

Fig. 2. VSWR versus frequency plot.

VSWR versus frequency plots of the resonators shown in Fig. 1 are given in Fig. 2. The (1:2) VSWR bandwidth of the microstrip resonator on a wedge-shaped dielectric is 28 percent and that on a stepped dielectric is 25 percent, whereas the bandwidth is 13 percent for an equivalent rectangular resonator. The maximum height for all the resonators was 0.01 m . This indicates that there is considerable improvement of bandwidth over that of a similar rectangular microstrip resonator. It may be mentioned that the feed point was in the same position for all the resonators.

## ACKNOWLEDGMENT

The authors gratefully acknowledge the cooperation extended to them by Telecommunication Research Center, New Delhi and the Radar and Communication Center, I. I. T. Kharagpur for providing HP network analyzer measurement facility.

## Cylindrical-Rectangular Microstrip Antenna

## CLIFFORD M. KROWNE

#### Abstract

Resonant frequencies $f_{r}$ of a cylindrical-rectangular microstrip antenna are theoretically calculated. Comparison is made to $f_{r}$ for a planar rectangular patch antenna, including the simplest planar patch modes having no field variation normal to the patch surface. The validity of using planar antenna patches to characterize microstrip antennas is examined.

## INTRODUCTION

In many applications pertaining to satellites, missiles, spacecraft, and aircraft, conformal microstrip antenna patches are used. Microstrip antenna patches are placed above what may be characterized as a conducting plane with a dielectric substrate separating the patch from the conducting plane [1]. However, often this plane surface is either distorted or the antenna elements are intentionally placed on a curved surface. Thus to determine the correct modal field solution to the electromagnetic cavity problem, which can be used to find the radiation field solution, this curvature should be taken into account. Here this is done for a rectangular patch on a cylindrical surface. The assumption that the conducting patch and the conducting cylinder (ground surface) act as electric walls, and that the open cavity ends act as magnetic walls is applied to the analysis for obtaining the fields and associated modal resonant frequencies [4]. This assumption should be particularly valid when using these fields for determining the radiation pattern for the limiting case of thin cavities ( $h \ll a$ ) which are utilized for most microstrip antenna applications. All of the analysis for simplicity also assumes that the permittivity $\epsilon$ and permeability $\mu$ are constant (homogeneous medium filling cavity) and real (no dielectric losses).

The eigenvalue equations for resonant frequencies $f_{r}$ are numerically solved and examined over a range of dielectric substrate thicknesses $h$. These resonant frequencies $f_{r C}$ for the curved cylindrical-rectangular antenna, representing a distortion of a planar rectangular microstrip antenna, are compared to resonant frequencies $f_{r R}$ of the planar patch antenna in order to assess the validity of the commonly used assumption that conformally mounted microstrip antennas may be treated as planar. The results demonstrate that this assumption is good for $h$ that is small compared to the surface curvature $a$, and that it is excellent when considering excitation of the antenna with no spatial field variation normal to the surface.

## THEORY

The geometry of the cavity is shown in Fig. 1 where Fig. 1(a) is a perspective drawing of a conducting patch on a cylindrical surface, Fig. l(b) is a cross section through the patch and normal to the $z$-axis, and Fig. 1(c) shows the cavity isolated by itself in cross section. The conducting patch and grounded cylindrical surface are treated as electric walls and the magnetic walls of the cavity are defined by dropping perpendiculars from the patch

edges to the cylindrical conducting surface. The electric walls are located at $\rho=a$ and $\rho=a+h$ where $h$ is the dielectric substrate thickness, and the magnetic walls are located at $z=0,-2 b$ and $\phi=0,2 \theta$.

Below follows the derivation of the fields and eigenfrequencies for the transverse electric ( $\mathrm{TE}_{z}$ ) modes, transverse magnetic $\left(\mathrm{TM}_{z}\right)$ modes, and the limiting case modal results where the radial thickness $h$ becomes vanishingly small.

The $\vec{E}$ and $\vec{H}$ phasor field solutions to Maxwell's harmonic equations in a source free cavity can be written as [3]

$$
\begin{align*}
& \vec{E}=-\nabla \times \vec{F}-j \omega \mu \vec{A}-\frac{j}{\omega \epsilon} \nabla(\nabla \cdot \vec{A})  \tag{1a}\\
& \vec{H}=\nabla \times \vec{A}-j \omega \epsilon \vec{F}-\frac{j}{\omega \mu} \nabla(\nabla \cdot \vec{F}),
\end{align*}
$$

where $\mu$ is the permeability and $\epsilon$ is the permittivity. $\vec{A}$ and $\vec{F}$ are arbitrary vector phasor potentials which satisfy the Helmholtz equations

$$
\begin{align*}
& \nabla^{2} \vec{F}+k^{2} \vec{F}=0  \tag{2a}\\
& \nabla^{2} \vec{A}+k^{2} \vec{A}=0 \tag{2b}
\end{align*}
$$

where

$$
\begin{equation*}
k^{2}=\omega^{2} \mu \epsilon \tag{2c}
\end{equation*}
$$

The TE to $z$ field solution is constructed by choosing $\vec{A}=0$ and $\vec{F}=\hat{u}_{z} \psi$ where $\hat{u}_{z}$ is the unit constant vector in the axial $z$-direction and $\psi$ is a scalar function. The fields are known once $\psi$ has been determined subject to the boundary conditions (BC) on $\vec{E}$ and $\vec{H}$ (Dirichlet conditions).

