# Cryptanalysis of CubeHash 

Eric Brier and Thomas Peyrin<br>Ingenico, France<br>eric.brier@ingenico.com,<br>thomas.peyrin@ingenico.com

#### Abstract

CubeHash is a family of hash functions submitted by Bernstein as a SHA-3 candidate. In this paper, we provide two different cryptanalysis approaches concerning its collision resistance. Thanks to the first approach, related to truncated differentials, we computed a collision for the CubeHash $-1 / 36$ hash function, i.e. when for each iteration 36 bytes of message are incorporated and one call to the permutation is applied. Then, the second approach, already used by Dai, much more efficient and based on a linearization of the scheme, allowed us to compute a collision for the CubeHash-2/4 hash function. Finally, a theoretical collision attack against CubeHash $-2 / 3$, CubeHash $-4 / 4$ and CubeHash $-4 / 3$ is described. This is currently by far the best known cryptanalysis result on this SHA-3 candidate.

Keywords: hash functions, CubeHash, collision.

## 1 Introduction

A cryptographic hash function is a very important tool in cryptography, used in many applications such as digital signatures, authentication schemes or message integrity. One of its main and most important security feature is the collision resistance: finding two messages $M$ and $M^{\prime}$ leading to the same hash value should require at least $2^{n / 2}$ operations, where $n$ is the output length of the hash function. Wang et al. 14161517 recently showed that most standardized hash functions (e.g. MD5 [12] or SHA-1 [10]) are not collision resistant. As a response, the National Institute of Standards and Technology (NIST) opened a public competition [9] to develop a new cryptographic hash algorithm that will be called SHA-3. 51 submissions met the minimum submission requirements, and had been accepted as the first round candidates. Among them, CubeHash is a new hash function designed by Bernstein [3] and currently under evaluation. One of its advantages is its simplicity of description which makes the analysis much easier for a cryptanalyst. This proposal can be considered as a stream-cipher oriented hash function. It maintains a big 1024-bit internal state, in which $b$ byte of message are incorporated at each iteration. After adding such a message block, a fixed permutation is then applied $r$ time. Generally, the bigger is $r$ (or the smaller is $b$ ) the harder it should be for the attacker to break the collision resistance of CubeHash- $r / b$.

Previous results. The first analysis of CubeHash was proposed by Aumasson et al. [12] in which the authors showed some non-random properties for several versions of CubeHash as well as a collision for CubeHash- $2 / 120$. Later, thanks to a linearization approach, Dai [6] computed a collision for CubeHash-1/45 and CubeHash-2/89. Those results were soon improved to CubeHash-2/12 [7].

Our contributions. In this paper, we provide two different cryptanalysis approaches concerning the collision resistance. The first approach, related to truncated differences, allowed us to compute a real collision for CubeHash-1/36. The second approach, i.e. linearizing the scheme, gives us much better results: we provide a real collision for CubeHash-2/4 and theoretical collision attacks against CubeHash- $2 / 3$, CubeHash $-4 / 4$ and CubeHash- $4 / 3$. This is currently the best known cryptanalysis result on CubeHash. To give an insight of the broken schemes, CubeHash $-4 / 3$ speed is about 26 cycles/byte, comparable to the speed of SHA-2 10.

## 2 Description of CubeHash

We refer to the specifications of CubeHash [3] for the complete description of the scheme. CubeHash- $r / b-h$ is the $h$-bit output version of CubeHash, for which $b$ bytes of message are incorporated and $r$ calls to the internal permutation $F$ is applied at each iteration. The function can hash messages up to $2^{128}-1$ bits. After an appropriate padding, the message is therefore divided into block $M_{i}$ of $b$ bytes each. A 1024-bit internal state is maintained, divided into 32 words $X_{i}$ of 32 bits each and initialized by the following process: set the first three state words $X_{0}$, $X_{1}, X_{2}$ to the integers $h / 8, b, r$ respectively and set the remaining state words to 0 . Then apply on the state $10 \times r$ times the internal permutation $F$.

