.

and one. However, investigation of the volatility of the residuals reveals a strong linear relationship with the square root of default probability.[33] Since almost all of our estimated default probabilities are small (so that $P(1 - P) \approx P$), this is consistent, for example, with a continuous time model of default probability and its common component in which the innovations are proportional to $(P_t(1 - P_t))^{\frac{1}{2}}$. Such a formulation does constrain default probability, under suitable initial conditions, to lie between zero and one. In addition, under this specification, OLS estimates of β_{CR} will be unbiased and consistent, since the first principal component is by construction orthogonal to the remaining residual variation. This means that we need only be concerned about heteroskedastic errors. We therefore use White standard errors to allow for heteroskedasticity of unknown form. We also cluster by date, to correct for cross-sectional correlation of the residuals.

4.2   Failure beta and credit rating

We estimate failure beta across 18 ratings ranging from AAA to CCC and below. Consistent with the previous suggestive evidence (figure 3) we find a strong relationship between failure beta and credit rating. Figure 6 plots estimates of failure beta by rating. The variation in failure beta is closely related to rating; highly-rated issuers have low failure betas while low-rated issuers have high failure betas. In fact, failure beta is monotonic in rating and the correlation between rating score and log failure beta is equal to 0.97. The relationship is strongly economically and statistically significant over the whole ratings spectrum and over the investment grade spectrum alone. We also find that the relationship is still strongly significant when controlling for average default probabilities.

Table 5 reports our estimates of failure beta by rating. As noted, failure beta increases monotonically with rating from good to poor. The results shown in figure 6 and table 5 establish that ratings are informative about the tendency of an issuer's propensity to default to worsen in bad times. Ratings, therefore, are measuring at least two distinct forms of credit risk: default probability and systematic risk.

---

[33]Results are available from the authors on request.

We note that our results are not at odds with the existing literature on the determinants of corporate bond spreads: The results in Huang and Huang (2012), Chen (2009), Coval at al., (2009), and Bhamra et al. (2010) indicate that a higher share of higher-rated credit spreads is due to systematic risk (e.g. that the fraction of the spread due to systematic risk is higher for AAA than it is for junk). Our results imply that even though the *share* of the spread due to systematic risk may be higher for higher-rated credit, the absolute *level* of the systematic risk is lower. For example, even though AAA bonds are unlikely to default in bad times (they have low systematic risk), if they ever default the default will almost surely occur in bad times and so the share of the spread due to systematic risk is high. However, they are very unlikely to default at any time. By contrast, BB firms are much more likely not to survive bad times than are AAA firms and so they have higher systematic risk (and higher failure beta). But BB bonds are also much more likely to default overall so their share of systematic risk may be lower. Elkamhi and Ericsson (2008) show that such a pattern is consistent with structural models of corporate bond pricing.

Our findings also have wider implications for the literature on credit and default risk. First, the high sensitivity of low-grade issuers to bad times (as well as the presence of an important common factor in default probability) establishes that the risk of failure is systematic. This means that our results contribute to the ongoing discussion of whether or not bankruptcy and default risk represent systematic risk. Dichev (1998) finds that high bankruptcy and distress risk is not associated with high equity returns and concludes that high bankruptcy risk is not a systematic risk.[34] In contrast, our results suggest that there is such a thing as systematic bankruptcy risk. In the next section we demonstrate that systematic default risk is reflected in asset prices. Specifically, we show that high failure beta is associated with high CDS risk premia.[35]

---

[34]Campbell et al. point out that low equity returns for financially distressed firms may be the result of information or arbitrage-related frictions. Consistent with this interpretation, Dichev and Piotroski (2001) find that after downgrades low returns occur mainly around earnings announcements which means that they are probably associated with under-reaction to news instead of low systematic risk.

[35]Consistent with our finding a close link between CDS risk premia and failure beta (discussed in the next section), Anginer and Yildizhan (2012) find that when using credit spreads to proxy for distress risk such stocks no longer deliver anomalously low returns.

