Abstract. In this paper we study the security of the **RadioGatún** family of hash functions, and more precisely the collision resistance of this proposal. We show that it is possible to find differential paths with acceptable probability of success. Then, by using the freedom degrees available from the incoming message words, we provide a significant improvement over the best previously known cryptanalysis. As a proof of concept, we provide a colliding pair of messages for **RadioGatún** with 2-bit words. We finally argue that, under some light assumption, our technique is very likely to provide the first collision attack on **RadioGatún**.

Key words: hash functions, **RadioGatún**, cryptanalysis.

1 Introduction

A cryptographic hash functions is a very important tool in cryptography, used in many applications such as digital signatures, authentication schemes or message integrity. Informally, a cryptographic hash function H is a function from $\{0, 1\}^*$, the set of all finite length bit strings, to $\{0, 1\}^n$ where n is the fixed size of the hash value. Moreover, a cryptographic hash function must satisfy the properties of preimage resistance, 2nd-preimage resistance and collision resistance [26]:

- **collision resistance:** finding a pair $x \neq x' \in \{0, 1\}^*$ such that $H(x) = H(x')$ should require $2^{n/2}$ hash computations.
- **2nd preimage resistance:** for a given $x \in \{0, 1\}^*$, finding a $x' \neq x$ such that $H(x) = H(x')$ should require 2^n hash computations.
- **preimage resistance:** for a given $y \in \{0, 1\}^n$, finding a $x \in \{0, 1\}^*$ such that $H(x) = y$ should require 2^n hash computations.

Generally, hash functions are built upon a *compression function* and a *domain extension algorithm*. A compression function h , usually built from scratch, should have the same security requirements as a hash function but takes fixed length inputs instead. Wang *et al.* [30, 32, 33, 31] recently showed that most standardized compression functions (e.g. MD5 or SHA-1) are not collision resistant. Then, a domain extension method allows the hash function to handle arbitrary length inputs by defining an (often iterative) algorithm using the compression

function as a black box. The pioneering work of Merkle and Damgård [15, 27] provided to designers an easy way in order to turn collision resistant compression functions onto collision resistant hash functions. Even if preserving collision resistance, it has been recently shown that this iterative process presents flaws [16, 18, 20, 19] and new algorithms [24, 7, 2, 1, 25] with better security properties have been proposed.

Most hash functions instantiating the Merkle-Damgård construction use a block-cipher based compression function. Some more recent hash proposals are based on construction principles which are closely related to stream ciphers. For example we can cite `Grindahl` [23] or `RadioGatún` [4]. The underlying idea of *stream-oriented* functions is to first absorb m -bit message blocks into a big internal state of size $c + m$ using a simple round function, and then squeeze the hash output words out. As the internal state is larger than the output of the hash function, the cryptanalytic techniques against the iterative constructions can not be transposed to the case of stream-oriented functions. In 2007, Bertoni *et al.* published a new hash construction mode, namely the *sponge functions* [6]. At Eurocrypt 2008, the same authors [5] published a proof of security for their construction : when assuming that the internal function F is a random permutation or a random transformation, then the sponge construction is indiffereniable from a random oracle up to $2^{c/2}$ operations.

However, even though the same authors designed `RadioGatún` and defined the sponge construction, `RadioGatún` does not completely fulfill the sponge definition. For evident performance reasons, the internal function F of `RadioGatún` is not a very strong permutation and this might lead to correlations between some input and output words. This threat is avoided by applying blank rounds (rounds without message incorporation) just after adding the last padded message word. More recently, some NIST SHA-3 candidates are using stream-oriented functions as well, for example `SHABAL` [10], or sponge functions, for example `Keccak` [3].