After the initialization, the message blocks are treated iteratively: exclusive or the incoming $b$-byte message block onto the first $b$ bytes of the internal state and apply the iteration function, composed of $r$ times the application of the internal permutation $F$. When all the message blocks have been treated, exclusive or the integer 1 to the state word $X_{31}$ and apply $10 \times r$ times the internal permutation $F$ without incorporating message blocks anymore. Finally, output the $h$ first bits of the internal state.

The internal permutation $F$ uses very simple operations: rotation, exclusive or, modular addition and word swapping. It is composed of 10 steps (represented graphically in Figure (1):

1. Add $X_{i}$ into $X_{i \oplus 16}$, for $0 \leq i \leq 15$.
2. Rotate $X_{i}$ on the left by seven bits, for $0 \leq i \leq 15$.
3. Swap $X_{i}$ and $X_{i \oplus 8}$, for $i \in[0,1,2,3,4,5,6,7]$.
4. Xor $X_{i \oplus 16}$ into $X_{i}$, for $0 \leq i \leq 15$.
5. Swap $X_{i}$ and $X_{i \oplus 2}$, for $i \in[16,7,20,21,24,25,28,29]$.
6. Add $X_{i}$ into $X_{i \oplus 16}$, for $0 \leq i \leq 15$.
7. Rotate $X_{i}$ on the left by eleven bits, for $0 \leq i \leq 15$.

Fig. 1. Internal permutation $F$ in CubeHash. Each cell represents a 32-bit word.
8. Swap $X_{i}$ and $X_{i \oplus 4}$, for $i \in[0,1,2,3,8,9,10,11]$.
9. Xor $X_{i \oplus 16}$ into $X_{i}$, for $0 \leq i \leq 15$.
10. Swap $X_{i}$ and $X_{i \oplus 1}$, for $i \in[16,18,20,22,24,26,28,30]$.

## 3 Truncated Differential Paths

In this section, we depict a cryptanalysis approach for CubeHash regarding its collision resistance, based on two very generic differential paths. The technique is
related to truncated differences, originally introduced by Knudsen [8] to cryptanalyze block ciphers and later utilized by Peyrin [11] in the hash functions setting. These one-round differential paths can potentially be used to build more complex differential characteristics on any number of rounds per iteration. Our results provide theoretical collision attacks for CubeHash- $2 / b$ with $r \leq 2$ and $b \geq 36$ and as a proof of concept, we computed a collision for the 512-bit version of CubeHash-1/36.

### 3.1 The Differential Paths

In the following, we say that a 32 -bit word is active when a non-zero difference exists on this word. We denote a differential path for the internal permutation by $A \longmapsto B$, where $A$ and $B$ are 32-bit words for which each bit represents one internal word (the LSB will denote $X_{31}$ and the MSB will denote $X_{0}$ ). Said in other words, we only check if the internal words are active or not, whatever are the values of the non-zero differences. For example, $0 \times 05000000 \longmapsto 0 \times 00000800$ means that we have $X_{5}$ and $X_{7}$ active on the input, and that we expect only $X_{20}$ to be active on the output of the permutation.

In this paper, we use two distinct differential paths for the internal permutation (see also Figure (2):

$$
\begin{aligned}
& \Delta_{1}: 0 x a 0800000 \longmapsto 0 x 0 a 020000 \\
& \Delta_{2}: 0 x 0 a 020000 \longmapsto 0 x a 0800000
\end{aligned}
$$

One can see that the two-round differential path composed of $\Delta_{1}$ and $\Delta_{2}$ has the interesting property that the input and output active words patterns are the same. In the difference mask 0xa0800000, only the nine first 32-bit words of the internal state are active. Therefore, we can look for an attack on CubeHashr/36 by using the differential paths $\Delta_{1}$ and $\Delta_{2}$ successively. In this section, we consider that the attacker insert 9 32-bit words of message at each iteration, i.e. he has full control on $X_{0}, \ldots, X_{8}$ at the beginning of each iteration.