Also, in unreported results, we investigate the relationship between failure beta and average stock returns for the Fama and French portfolios. We find that, excluding the small growth portfolio, there is in fact a negative relationship between average stock returns and CAPM beta, while there is a positive and significant relationship between failure beta and average stock returns. The positive relationship remains even once we control for average default probability, underscoring the multi-dimensionality of credit risk we document.[36]

Second, even though systematic default risk is present (and important to a risk-averse diversified investor), systematic default risk does not entirely determine default probability. Table 5 reports the share of the variation in firm-level default probability over time explained by the common component (within R^2s of regressions that include firm fixed effects). While variation in the common component of default probability is clearly significant, firm-level default probability also contains an important idiosyncratic component. In fact, consistent with the substantial variation of default probability within rating (figure 2), the share of firm-level default probability unexplained by the common component tends to vary between 80% and 95%. We discuss the importance of distinguishing between idiosyncratic and systematic default probability further in Section 4.5.

4.3   Failure beta and CDS risk premia

In this section we show that variation in failure beta can explain variation in CDS risk premia, providing supporting evidence that failure beta is related to systematic risk and that investors demand compensation for exposure to it. Economic theory suggests that investors will demand a higher expected return (and that they will use a higher discount rate) for those firms' credit risks that have higher levels of systematic risk. This means that if failure beta is a good measure of systematic risk, and if variation in systematic risk is priced in the credit market, we should expect failure beta to be related to CDS risk premia.

We use our measure of default probability and expected recovery rate data from Markit

---

[36]In independent work, Anginer and Yildizhan (2012) find that using failure beta demonstrates a distinction between the relationship of stock returns with default probability and systematic risk. Kapadia (2011) also finds that exposure to aggregate distress risk is priced.

to calculate a simple measure of CDS risk premia. We consider the price of a discount bond that defaults with probability P_t. In the case of no default it has a payoff of 1 and in the case of default its expected payoff equals the expected recovery rate, which we denote as rec. The expected payoff is discounted at a rate that includes a risk premium RP and the risk-free rate R_f.[37] Today's price then satisfies:

$$price = \frac{1 - P_t(1 - rec)}{1 + R_f + RP}. \tag{4}$$

Holding default probability P_t constant, a higher failure beta, which is reflected in a lower rating, should result in a higher risk premium. Thus our results suggest that ratings do not exclusively relate to the numerator, the expected payoff, but are also important in identifying the denominator, the expected return. We now evaluate this idea more directly by extracting risk premia from CDS spreads and relating them to failure beta.

For a pure discount bond spreads are defined as

$$price = \frac{1}{1 + R_f + spread}. \tag{5}$$

Therefore

$$RP = (1 + R_f + spread)(1 + P_t(1 - rec)) - (1 + R_f). \tag{6}$$

Using CDS spreads and recovery rates from Markit,[38] together with our estimated failure probabilities, we use this relationship to calculate implied risk premia for all issuers in our CDS sample. We then calculate the median risk premium for each rating-year group for which we have data.

Figure 7 plots median log risk premia for 5-year CDS contracts from 2001 to 2007 against log failure betas estimated as above by rating group. Each vertical group of points corresponds

---

[37]Similar calculations have been used by Elton, Gruber, Agarwal, and Mann (2001), De Jong and Driessen (2007), Campbello, Chen, and Zhang (2008), and Anginer and Yildizhan (2010).

[38]We have checked that our results are robust to using alternative measures of expected recovery rates: following Elton, Gruber, Agarwal, and Mann (2001) we use recovery rates from Altman and Kishore (1998). We have also used zero recovery rates. Our results are robust to either of these two alternatives.

to a rating, for each of which we estimate a separate failure beta. As expected, there is a strong positive relationship between failure beta and CDS risk premia.

Table 6 quantifies the relationship between risk premia and failure beta. We find a strongly statistically significant relationship that is steeper for investment grade issuers. Column (1) regresses median log risk premia on log failure beta. Log failure beta is statistically significantly related to CDS risk premia and explains 82.9% of the variation in risk premia across the 108 rating-years. Column (2) shows that this result is robust to the inclusion of year fixed effects. Column (3) adds an interaction of log failure beta with an investment grade dummy and shows that the relationship is significantly stronger for investment grade ratings.

Column (4) includes log default probability as an additional control. Our calculation of CDS risk premia (equation (6)) already controls for the level of default probability and so we do not expect default probability to contain explanatory power.[39] Consistent with our intuition we find that default probability is not important in explaining variation in risk premia over and above failure beta and that the relationship between risk premia and failure beta is robust to this control.