Regarding the `Grindahl` family of hash functions, apart from potential slide attacks [17], it has been shown [28, 22] that it can not be considered as collision resistant. However, `RadioGatún` remains yet unarmed by the preliminary cryptanalysis [21]. The designers of `RadioGatún` claimed that for an instance manipulating w -bit words, one can output as much as $19 \times w$ bits and get a collision resistant hash function. That is, no collision attack should exist which requires less than $2^{9,5 \times w}$ hash computations. The designers also stated [4] that the best collision attack they could find (apart from generic birthday paradox ones) requires $2^{46 \times w}$ hash computations. A first cryptanalysis result by Bouilagué and Fouque [8] using algebraic technique showed that one can find collisions for `RadioGatún` with $2^{24,5 \times w}$ hash computations. Finally, Khovratovich [21] described an attack using $2^{18 \times w}$ hash computations and memory, that can find collisions with the restriction that the IV must chosen by the attacker (semi-free-start collisions).

Our contributions. In this paper, we provide an improved cryptanalysis of `RadioGatún` regarding collision search. Namely, using an improved computer-

aided backtracking search and symmetric differences, we provide a technique that can find a collision with $2^{11 \times w}$ hash computations and negligible memory. As a proof of concept, we also present a colliding pair of messages for the case $w = 2$. Finally, we argue that this technique has a good chance to lead to the first collision attack on **RadioGatún** (the computation cost for setting up a complete collision attack is below the ideal bound claimed by the designers, but still unreachable for nowadays computers).

Outline. The paper is organized as follows. First, in Section 2, we describe the hash function proposal **RadioGatún**. Then, in Section 3, we introduce the concepts of *symmetric differences* and *control words*, that will be our two main tools in order to cryptanalyze the scheme. In Section 4, we explain our differential path generation phase and in Section 5 we present our overall collision attack. Finally, we draw the conclusion in last section.

2 Description of RadioGatún

RadioGatún is a hash function using the design approach and correcting the problems of **Panama** [14], **StepRightUp** [13] or **Subterranean** [11, 13].

RadioGatún maintains an internal state of 58 words of w bits each, divided in two parts and simply initialized by imposing the zero value to all the words. The first part of the state, the *mill*, is composed of 19 words and the second part, the *belt*, can be represented by a matrix of 3 rows and 13 columns of words. We denote by M_i^k the i -th word of the belt state before application of the k -th iteration (with $0 \leq i \leq 18$) and $B_{i,j}^k$ represents the word located at column i and row j of the mill state before application of iteration k (with $0 \leq i \leq 12$ and $0 \leq j \leq 2$).

The message to hash is first padded and then divided into blocks of m words of w bits each that will update the internal state iteratively. We denote by m_i^k the i -th word of the message block m^k (with $0 \leq i \leq 2$). Namely, for iteration k , the message block m^k is firstly incorporated into the internal state and then a permutation P is applied on it. The incorporation process at iteration k is defined by :

$$\begin{aligned} B_{0,0}^k &= B_{0,0}^k \oplus m_0^k & B_{0,1}^k &= B_{0,1}^k \oplus m_1^k & B_{0,2}^k &= B_{0,2}^k \oplus m_2^k \\ M_{16}^k &= M_{16}^k \oplus m_0^k & M_{17}^k &= M_{17}^k \oplus m_1^k & M_{18}^k &= M_{18}^k \oplus m_2^k \end{aligned}$$

where \oplus denotes the bitwise *exclusive or* operation.

After having processed all the message blocks, the internal state is finally updated with N_{br} blank rounds (simply the application of the permutation P , without incorporating any message block). Eventually, the hash output value is generated by successively applying P and then outputting M_1^k and M_2^k as many time as required by the hash output size.

The permutation P can be divided into four parts. First, the *Belt* function is applied, then the *MillToBelt* function, the *Mill* function and eventually the *BeltToMill* function. This is depicted in Figures 1 and 2.

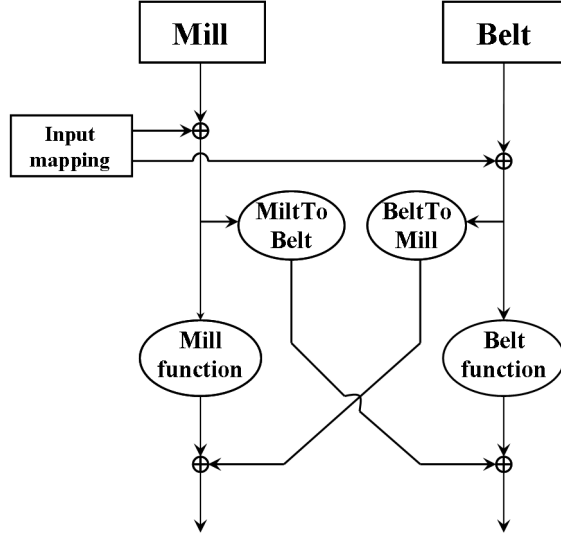

Fig. 1. The permutation P in RadioGatún.