We denote by $X^{\lll y}$ the rotation of $y$ positions on the left applied to the word $X$ and by $\bar{X}$ the complement value of $X$. Also, $X^{\prime}$ will represent the second member of the pair when $X$ is an active word. For each differential path $\Delta_{1}$ and $\Delta_{2}$, a system of four equations on 32 -bit words must be satisfied:

System 1 (for $\Delta_{1}$ ):

$$
\begin{aligned}
& \left(X_{24}+X_{8}\right) \oplus X_{0}^{\lll 7} \quad=\left(X_{24}+X^{\prime}{ }_{8}\right) \oplus X_{0}^{\prime \lll 7} \\
& X_{8}+\left[\left(X_{26}+X_{10}\right) \oplus X_{2}^{\lll 7}\right]=X^{\prime}{ }_{8}+\left[\left(X_{26}+X_{10}\right) \oplus X_{2}^{\prime \ll 7}\right] \\
& X_{0}+\left[\left(X_{18}+X_{2}\right) \oplus X_{10}^{\ll 7}\right]=X^{\prime}{ }_{0}+\left[\left(X_{18}+X^{\prime}{ }_{2}\right) \oplus X_{10}^{\lll 7}\right] \\
& X_{2}+\left[\left(X_{16}+X_{0}\right) \oplus X_{8}^{\lll 7}\right]=X^{\prime}{ }_{2}+\left[\left(X_{16}+X^{\prime}{ }_{0}\right) \oplus X^{\prime}{ }_{8}{ }^{\ll 7}\right]
\end{aligned}
$$

Fig. 2. Differential paths $\Delta_{1}$ (left) and $\Delta_{2}$ (right) for the internal permutation of CubeHash. A cell stands for a 32 -bit word of the internal state and the boxes represent in hexadecimal display the active words during the computation.

System 2 (for $\Delta_{2}$ ):

$$
\begin{array}{ll}
\left(X_{30}+X_{14}\right) \oplus X_{6} \ll 7 & =\left(X_{30}+X^{\prime}{ }_{14}\right) \oplus X_{6}^{\prime \ll} \\
X_{14}+\left[\left(X_{28}+X_{12}\right) \oplus X_{4}^{\ll 7}\right] & =X^{\prime}{ }_{14}+\left[\left(X_{28}+X_{12}\right) \oplus X_{4}^{\prime \ll 7}\right] \\
X_{6}+\left[\left(X_{20}+X_{4}\right) \oplus X_{12}^{\ll 7}\right] & =X^{\prime}{ }_{6}+\left[\left(X_{20}+X^{\prime}{ }_{4}\right) \oplus X_{11}^{\ll 7}\right] \\
X_{4}+\left[\left(X_{22}+X_{6}\right) \oplus X_{14}^{\ll 7}\right] & =X^{\prime}{ }_{4}+\left[\left(X_{22}+X^{\prime}{ }_{6}\right) \oplus X_{14}^{\prime}{ }_{14}\right]
\end{array}
$$

We describe here a fast method to resolve the first system of equations. Exactly the same method will also apply for the second system, so we will only focus on the first one. The internal state words $X_{10}, X_{16}, X_{18}, X_{24}$ and $X_{26}$ are given inputs of the system. The words $X_{0}, X^{\prime}{ }_{0}, X_{2}, X^{\prime}{ }_{2}, X_{8}$ and $X^{\prime}{ }_{8}$ are fully controlled by the attacker. Our method directly finds a solution for the three first equations. We will repeat this process several times until the last equation is also verified. More precisely, if we assume the equations to be independent, we will repeat the process $2^{32}$ times on average in order to get a solution for the complete system.