Our conclusion is that our straightforward measure of systematic default risk is strongly related to credit rating and CDS risk premia. This relationship is robust to controlling for time effects and default probabilities. Therefore, ratings appear to measure, at least partly, the tendency for credit quality to deteriorate in bad times, as well as the raw tendency to default.

4.4 Alternative measures of systematic risk

Failure beta is an explicit measure of the tendency of default probability to increase in bad times. We now consider the robustness of the relationship between credit ratings and systematic risk to obvious alternative measures of issuer systematic risk. Our objective is first, to investigate the robustness of our finding of the relationship between rating and systematic risk and second, to increase our understanding of the reason why failure beta and CDS risk

---

[39]This is in contrast to the earlier regression in table 4 where we relate CDS spreads (as opposed to risk premia) to default probabilities.

premia are related.

The first measure of systematic risk we consider is CAPM beta. Table 7 presents evidence on how CAPM beta is related to rating. In panel A we include all firms, while in panel B we focus on investment grade firms only. As before, our estimates of beta are pooled by rating group. The left half of the table presents evidence on how credit rating is related to measures of systematic risk and the right half of the table relates our estimates of CDS risk premia to these same measures. We find that CAPM beta is strongly related to rating: variation in CAPM beta explains 87% of the variation in rating. Even though rating and beta are widely studied measures of risk, to our knowledge this relationship is not widely appreciated. Yet it was pointed out in an early study by Schwendiman and Pinches (1975), who document that CAPM beta is higher for lower-rated issuers.[40] However, although CAPM beta is strongly related to rating overall, we find that the relationship is weaker than it is for failure beta, which explains 95% of variation in rating. Furthermore, CAPM beta explains a much smaller share of the variation in rating for investment grade issuers (68%) than does failure beta (95%). The pattern for CDS risk premia is similar: CAPM beta explains 50% of the variation in risk premia across investment grade firms compared to 91% of variation explained by failure beta. We conjecture that this pattern is due to the greater ability of failure beta to identify off bad times, such as severe crises and recessions.

To investigate this hypothesis we also consider up and down beta, which are simply estimates of CAPM beta that condition respectively on positive and negative equity index excess returns. If stock returns are non-linearly related to market returns, then up and down beta can be different and risk premia may be more strongly related to downside risk as measured by down beta (Ang, Chen, and Xing (2006)). If failure beta has a greater ability to identify sensitivity to bad times than CAPM beta, we would expect down beta to be related more closely to rating than up beta. This is indeed what we find.

The relationship between beta and rating and between beta and risk premia is strongest for failure beta, followed by down beta, then followed by CAPM beta. When considering

---

[40] Consistent with this finding, Kaplan and Urwitz (1979) find that both accounting ratios and CAPM beta contain information about rating.

investment grade only (panel B) the relationships are similar, but more pronounced. Up beta is not significant and enters with a counterintuitive negative coefficient estimate both when explaining variation in rating as well as risk premia. These results suggest that failure beta captures more of the variation in rating and risk premia than CAPM beta because failure beta is better at measuring the risk of negative events. The fact that failure beta captures more variation than down beta suggests that failure beta measures somewhat more extreme downside risk than down beta. Since a negative market return of ordinary magnitude should not increase the default probability of a typical investment grade issuer by very much, it is likely that failure beta measures exposure to a more drastic event than an average negative market return month and that this is the reason for its greater ability to explain variation in risk premia.

We conclude that the relationship between rating and systematic risk is robust to alternative measures of systematic risk, though the relationship with rating and risk premia is strongest with failure beta. We argue that this is because failure beta directly measures the tendency of issuers' credit quality to deteriorate in bad times. These are the risks that diversified corporate bond investors care about and ratings seem to reflect this. Moreover, market participants seem to set prices in accordance with this idea given that failure beta is most closely related to CDS risk premia.

4.5   Systematic risk and long-run default probability

In this last subsection, we investigate one final possibility. Since systematic default risk and long-run firm-specific default risk are positively related, credit ratings may end up being related to systematic default risk because they focus on measuring long-run default probability. We now present evidence that this is not the case: Long-run firm-level default probability varies both because of differences in systematic risk as well as because there is important firm-level idiosyncratic variation in default probability. Thus long-run default probability and systematic risk represent different attributes of risk, and ratings appear more closely related to systematic risk.