Fig. 2. The permutation P in RadioGatún.

The *Belt* function simply consists of a row-wise rotation of the belt part of the state. That is, for $0 \leq i \leq 12$ and $0 \leq j \leq 2$:

$$B'_{i,j} = B_{i+1 \bmod 13,j}.$$

The *MillToBelt* function allows the mill part of the state to influence the belt one. For $0 \leq i \leq 11$, we have :

$$B'_{i+1, i \bmod 3} = B_{i+1, i \bmod 3} \oplus M_{i+1}.$$

The *Mill* function is the most complex phase of the permutation P and it updates the mill part of the state (see Figure 3). In the following, all the indexes should be taken modulo 19. First, a non linear transformation is applied on all the words. For $0 \leq i \leq 18$:

$$M'_i = M_i \oplus \overline{\overline{M_{i+1}}} \wedge M_{i+2}$$

where \overline{X} denotes the bitwise negation of X and \wedge represents the bitwise *and* operation. Then, a diffusion phase inside the words is used. For $0 \leq i \leq 18$:

$$M'_i = M_{7 \times i} \ggg (i \times (i + 1)/2)$$

where $X \ggg (y)$ denotes the rotation of X on the right over y positions. Then, a diffusion phase among all the words is applied. For $0 \leq i \leq 18$:

$$M'_i = M_i \oplus M_{i+1} \oplus M_{i+4}.$$

Finally, an asymmetry is created by simply setting $M_0 = M_0 \oplus 1$.

The *BeltToMill* function allows the belt part of the state to influence the mill one. For $0 \leq i \leq 2$, we have :

$$M'_{i+13} = M_{i+13} \oplus B_{12, i}.$$

Fig. 3. The *Mill* function in RadioGatún.

The RadioGatún security claims. Although RadioGatún has some common features with the sponge functions, the security proof of the sponge construction does not apply for this proposal. In their original paper [4], the authors claim that RadioGatún can output as much as 19 words and remain a secure hash function. Thus, it should not be possible for an attacker to find a collision attack running in less than $2^{9,5 \times w}$ hash computations.

3 Symmetric differences and control words

3.1 Symmetric differences

The first cryptanalysis tool we will use are symmetric differences, already mentioned in [4]. More precisely, a symmetric difference is an intra-word *exclusive or* difference that is part of a stable subspace of all the possible differences on a w -bit word. For example, in the following we will use the two difference values 0^w and 1^w (where the exponentiation by x denotes the concatenation of x identical strings), namely either a zero difference or either a difference on every bit of the word.

Considering those symmetric differences will allow us to simplify the overall scheme. Regarding the intra-word rotations during the *Mill* function, a 0^w or a 1^w difference will obviously remain unmodified. Moreover, the result of an *exclusive or* operation between two symmetric differences will naturally be a symmetric difference itself :

$$0^w \oplus 0^w = 0^w \quad 0^w \oplus 1^w = 1^w \quad 1^w \oplus 0^w = 1^w \quad 1^w \oplus 1^w = 0^w$$

The non linear part of the *Mill* function is more tricky. We can write :

$$\overline{a \wedge b} = a \vee \overline{b}.$$

The output of this transformation will remain a symmetric difference with a certain probability of success, given in Table 1.

Due to the use of symmetric differences, the scheme to analyze can now be simplified : we can concentrate our efforts on a $w = 1$ version of RadioGatún, for which the intra-word rotations can be discarded. However, when building a differential path, for each differential transition during the non linear part of the *Mill* function, we will have to take the corresponding probability from Table 1 in account³. Note that this probability will be the only source of uncertainty in the differential paths we will consider (all the differential transitions through exclusive or operation always happen with probability equal to 1) and the product of all probabilities will be the core of the final complexity of the attack.