We now describe how to solve the three first equations of the system. First, we pick random values for $X_{2}$ and $X^{\prime}{ }_{2}$, such that $X_{2} \neq X^{\prime}{ }_{2}$. We can rewrite the second and third equations respectively, so we directly get

$$
\begin{align*}
& X_{8}^{\prime}-X_{8}=A  \tag{1}\\
& X_{0}^{\prime}-X_{0}=B \tag{2}
\end{align*}
$$

where $A$ and $B$ are constant terms. We then set $Y=X_{8}+X_{24}$ and $Y^{\prime}=$ $X^{\prime}{ }_{8}+X_{24}$, so we can rewrite the first equation as:

$$
\begin{equation*}
Y \oplus X_{0}^{\lll 7}=Y^{\prime} \oplus X_{0}^{\prime \ll 7} \tag{3}
\end{equation*}
$$

Finally, we combine the three equations together:

$$
\begin{equation*}
Y \oplus(A+Y)=X_{0}^{\lll 7} \oplus\left(B+X_{0}\right)^{\lll 7} . \tag{4}
\end{equation*}
$$

We need a trick to solve this equation quickly: one can check that $x \oplus(x+k)$ is always equal to 0xffffffff when $x=\bar{k} / 2$ and when the least significant bit of $k$ is equal to one. Thus, we wait for $A$ and $B$ values so that their least significant bit is equal to one and we set $Y=\bar{A} / 2$ and $X_{0}=\bar{B}^{\ll 25} / 2$. The two sides of the equations are therefore equal to $0 x f f f f f f f f$ and we can finally deduce a solution that verifies the three first equations of our system.

### 3.2 A Collision for CubeHash-1/36

Using the differential paths $\Delta_{1}$ and $\Delta_{2}$ and the solving technique previously explained, we computed within a few minutes on an average PC (Processor Intel Core 2 Duo 2.0 GHz , with 2 GB of RAM) a collision for CubeHash- $1 / 36$ with 512 bits of output.

The collision attack uses four message inputs. The first message block is used without any difference in order to randomize the values of the internal state just after the initialisation (randomization of the equations systems). Then, the second message pair verifies the differential path $\Delta_{1}$ and the third message pair the differential path $\Delta_{2}$. Finally, the fourth and last message pair will erase the remaining differences (0xa0800000) in the internal state, and thus leads to an internal collision. Obviously, by adding some other message words without difference, one will maintain colliding pairs of internal states until the end of the computation of the hash function.

The values of the message words to insert and the final hash value are given in Table 4 in the Appendix A.

### 3.3 Extensions to Other Versions

One can easily extend this practical attack against CubeHash- $1 / 36$ to theoretical attacks against stronger versions. First, it is obvious that when $b \geq 36$, our attack remains valid. When $r=2$, one has to verify equations from system 1 in the first internal permutation call, and equations from system 2 in the second internal permutation call of the iteration function.

We managed to generate input blocks verifying directly five equations among the eight of the two systems. Thus, one can assume that the three other equations will be verified with probability $2^{-32 \times 3}$. Therefore, one can find a collision for CubeHash- $2 / 36$ with a computation complexity of about $2^{96}$ function calls.

## 4 Linear Differential Paths

In this section, we will try to find interesting differential paths by using a $\mathcal{F}^{2}$ linear version of the scheme. More precisely, in the internal permutation $F$, we replace all the modular additions by bitwise XOR operations on 32-bit words. Overall, this simplification makes sense since non-linear components are quite few in CubeHash. This technique is very frequently used in order to study hash functions, for example in the case of SHA-1 [4]. Dai 6|7] also used this simplification to compute a collision for CubeHash-2/12 and CubeHash-1/45.

### 4.1 The Differential Path

In this section, we are interested in attacking CubeHash-2/4. Said in other words, after a 2 -round iteration, the attacker hash complete control over $X_{0}$ (and only $X_{0}$ ). The linear differential path we use is very simple, almost the simplest someone can think of. We first insert a one-bit perturbation in $X_{0}$ and apply the first 2-round iteration. We then erase all the differences present in $X_{0}$ and we apply the second 2-round iteration. Finally, we get a collision on the internal state by erasing a very last difference in $X_{0}$.