Earlier we showed evidence in favor of this finding: Default probability contains both a

systematic as well as an idiosyncratic component (table 5), which means that an optimal measure of default probability cannot be the same as a measure of systematic risk. Also, ratings, which we show measure systematic risk, underperform failure score when predicting failure at ten-year horizons (table 3), and are thus sub-optimal predictors of long-run default.

In table 8 we decompose default probability into a systematic component (multiplying failure beta and median default probability) and an idiosyncratic component (the remainder).[41] If all the information about long run default probability were captured by systematic risk , we would expect that idiosyncratic default risk should have no additional explanatory power to predict firm-level default at long horizons. Panel A shows that this is not the case. Although our measure of systematic risk is a strong predictor of default at 1-, 5- and 10-year horizons, the combined failure score is better, increasing pseudo-R^2 at 10-year horizons from 16.4% (systematic risk only) to 18.7%, and adding more power at all shorter horizons. When both components of our default probability estimates are included separately (panel B), both are strongly statistically significant. For comparison we also report the pseudo-R^2 for rating only and find that it is lower than systematic risk and failure score at all horizons.[42]

However, ratings are not related to systematic risk by virtue of their measuring long-run default risk: ratings relate primarily to systematic risk rather than firm-level default probability. The final column of each panel shows results from regressing rating on each component separately. As expected, rating is strongly related to systematic risk, but it is not well explained by the idiosyncratic component of default probability (panel A). When including both components (panel B) we find that the systematic component is very important while the idiosyncratic component does not add any explanatory power. We conclude that long-run default prediction and systematic default risk are economically and statistically distinguishable and that credit rating is more closely related to systematic risk than to long-run default risk.

---

[41]Specifically, we calculate the log odds ratio of βP_t^{median}. We then subtract this quantity from failure score to measure the idiosyncratic component.

[42]We note that this check underscores the robustness of the patterns in relative forecast accuracy we present in table 3: Estimating failure beta and multiplying it by the common component of default probability does not outperform failure score at any horizon.

5   Conclusion

In this paper we investigate the information in corporate credit ratings relevant to investors concerned about credit risk. We ask: (a) what should credit ratings measure, (b) what do ratings measure, and (c) is using a single measure to capture credit risk the right approach? Since risk-averse investors care about both raw default probability (expected payoff) and systematic default risk, or the tendency to default in bad times (discount rate), a useful measure of credit risk should capture both.

We first demonstrate that ratings are not an optimal predictor of default probability: they are dominated by a simple default prediction model based on publicly available accounting and market based measures; they explain little of the variation in default probability across firms; and they fail to capture the considerable variation in default probabilities and empirical failure rate over the business cycle. At the same time, ratings are strongly related to systematic risk, as measured by failure beta. In addition, variation in systematic risk is priced in CDS risk premia. Finally, systematic risk is economically distinct from idiosyncratic default risk. Previous studies have not focused on analyzing the relationship between credit rating and systematic risk. In addition to being an important dimension in its own right, this second dimension of credit risk undermines the often implicit maintained assumption that credit risk can be measured by a single indicator, which necessarily reflects neither dimension optimally.

This insight is relevant for the ongoing policy debate regarding the appropriate role of ratings agencies and the call for potential alternatives to credit ratings. Our findings imply that, given the nature of credit risk, a meaningful measure of credit risk should contain at least two dimensions. As such, any implicit or explicit restriction stating that credit risk has to be summarized by only one measure or that such a measure needs to be either smooth or insensitive to aggregate credit conditions will result in a loss of relevant information. Instead, it is fruitful to break out default prediction from the measurement of systematic risk. The former measure could update frequently and rapidly and respond to firm-specific news while the latter could be a combination of current credit ratings and aggregate credit conditions.