Also, one can check that the conditions on the *Mill* function input words are not necessarily independent. One may have to control differential transitions for non linear subfunctions located on adjacent positions (for example the first

³ In a dual view, all the conditions derived from Table 1 must be fulfilled.

Δ_a	Δ_b	$\Delta_{a \vee \bar{b}}$	Probability	Condition
0^w	0^w	0^w	1	
0^w	1^w	0^w	2^{-w}	$a = 1^w$
0^w	1^w	1^w	2^{-w}	$a = 0^w$
1^w	0^w	0^w	2^{-w}	$b = 0^w$
1^w	0^w	1^w	2^{-w}	$b = 1^w$
1^w	1^w	0^w	2^{-w}	$a = b$
1^w	1^w	1^w	2^{-w}	$a \neq b$

Table 1. Differential transitions for symmetric differences during the non linear part of the *Mill* function of **RadioGatún**. Δ_a and Δ_b denote the difference applied on a and b respectively, and $\Delta_{a \vee \bar{b}}$ the difference expected on the output of $a \vee \bar{b}$. The last column gives the corresponding conditions on the values of a and b in order to validate the differential transition. By $a = b$ (respectively $a \neq b$) we mean that all the bits of a and b are equal (respectively different), i.e. $a \oplus b = 0^w$ (respectively $a \oplus b = 1^w$).

subfunction, involving M_0 and M_1 , and the second, involving M_1 and M_2). This has two effects : potential incompatibility or condition compression (concerning M_1 in our example). In the first case, two conditions are located on the same input word and are contradicting (for example, one would have both $M_1 = 0^w$ and $M_1 = 1^w$). Thus, the differential path would be impossible to verify and, obviously, one has to avoid this scenario. For the second case, two conditions apply on the same input word but are not contradicting. Here, there is a chance that those conditions are redundant and we only have to account one time for a probability 2^{-w} . Finally, note that all those aspects have to be handled during the differential path establishment and not during the search for a valid pair of messages.

3.2 Control words

When trying to find a collision attack for a hash function, two major tools are used : the differential path and the freedom degrees. In the next section, we will describe how to find good differential paths using symmetric differences. If a given path has probability of success equal to P , the complexity of a naive attack would be $1/P$ operations : if one chooses randomly and non-adaptively $1/P$ random message inputs that are coherent with the differential constraints, there is a rather good chance that a pair of them will follow the differential path entirely. However, for the same differential path, the complexity of the attack can be significantly decreased if the attacker chooses its inputs in a clever and adaptive manner.

In the case of **RadioGatún**, 3 w -bit message words are incorporated into the internal state at each round. Those words will naturally diffuse into the whole internal state, but not immediately. Thus, it is interesting to study how this diffusion behaves. Since the events we want to control through the differential path

are the transitions of the non linear part of the *Mill* function (which depend on the input words of the *Mill* function), we will only study the diffusion regarding the input words of the *Mill* function.

Table 2 gives the dependencies between the message words incorporated at an iteration k , and the 19 input words of the *Mill* function at iteration k , $k + 1$ and $k + 2$. One can argue that a modification of a message block does not necessarily impacts the input word marked by a tick in Table 2 because the non linear function can sometimes “absorb” the diffusion of the modification. However, we emphasize that even if we depict here a behavior on average for the sake of clarity, all those details are taken in account thanks to our computer-aided use of the control words.

Table 2. Dependencies between the message words incorporated at an iteration k , and the 19 input words of the *Mill* function of **RadioGatún** at iteration k , $k + 1$ and $k + 2$. The first table (respectively second and third) gives the dependencies regarding the message block m_0^k (respectively m_1^k and m_2^k). The columns represent the input words of the *Mill* function considered and a tick denotes that a dependency exists between the corresponding input word and message block.

4 An improved backtracking search

Our aim is to find internal collisions, i.e. collisions on the whole internal state before application of the blank rounds.