More precisely, we first insert a message pair with a one-bit difference located at bit position $y$. Then, the next message pair will correct three differences located at bit position $y+4, y+14$ and $y+22$ (the positions are to be taken modulo 32 ). Finally, the last message pair will correct the last difference located at bit position $y+4$. The differential path is described in Figure 3,

In the linear model, a collision can be computed directly. However, as any differential path, for the real function there is a certain probability of success that a random message pairs fulfilling the input differential constraints will also fulfill the output differential constraints. This probability can often be translated to a set of sufficient conditions to verify. In our case, the conditions directly depict the expected linear behavior of the scheme. The real CubeHash uses two modular additions in each call of the internal permutation $F$, which are non-linear components because of the carry potentially created. Thus, two interesting situations can occur:

1. a perturbation at a certain bit position is added to another bit containing no difference (move).
2. a perturbation at a certain bit position is added to another bit containing a difference (correction).

Each such situation will lead to exactly one sufficient condition because we want the modular addition carry to be unaffected by the perturbation. Said in other words, when we add together two word pairs $A, B$ and $A^{\prime}, B^{\prime}$, the number of conditions will be the hamming weight of $\left(A \oplus A^{\prime}\right) \vee\left(B \oplus B^{\prime}\right)$, where $\vee$ stands for the bitwise or operation. When all the conditions from situations 1 and 2 are verified through the entire differential path, we are assured that the scheme behaved completely linearly regarding the bit perturbations and we can finally get our collision.

In total, the differential path presented possesses 46 sufficient bit conditions ( 24 for the first iteration and 22 for the second). This means that by testing

| it. | round | step | active bits | nb. cond. |

Fig. 3. Linear differential path for CubeHash $-2 / 4$ and CubeHash $-2 / 3$. The three first columns give in order the iteration number, the round number and the step number in the internal permutation. A step denoted $M$ represents the active bits of the message block inserted. The fourth column provides the active bits, where $X_{i}^{j}$ denotes the $j$ th bit of the internal word $X_{i}$. Finally, the number of conditions is given in the last column.
about $2^{46}$ different messages pairs, one has a rather good chance to find a valid candidate. However, this can be improved by carefully choosing the bit position on which the initial difference is inserted. Indeed, some conditions can be placed on bit position 31 and will therefore be always verified with probability 1 . We give in Table 1 the number of bit conditions of the differential path from Figure 3 , according to the bit position of the initial difference inserted.

Table 1. Number of conditions for the differential path from Figure 3 according to the bit position of the first difference inserted

| bit position | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| nb. conditions | 46 | 46 | 46 | 46 | 46 | 46 | 41 | 46 | 46 | 46 | 46 | 46 | 46 | 38 | 46 | 46 |

| bit position | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28 | 29 | 30 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| nb. conditions | 46 | 43 | 46 | 46 | 41 | 46 | 46 | 46 | 32 | 46 | 46 | 46 | 46 | 46 | 46 |

Note also that valid candidate search speed-ups are very likely to exist. Indeed, the complexity cost here only takes in account the probability of the differential path. However, in hash functions cryptanalysis, the use of the available degrees of freedom can drastically improve the overall complexity of the attack. For example, it is easy to force some bits of the first inserted message word in order to validate with probability 1 the very first condition of the differential path. Also, one can try to validate some conditions of the first iteration and some conditions of the second iteration independently, by playing with the message word inserted just before the second iteration.

### 4.2 Collision Attack for CubeHash-2/4 and CubeHash-2/3

According to Table 1 using the differential path from Figure 3 on bit position 24 provides a collision attack on CubeHash- $2 / 4$ with an overall complexity of $2^{32}$ operations. An example of such a collision for the 512 -bit output version of the scheme is given here. It required a few minutes of computation on an average PC (Processor Intel Core 2 Duo 2.0 GHz , with 2 GB of RAM). No specific search speed-up were used which leaves room for further improvements.

This colliding pair is composed of five message inputs. The two first message blocks are used without any difference in order to randomize the values of the internal state just after the initialisation. Then, the third message pair inserts the initial one-bit difference at position 24 , and the fourth message pair permits to prepare the internal state for the second part of the differential path. Finally, the fifth and last message pair will erase the remaining difference in the first word of the internal state, and thus leads to an internal collision.

The values of the message words to insert and the final hash value are given in Table 5 in the Appendix B.