Table 1: Failures over time - all firms and rated firms

Panel A lists the number of firms and failures for all active firms (1963 to 2008) and for all firms with a S&P credit rating (1986 to 2008). Failure is defined as the first of bankruptcy (chapter 7, chapter 11), de-listing for performance related reason, default (D) or selective default (SD) rating, and government-led bailout. The number of firms is the average number of firms in a given year or over a given range of years. Firms are included as active if they have either available accounting or equity market data. Panel B reports failure rates during the 12 months after NBER recessions and financial crises (October 1987, September 1998).

	all firms			rated firms		
year	firms	failures	rate (%)	firms	failures	rate (%)
1963-1975	2218	50	0.14	.	.	.

Table 2: Failure prediction in a logit model

This table reports results from logit regressions of the failure indicator for all active firms including unrated firms on a set of monthly explanatory variables. We follow the model used in Campbell, Hilscher, and Szilagyi (2008, 2011). The sample period is the same as in Campbell et al. (2011) and the results presented here correspond to their Table 2. Coefficients are defined as follows: weighted average of net income over market value of total assets over the previous 12 months (NIMTAAVG), total liabilities over market value of total assets (TLMTA), weighted average of annualized log excess return relative to value-weighted S&P 500 return over the previous 12 months (EXRETAVG), log of firm's market equity over the total valuation of S&P 500 (RSIZE), square root of the sum of squared firm stock returns over the previous three-month period, annualized (SIGMA), stock of cash and short term investments over the market value of total assets (CASHMTA), market-to-book ratio of the firm (MB), and log of price per share winsorized above \$15 (PRICE). Market value of total assets is the sum of market value of firm equity and total liabilities. Z-statistics (reported in parentheses) are calculated using standard errors that are robust and clustered by year; ** denotes significant at 1%.

Table 3: Failure score vs. S&P credit ratings (1986 to 2008)

This table reports results from monthly logit regressions of our failure indicator on failure score and S&P long-term credit rating (AAA=1, AA+=2, …, CCC-=19, CC=20, C=21). Failure score is estimated recursively: at the beginning of each year we re-estimate the model in Table 2 using only data from the beginning of the sample to the end of the previous year. We estimate logit specifications using data lagged 1, 3, 6, 12, 24, 36, 48, and 60 months. The sample period is from 1986 to 2008 and contains rated companies only, while failure score is estimated using the full sample of all active firms. Panel A reports McFadden's pseudo R-squared and accuracy ratio as measures of model performance. Panel B reports coefficients on failure score and rating when both are included. Z-statistics (reported in parentheses) are calculated using standard errors that are robust and clustered by year; ** denotes significant at 1%, * significant at 5%. Panel C reports performance measures when forecasting failure events every January over the next 1, 2, 3, 4, 5, 7, and 10 years using 12-month failure score (based on the methodology used in Table 2, and re-estimated recursively at the beginning of each year).

Panel A: Accuracy of failure prediction							
prediction month	1	3	6	12	24	36	48	60
Pseudo R-squared								
failure score only	39.1%	33.7%	27.2%	18.8%	8.4%	6.4%	4.4%	2.7%
credit rating only	29.2%	20.6%	16.0%	12.0%	8.4%	7.2%	6.4%	5.4%
both	42.0%	35.2%	28.6%	20.4%	10.8%	8.6%	7.0%	5.5%

failure score only	40.0%	31.5%	25.8%	23.0%	20.9%	18.4%	17.0%	
credit rating only	24.1%	21.4%	19.6%	18.7%	18.0%	16.5%	14.8%	
both	41.6%	34.2%	29.4%	27.1%	25.2%	22.8%	20.9%	

Table 4: Information in default probabilities and failure score

Panel A reports results from regressions of log(CDS spread) on log(12-month failure probability) and sets of dummy variables: S&P credit rating, year, and firm. CDS spread data are from Markit and are end-of-month spreads for the 5-year contract. The sample period is 2001 to 2007. All firms with CDS spread, ratings, and available default probability data in the CRSP-COMPUSTAT universe are included. t-statistics (reported in parentheses) are calculated using standard errors that are robust, clustered by month, and corrected for autocorrelation; ** denotes significant at 1%. Panel B reports results from logit regressions of downgrades (a decrease in S&P credit rating, e.g. from BB to BB-) on 12-month failure score estimated using the model in Table 2. Z-statistics (reported in parentheses) are calculated using standard errors that are robust and clustered by year.