In order to build a good differential path using symmetric differences, we will use a computer-aided meet-in-the-middle approach, similar to the technique in [28]. More precisely, we will build our differential path DP by connecting together separate paths DP_f and DP_b . We emphasize that, in this section, we only want to build the differential path and not to look for a colliding pair of messages. DP_f will be built in the forward direction starting from an internal

state containing no difference (modeling the fact that we have no difference after the initialization of the hash function), while DP_b will be built in the backward direction of the hash computation starting from an internal state containing no difference (modeling the fact that we want a collision at the end of the path).

Starting from an internal state with no difference, for each round the algorithm will go through all the possible differences incorporation of the message input (remember that we always use symmetric differences, thus we only have $2^3 = 8$ different cases to study) and all the possible symmetric differences transitions during the *Mill* function according to Table 1 (the differential transitions through exclusive or operations are fully deterministic). The algorithm can be compared to a search tree in which the depth represents the number of rounds of *RadioGatún* considered and each leaf or sub-leaf is a reachable differential internal state.

4.1 Entropy

An exhaustive search in this tree would obviously imply making useless computations (some parts of the tree provide too costly differential path anyway). To avoid this, we always compute an estimation of the cost of finding a message pair fulfilling the differential paths during the building phase of the tree, from an initial state to the current leaf in the forward direction, and from the current leaf to colliding states in the backward direction.

A first idea would be to compute the current cost of DP_f and DP_b during the *meet-in-the-middle* phase. But, as mentioned in Section 3, some words of the mill only depend on the inserted message block after 1 or 2 rounds. Therefore, some conditions on the mill value have to be checked 2 rounds earlier, and some degrees of freedom may have to be used to fulfill conditions two rounds later. As DP_f and DP_b are computed round per round, it is difficult to compute their complexity during the search phase, while having an efficient early-abort algorithm.

Therefore, we use an *ad hoc* parameter, denoted H^k and defined as follows. If c^k is the total number of conditions on the mill input words at round k (from Table 1), we have for a path of length n :

$$\begin{cases} H^k = \max(H^{k+1} + c^k - 3, 0), \forall k < n \\ H^n = 0 \end{cases}$$

The idea is to evaluate the number of message pairs required at step k in order to get $2^{w \times H^{k+1}}$ message pairs at step $k+1$ of the exhaustive search phase. To achieve this, one needs to fulfill $c^k \times w$ bit conditions on the mill input values, with $3 \times w$ degrees of freedom. Therefore, the values of H^k can be viewed as the relative entropies on the successive values of the internal state during the hash computation.

The final collision search complexity would be $2^{w \times H_{max}}$, where H_{max} is the maximum value of H^i along the path, if the adversary could choose 3 words of

his choice at each step, and if each output word of the *Mill* function depended on all the input words. In the case of **RadioGatún**, the computation cost is more complex to evaluate, and this is described in Section 5.

4.2 Differential path search algorithm

The path search algorithm works as follows. We first compute candidates for DP_f with a modified breadth-first search algorithm, eliminating those for which the maximum entropy exceeds the minimum entropy by more than $8 \times w$ (because we want to remain much lower than the $9, 5 \times w$ bound from the birthday paradox). The algorithm differs from a traditional breadth-first search as **we do not store all the nodes, but only those with an acceptable entropy** : to increase the probability of linking it to DP_b , one only stores the nodes whose entropy is at least $(H_{max} - 4) \times w$. We also store the state value of the previous node with entropy at least $(H_{max} - 4) \times w$, to enable an efficient backtracking process once the path is found.

We then compute DP_b , using a depth-first search among the backwards transitions of the *Mill* function, starting from colliding states. We set the initial entropy to $H^n = 0$, and we do not search the states for which $H > 8$ (same reason as for DP_f : we want to remain much lower than the bound from the birthday paradox). For each node having an entropy at most 4, we try to link it with a candidate for DP_f .

4.3 Complexity of the path search phase

The total amount of possible values for a symmetric differential on the whole state is $2^{13 \times 3 + 19} = 2^{58}$. We use the fact that for **RadioGatún**, the insertion of $M \oplus M'$ can be seen as the successive insertions of M and M' without applying the round function. Therefore, we can consider setting the words 16, 17, 18 of the stored mill to 0 by a message insertion before storing it in the forward phase, and doing the same in the backward phase before comparing it to forward values. Therefore, the space on which the meet-in-the-middle algorithm has to find a collision has approximately 2^{55} elements. We chose to store 2^{27} values of DP_f , and thus we have to compare approximately 2^{28} values for DP_b .