In the implementation of CubeHash, one can check that if 3 bytes are inserted at each iteration, they will be xored to the 3 first least significant bytes of $X_{0}$ (the

Fig. 4. Linear differential path for CubeHash-4/4 and CubeHash-4/3. The three first columns give in order the iteration number, the round number and the step number in the internal permutation. A step denoted $M$ represents the active bits of the message block inserted. The fourth column provides the active bits, where $X_{i}^{j}$ denotes the $j$ th bit of the internal word $X_{i}$. Finally, the number of conditions is given in the last column. The display of this differential path has been simplified because of the big number of active bits.
first byte of a word is considered to be the least significant one). Thus, using the same differential path but by inserting the initial perturbation at bit position 0 gives us a collision attack against CubeHash- $2 / 3$ with only $2^{46}$ operations. Indeed, if one inserts the perturbation at bit position 0 (in the first byte of $X_{0}$ ), the first message correction after one iteration will occur on bit positions 4,14 and 22 (all located in the three first bytes of $X_{0}$ ). Finally, after another iteration, the attacker will have to erase the difference located at bit position 4 (in the first byte of $X_{0}$ ) in order to get an internal collision. One can see that all the control needed by the attacker is located in the three first bytes of $X_{0}$. Thus, a collision for CubeHash- $2 / 3$ can be found with only $2^{46}$ operations.

### 4.3 Collision Attack for CubeHash-4/4 and CubeHash-4/3

One can use the same linearization technique to cryptanalyze CubeHash- $4 / 4$ and CubeHash- $4 / 3$. The differential path will be a little bit more complicated than

Table 2. Number of conditions for the differential path from Figure 4, according to the bit position of the first difference inserted

|  | 4 | 3 |  |
|  | 2 | 5 | $2^{2614}$ |
|  | 1 | 5 |  |

the one from Figure 3 and its probability of success will also be much lower. We give in Figure 4 the new differential path for CubeHash- $4 / 4$. The display has been simplified because of the big number of conditions. However, since we use the linear model, the entire set of sufficient conditions can be easily retrieved from the input differences.

As for the previous differential path, the number of conditions depends on the bit position of the first perturbation inserted (because the conditions on bit position 31 are automatically verified). We give in Table 2 the number of bit conditions of the differential path from Figure [4, according to the bit position of the initial difference inserted.

One can directly conclude that a collision attack requiring $2^{189}$ operations can be mounted on CubeHash- $4 / 4$ by selecting the bit position 20 for the first perturbation inserted. Concerning CubeHash- $4 / 3$, only the bit positions 4 to 11 can be selected to insert the first perturbation, so that the control required by the attacker only involves the three least significant bytes of the internal word
$X_{0}$. Thus, by choosing the bit position 9 , one gets a collision attack against CubeHash- $4 / 3$ with only $2^{195}$ operations.

### 4.4 Others Versions of CubeHash

We can apply similar techniques to cryptanalyze other versions of CubeHash. We give in Table 3 the best possible linear differential path probabilities, according to the parameters of the hash function considered and the maximum number of iterations. One can check that for some slower versions of CubeHash the probabilities of success of the linear differential paths are too low. However, it may be possible to use more iterations and aim to build a more complex attack composed of the concatenation of several individual linear differential paths. Also, depending on the amount of degrees of freedom available, one may be able to improve the overall complexity of the attack.

## 5 Conclusion

In this paper, we provided two different cryptanalysis approaches that led to the computation of a real collision for CubeHash- $1 / 36$ and CubeHash- $2 / 4$. The linear differential paths also give a theoretical collision attack against CubeHash-2/3 in $2^{46}$ operations, against CubeHash- $4 / 4$ in $2^{189}$ operations and against CubeHash$4 / 3$ in $2^{195}$ operations. Those complexities have to be compared to $2^{128}$ and $2^{256}$ for an ideal hash function of 256 and 512-bit output respectively.

## Acknowledgments

The authors would like to thank Jean-Philippe Aumasson, Shahram Khazaei, Willi Meier and María Naya-Plasencia for the very interesting discussions on CubeHash.