Panel A: Explaining variation in CDS spreads using default probability						
	(1)	(2)	(3)	(4)	(5)	(6)
log(failure probability)		0.612		0.442		0.713
		(4.45)**		(6.01)**		(7.43)**
R-squared (overall)	64.5%	75.2%	77.7%	82.6%	76.5%	83.7%
R-squared (within)		30.0%				30.5%
Rating fixed effects	X	X	X	X		
Year fixed effects			X	X		
Firm fixed effects					X	X

Number of observations: 38,569

Panel B: Predicting downgrades using failure score				
	(1)	(2)	(3)	(4)
Failure score		1.068		1.080
		(26.55)**		(26.37)**
Pseudo R-squared	1.3%	10.6%	2.4%	11.4%
Accuracy Ratio	58.0%	75.3%	62.7%	76.4%
Rating fixed effect	X	X	X	X
Year fixed effect			X	X

Number of observations: 340,496
Number of downgrades: 5,277

Table 5: Failure beta

We report results of regressions of firm-level 12-month default probability (annualized) on the common component of default probability (proxied by median default probability). Regressions are estimated using default probability changes, are run by rating, and include firm fixed effects. Standard errors are robust and clustered by month. We report the percentage of firm-level variation of default probability explained by the common component of default probability (within R^2) both for default probability levels and changes.

rating	failure beta	standard error	R^2 (levels)	R^2 (changes)
AAA	0.38	0.06	9.9%	9.2%
AA+	0.52	0.09	19.0%	11.0%
AA	0.53	0.07	16.9%	13.0%
AA-	0.57	0.08	20.1%	11.3%
A+	0.60	0.07	21.2%	9.4%
A	0.61	0.07	16.5%	8.2%
A-	0.73	0.06	20.5%	10.6%
BBB+	0.86	0.05	15.4%	8.6%
BBB	0.91	0.06	14.8%	8.3%
BBB-	1.10	0.07	17.0%	8.6%
BB+	1.78	0.08	9.1%	5.3%
BB	2.10	0.13	9.8%	6.3%
BB-	2.57	0.11	10.4%	5.7%
B+	3.36	0.24	5.4%	3.0%
B	4.60	0.79	6.4%	2.8%
B-	4.91	0.72	3.6%	2.1%
CCC+	4.96	1.53	2.6%	0.6%
CCC	8.44	1.79	5.0%	1.1%

Table 6: Regression of risk premia on failure beta

This table reports results from regressions of log risk premium (calculated using 1-year cumulative default probability using our logit model and recovery rates from Markit) on failure beta and default probability. t-statistics (reported in parentheses) are calculated using standard errors that are robust, clustered by year, and corrected for autocorrelation; ** denotes significant at 1%, * significant at 5%. We include median annual observations for 16 rating groups. For rating groups 15 and 16 there is no data for 2001 and for rating group 17 there is no data for 2001-2002, resulting in a total of 108 observations.

	(1)	(2)	(3)	(4)
log(failure beta)	1.90	1.96	1.41	1.57
	(9.29)**	(9.61)**	(16.18)**	(3.10)**
log(failure beta)*inv. grade			1.86	
			(6.58)**	
log(default probability)				0.155
				(0.98)
Year fixed effects		X	X	
R-squared (overall)	82.9%	93.1%	96.8%	84.3%
R-squared (within)		92.6%	96.6%	
Number of observations: 108				

Table 7: Failure beta and alternative measures of systematic risk

This table reports results from regressions of rating and risk premia on different measures of systematic risk (failure beta, CAPM equity beta, up beta, down beta). Panel A reports results when including 18 rating groups and Panel B reports results for investment grade issuers (rated AAA to BBB-). For risk premia calculations we use median annual risk premia by rating. CAPM equity beta is estimated using equally-weighted equity portfolio returns; up beta and down beta are estimated by allowing the coefficient on the market factor RM (from Ken French's website) to vary for the factor being below and above 0. For regressions of risk premia on beta we include year fixed effects and report within-R^2; standard errors are robust and clustered by year as well as adjusted for autocorrelation.