5 The collision attack

In this section, we depict the final collision attack, and compute its complexity. Once a differential path is settled, the derived collision attack is classic : we will use the control words to increase as much as possible the probability of success of the differential path.

5.1 Description

The input for this attack is a differential path, with a set of sufficient conditions on the values of the mill to ensure that a pair of messages follow the path. The

adversary searches the colliding pairs in a tree, in which the nodes are messages following a prefix of the differential path. The leaves are messages following the whole differential path. Thanks to an early-abort approach, the adversary eliminates candidates as soon as they differ from the differential path. Nodes are associated with messages, therefore they will be denoted by the message they stand for. The sons of node M are then messages $M||b$, where b is a given message block, and the hash computation of $M||b$ fulfills all the conditions.

The adversary then uses a depth-first approach to find at least one node at depth n , where n is the length of the differential path. It is based on the trail backtracking technique, described in [4, 28]. To decrease the complexity of the algorithm, we check the conditions on the words of the mill as soon as they cannot be modified anymore by a message word inserted later.

From Table 2, we know that the k -th included message block impacts some words of the mill before the k -th iteration of the *Mill* function, some other words before the $k + 1$ -th iteration, and the rest of the mill words before the $k + 2$ -th iteration. We recall that m^k is the k -th inserted block, and we now set that M_j^k is the value of the j -th mill word after the k -th message insertion. Let also \hat{M}_j^k be the value of the j -th word of the mill after the k -th nonlinear function computation.

After inserting m^k , one can then compute $M_{16}^k, M_{17}^k, M_{18}^k$, but also M_j^{k+1} for $j = \{1, 2, 4, 5, 7, 8, 9, 12, 13, 15\}$, and M_j^{k+2} for $j = \{0, 3, 6, 10, 11, 14\}$. Similarly, one can compute $M_j^k \oplus M_{j+1}^k$, for $j = \{15, 16, 17, 18\}$, $M_j^{k+2} \oplus M_{j+1}^{k+2}$ for $j = \{7, 11\}$, and $M_j^{k+1} \oplus M_{j+1}^{k+1}$ for all other possible values of j . Therefore, the adversary has to check conditions on three consecutive values of the mill on message insertion number k .

The most naive way to do it would be to choose m^k at random and hoping the conditions are verified, but one can use the following facts to decrease the number of messages to check :

- The conditions on words M_{16}^k, M_{17}^k and M_{18}^k as well as these on the values $M_{15}^k \oplus M_{16}^k, M_{16}^k \oplus M_{17}^k, M_{17}^k \oplus M_{18}^k$ and $M_{18}^k \oplus M_0^k$ at step k can be fulfilled by *xor*-ing the adequate message values at message insertion k .
- Using the linearity of all operations except the first one, the adversary can rewrite the values M_j^{k+1} as a linear combination of variables \hat{M}_j^k , with $j = \{0, \dots, 18\}$. Words \hat{M}_0^k to \hat{M}_{13}^k do not depend on the last inserted message value, therefore can be computed before the message insertion.
- A system of equations in variables $\hat{M}_{14}^k, \dots, \hat{M}_{18}^k$ remains. More precisely, these equations define the possible values of these variables, or of the *xor* of two of these variables, one of them being rotated.

The computation of the sons of a node at depth k work as follows :

1. The adversary checks the consistency of the equations on $\hat{M}_{14}^k, \dots, \hat{M}_{18}^k$. The probability that this system is consistent depends on dimension of the Kernel of the system and can be computed *a priori*.

2. The adversary exhausts the possible joint values of $\hat{M}_{14}^k, \dots, \hat{M}_{18}^k, M_{16}^k, M_{17}^k$ and M_{18}^k . This can be achieved bitwise, as the nonlinear part of the *Mill* function works bitwise. The cost of this phase is then linear in w . The mean number of sons depends on the number of conditions.
3. For each remaining message block, the adversary checks all the other linear conditions on $\hat{M}_{14}^k, \dots, \hat{M}_{18}^k$ and the conditions on the mill values 2 rounds later.