	Regression of rating on beta		Regression of risk premia on beta	
	Coefficient	R-squared	Coefficient	R-squared
Panel A: Investment grade and non-investment grade				
failure beta (log)	12.41	95.5%	1.96	92.6%
	(18.38)**		(9.61)**	
CAPM beta	16.24	87.4%	2.34	81.0%
	(10.53)**		(5.52)**	
Up beta	23.81	50.0%	3.40	50.6%
	(4.00)**		(3.50)**	
Down beta	12.09	93.0%	1.78	86.8%
	(14.63)**		(6.87)**	
Panel B: Investment grade only				
failure beta (log)	21.79	94.9%	3.16	90.7%
	(12.20)**		(8.10)**	
CAPM beta	29.01	68.0%	3.76	50.0%
	(4.12)**		(3.44)**	
Up beta	-19.65	16.6%	-2.52	8.6%
	(1.26)		(1.41)	
Down beta	18.78	86.4%	2.78	69.6%
	(7.12)**		(4.18)**	

Table 8: Using systematic and idiosyncratic default probability to explain variation in long run default probabilty and credit rating

In this table we explore the extent to which systematic and idiosyncratic default probability contributes to explaining variation in long run default probability and credit rating. We break up a firm's default probability into two components: systematic default probability (the company's default probability due to its exposure to the common component of default probability) and idiosyncratic default probability (the remainder of the default probability). Specific definitions of the two components are provided in the text of the paper. Panel A reports explanatory power; when predicting long run default we report pseudo R^2 for logit regressions (same as in Table 3), to explain variation in credit rating we use OLS regressions including year fixed effects. Panel B reports coefficients on the systematic and idiosyncratic components of default probability when both are included separately. Standard errors are robust, clustered by year and, where appropriate, corrected for serial correlation.

Panel A: Explanatory power				
	1-year	5-year	10-year	rating
Credit rating	24.3%	17.9%	14.6%	
Systematic (beta*PD)	25.3%	19.9%	16.5%	94.5%
Failure score (systematic + idiosyncratic)	41.6%	23.2%	18.8%	27.1%

Panel B: Coefficients				
systematic (beta*PD)	2.07	1.78	1.59	4.93
	(12.44)**	(24.42)**	(31.76)**	(22.60)**
idiosyncratic (alpha + e)	1.38	0.82	0.73	-0.02
	(19.80)**	(13.42)**	(12.37)**	(0.26)
Number of observations	26,941	26,941	26,941	26,941

**Figure 1: Predicting corporate failure using failure score and S&P credit rating**

Figure 2: Failure probability distribution by S&P credit rating

This figure plots the percentiles of the de-medianed 12-month failure probability, annualized (10th, 25th, median, 75th, 90th of the distribution), by S&P credit rating (AAA=1, AA+=2, ..., CCC-=19, CC=20). The failure probability is the annualized 12-month failure probability (from Table 2) and is de-medianed using the overall yearly median failure probability. The data included is from 1985 to 2008.

Figure 3: Median failure probability by rating
Figure 4: Share in different ratings

Legend: B (red), BB (orange), BBB (green), A (light blue), AA (dark blue)

Annotations: "1987 stock market crash", "LTCM collapse and Russian crisis"
Y-axis: Share rated AA, A, etc.

X-axis: Date

## Figure 5: Average failure probability over time

This figure plots the median, and total liability-weighted mean 12-month failure probability, as well as the common factor from 1986 to 2008. It also plots the annual empirical failure rate, which is normalized to the mean predicted failure probability for ease of comparison. The annual failure rate is reported in January.