5.2 Computation of the cost

We will now explain how to compute the complexity of the collision search algorithm. The most expensive operation is the search of the sons of nodes. The total complexity of a given depth level k is the product of the number of nodes that have to be explored at depth k by the average cost of the search of these nodes. These parameters are exponential in w , therefore the total cost of the search can be approximated by the search of the most expensive nodes.

To compute the search cost, we assume that for all considered messages, the words of the resulting states for which no condition is imposed are independent and identically distributed. This is true at depth 0, provided the attacker initializes the search phase with a long random message prefix. The identical distribution of the variables can be checked recursively, their independence is an hypothesis for the attack to work. This assumption is well-known in the field of hash function cryptanalysis for computing the cost associated to a differential path (see e.g. [28]).

Let A^k be the number of nodes that have to be reached at depth k , and C^k the average cost of searching one of these nodes. Let P^k be the probability that a random son of a node at depth k follows the differential path, and Q^k the probability that a given node at depth k has at least one valid son. At depth k , the average number of explored nodes is related to the average number of explored nodes at depth $k + 1$. When only a few nodes are needed, the average case is not sufficient, and one has to evaluate the cost of finding at least one valid node of depth $k + 1$.

One has the following relations, for $k \in \{0, \dots, n - 1\}$:

$$\begin{cases} A^k = \max\left(\frac{A^{k+1}}{2^{3w} P^k}, \frac{1}{Q^k}\right) \\ A^n = 1 \end{cases}$$

Let K^k be the dimension of the Kernel of the linear system that has to be solved at depth k , and \hat{P}^k the probability that the bitwise system of equations on the values of the mill before and after the nonlinear function has solutions. \hat{P}^k can be computed exhaustively *a priori* for each value of k . which is true provided the free words - *i.e.* without conditions fixing their values, or linking it to another word - are *i.i.d.* A random node at depth k has at least one valid son if the two following conditions happen :

- The bitwise conditions at depth k and $k + 1$ can be fulfilled,
- The remaining freedom degrees can be used to fulfill all the remaining conditions.

The first item takes account of the fact that some conditions might not depend on all the freedom degrees. Therefore, we have :

$$Q^k = \min(2^{-K^k} \hat{P}^k, 2^{3w - N_{COND}^k}),$$

where N_{COND}^k is the total number of conditions that has to be checked on the k -th message insertion. We also have $P^k = 2^{-N_{COND}^k}$, because each condition is supposed to be fulfilled with probability half in the average case, which is true provided the free words - *i.e.* without conditions fixing their values, or linking it to another word - are *i.i.d.* .

Searching a node works as follows : one solves the bitwise system of equations on the values of $M_{16}, M_{17}, M_{18}, \hat{M}_{14}, \dots, \hat{M}_{18}$. The set of message blocks that fulfill this equation system then has to be searched exhaustively to fulfill the other conditions, and to generate nodes at depth $k + 1$. C^k is then the cost of this exhaustive search, and can be computed as the average number of message blocks that fulfill the system of equations. Therefore, we have $C^k = 2^{3w} \hat{P}^k$.

For each node at depth k , the attacker can first check the consistency of the conditions on the mill words at steps k and $k + 1$, which allows him not to search inconsistent nodes. Therefore, we have the following overall complexity :

$$T = O(\max_k(\frac{C^k A^k}{2^{K^k}}))$$

The best path we found has complexity about $2^{11 \times w}$, which is above the security claimed by the designers of **RadioGatún**[4], it is given in Appendix. As a proof of concept, we also provide in Appendix an example of a colliding pair of messages following our differential path for **RadioGatún** with $w = 2$. One can check that the observed complexity confirms the estimated one.

5.3 Breaking the birthday bound

Finding a final collision attack for **RadioGatún** with a computation complexity of 2^{11w} required us to own a computer with a big amount of RAM for a few hours of computation. Yet, the memory and computation cost of the differential path search phase is determined by the H_{max} chosen by the attacker. We conducted tests that tend to show that the search tree is big enough in order to find a collision attack with an overall complexity lower than the birthday bound claimed by the designers⁴. **The problem here is that the memory and computation cost of the differential path search will be too big for nowadays computers, but much lower than the birthday bound.** This

⁴ Note also that the size of the search tree can be increased by considering more complex symmetric differences, such as 0^w , 1^w , $01^{w/2}$ and $10^{w/2}$.

explains why we are now incapable of providing a fully described collision attack for **RadioGatún**. However, we conjecture that applying our techniques with more memory and computation resources naturally leads to a collision attack for **RadioGatún**, breaking the ideal birthday bound.

Conclusion

In this paper, we presented an improved cryptanalysis of **RadioGatún** regarding collision search. Our attack can find collisions with a computation cost of about 2^{11w} and negligible memory, which is by far the best known attack on this proposal.

We also gave arguments that shows that **RadioGatún** might not be a collision resistant hash function. We conjecture that applying our differential path search technique with more constraints will lead to collision attacks on **RadioGatún**.

Appendix A: the differential path

We give here the differential path for the $2^{11 \times w}$ collision attack for **RadioGatún**. For each step, it gives the input value of the internal state after the message insertion, and the output value of the state after the update function.

As the path is 143-block long, we use a hexadecimal notation to describe the differential values of internal states. Each mill value is written as $\sum_{i=0}^{18} \delta M_i 2^i$ where $\delta M_i = 1$ if word i of the mill contains a difference and $\delta M_i = 0$ otherwise. Similarly, we write the belt values as $\sum_{i=0}^{12} \delta B_{i,j} 2^i$. The belt values are given in the order $B_{-,0}, B_{-,1}, B_{-,2}$.

We also give an estimation of the search cost at each step, as computed in section 5. In the column **Nodes**, we give the estimated value of $\log_{2^w}(A^i)$, which is the logarithmic value of the estimated number of nodes the attacker has to search at depth i . In the column **Cost**, we give the estimated value of $\log_{2^w}(\frac{C^i A^i}{2^{-K^i}})$, which is the logarithmic value of the estimated search cost at depth i .

For large values of w , we can approximate the total search cost by the search cost of the most expensive states. Here we have 4 steps with search cost 2^{11w} , therefore we can approximate the collision search cost by :

$$T = 4 \times 2^{11w}.$$

Appendix B: collision for RadioGatún[2]

We give here a collision for the 2-bit version of RadioGatún. One can easily check that it follows the differential path given above. We write the message words using values between 0 and 3, which stand for the possible values of 2-bit words. In the column *Nodes*, we give the number A^i of nodes that have been searched at depth i to find a collision. In the column $\log_4(\text{Nodes})$, we give the logarithm with base 4 of A_i , which can be compared with the theoretic values given by the computation of the path, as $4 = 2^w$.

We can notice some differences between the theoretic cost and the observed cost. Let us recall that the theoretic number of nodes at step i linearly depends on the theoretic number of nodes at step $i + 1$. As a consequence, if at some step i_0 , more nodes have to be searched than expected, it will also affect the number of searched nodes at the previous steps. In our collision, we notice that these differences mainly arise at steps for which only a few nodes are needed, which can be explained as the theoretic number of nodes is computed on average.

To ensure that one has enough starting points, we used a 5-block common prefix.

The common value of the internal state is then :

$$\begin{aligned} \text{belt}[0] &= (0, 0, 2, 1, 2, 0, 3, 0, 2, 1, 1, 1, 3), \\ \text{belt}[1] &= (3, 1, 0, 2, 3, 2, 2, 3, 1, 2, 3, 0, 2), \\ \text{belt}[2] &= (2, 3, 3, 2, 2, 2, 1, 1, 1, 3, 2, 0, 3), \\ \text{mill} &= (2, 0, 2, 2, 1, 0, 1, 0, 3, 1, 3, 3, 2, 2, 3, 3, 0, 3, 3) \end{aligned}$$

Step i	M_0	M_1	<i>Nodes</i>	$\log_4(\text{Nodes})$