Figure 6: Failure beta by S&P credit rating
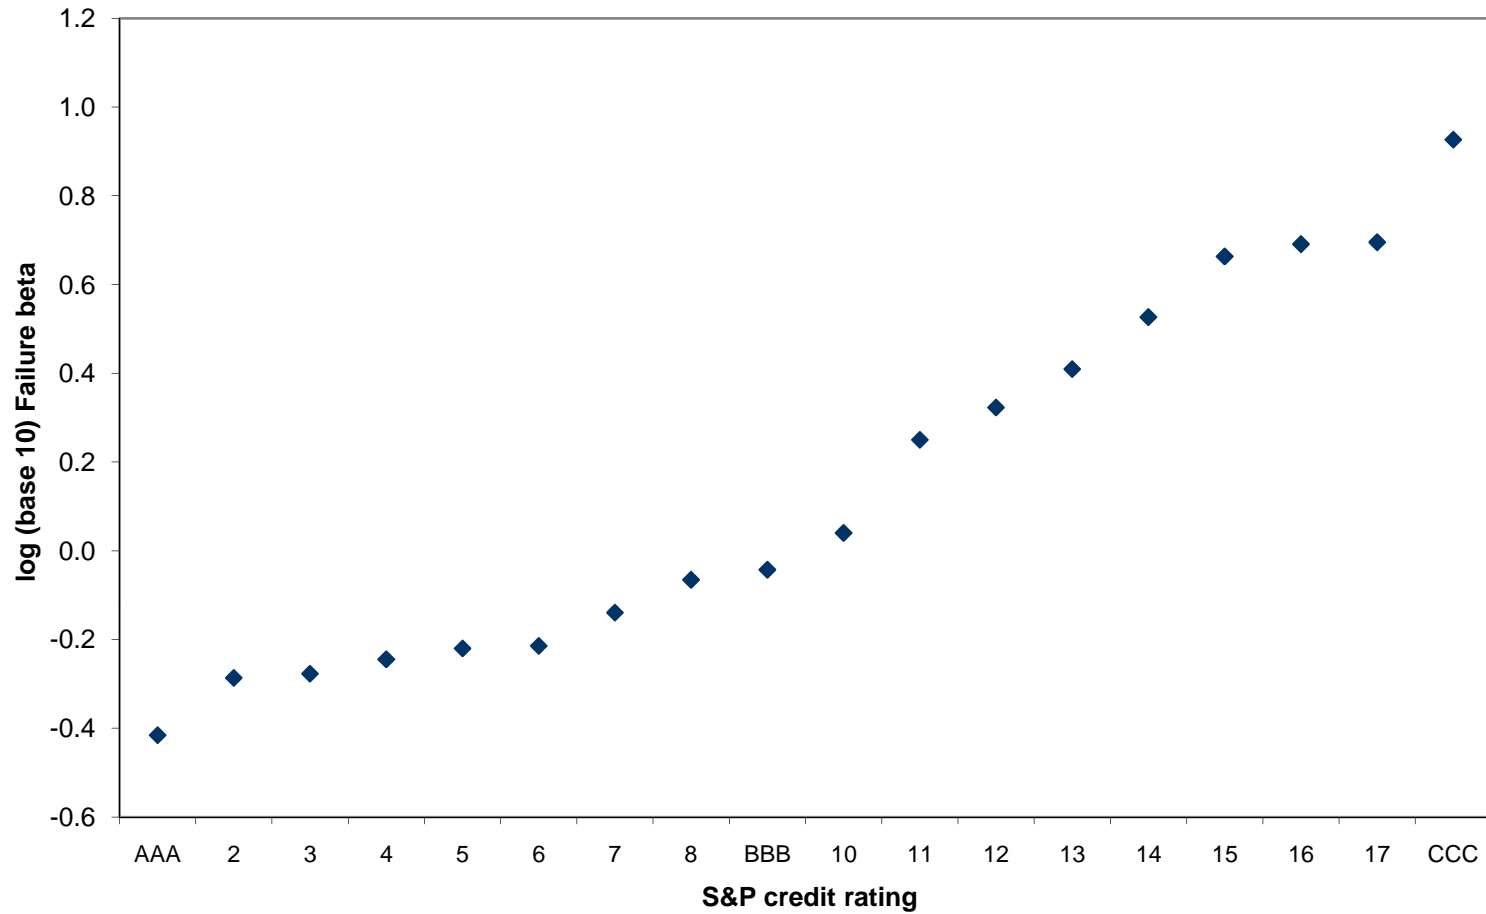

This figure plots the failure beta (12-month failure sensitivities) by S&P credit rating. The failure beta is measured as the coefficient from a regression of failure probability on median failure probability (estimated using changes), including firm fixed effects.

Figure 7: Risk premium and failure beta
This figure plots the failure beta (12-month failure sensitivities), calculated by S&P credit rating, and median risk CDS premium (de-meaned by year) for each year from 2001 to 2007. The risk premium is calculated using the 1-year cumulative default probability, the 1-year USD swap rates as the risk-free rate, and Markit recovery values.