Using (1) and (2) and applying magnetic wall BC's, $\psi$ can be
expressed as

$$
\begin{equation*}
\psi_{m l i}=A_{m l i} R_{v}\left(k_{m i} \rho\right) \sin \left(\frac{m \pi}{2 \theta} \phi\right) \cos \left(\frac{l \pi}{2 b} z\right) \tag{3}
\end{equation*}
$$

Here $A_{m l i}$ is a constant for the mlith mode, $m=1,2, \cdots$, and $l=$ $0,1, \cdots, v=m \pi / 2 \theta$, and $R_{v}$ satisfies Bessel's equation [4]-[6]

$$
\begin{equation*}
p \frac{d}{d p}\left[p \frac{d R_{v}(p)}{d p}\right]+\left[p^{2}-v^{2}\right] R_{v}(p)=0 \tag{4}
\end{equation*}
$$

with $p=k_{m i} \rho$. Solutions to (4) are Bessel functions of the first kind $J_{v}$ and of the second kind $N_{v}$ which are linearly independent. Thus

$$
\begin{equation*}
R_{v}(p)=c_{1} J_{v}(p)+c_{2} N_{v}(p) \tag{5}
\end{equation*}
$$

If the special case $\theta=\pi / 2 q$ occurs where $q$ is an integer, then $v=m q$ is an integer, and $J_{v}$ and $N_{v}$ should be used to construct $R_{v}(p)$, otherwise $J_{-v}$ may be used in place of $N_{v}$ if $v \neq$ integer. Subjecting (5) to the electric wall BC's requires

$$
\begin{equation*}
\left.R_{v}^{\prime}(p)\right|_{\rho=a, a+h}=0 \tag{6}
\end{equation*}
$$

or

$$
\begin{align*}
& c_{1} J_{v}^{\prime}\left(k_{m i} a\right)+c_{2} N_{v}^{\prime}\left(k_{m i} a\right)=0  \tag{7a}\\
& c_{1} J_{v}^{\prime}\left(k_{m i}[a+h]\right)+c_{2} N_{v}^{\prime}\left(k_{m i}[a+h]\right)=0 \tag{7~b}
\end{align*}
$$

where the primes denote differentiation with respect to the argument. For there to be a nontrivial solution to (7), two linear equations in two unknowns $c_{1}$ and $c_{2}$, the determinant of the matrix formed by the $c_{i}$ coefficients must be zero:

$$
\begin{align*}
& J_{v}^{\prime}\left(k_{m i} a\right) N_{v}^{\prime}\left(k_{m i}[a+h]\right) \\
& \quad-J_{v}^{\prime}\left(k_{m i}[a+h]\right) N_{v}^{\prime}\left(k_{m i} a\right)=0 \tag{8}
\end{align*}
$$

Equation (8) produces an infinite denumerable set of $k_{m i}$ eigenvalues with $i=1,2, \cdots$. Arbitrarily set $c_{2}=1$ and determine $c_{1}$ from (7a):

$$
\begin{equation*}
c_{1}=c_{m i}=-N_{v}^{\prime}\left(k_{m i} a\right) / J_{v}^{\prime}\left(k_{m i} a\right) \tag{9}
\end{equation*}
$$

The field solution is found from (3) and (4), [7] :

$$
\begin{align*}
& E_{\rho}=-\frac{1}{\rho} A_{m l i}\left(\frac{m \pi}{2 \theta}\right) R_{v}\left(k_{m i} \rho\right) \cos \left(\frac{m \pi}{2 \theta} \phi\right) \cos \left(\frac{l \pi}{2 b} z\right)  \tag{10a}\\
& E_{\phi}=A_{m l i} k_{m i} R_{v}^{\prime}\left(k_{m i} \rho\right) \sin \left(\frac{m \pi}{2 \theta} \phi\right) \cos \left(\frac{l \pi}{2 b} z\right) ; E_{z}=0 \tag{10b}
\end{align*}
$$

$$
\begin{align*}
H_{\rho}= & \frac{j}{\omega \mu} A_{m l i} k_{m i}\left(\frac{l \pi}{2 b}\right) R_{v}\left(k_{m i} \rho\right) \\
& \cdot \sin \left(\frac{m \pi}{2 \theta} \phi\right) \sin \left(\frac{l \pi}{2 b} z\right) \tag{10c}
\end{align*}
$$

$$
\begin{align*}
H_{\phi}= & \frac{j}{\omega \mu \rho} A_{m l i}\left(\frac{m l \pi^{2}}{4 \theta b}\right) R_{v}\left(k_{m i} \rho\right) \\
& \cdot \cos \left(\frac{m \pi}{2 \theta} \phi\right) \sin \left(\frac{l \pi}{2 b} z\right) \tag{10d}
\end{align*}
$$

$$
\begin{equation*}
H_{z}=\frac{-j}{\omega \mu} A_{m l i}\left(k_{m i}\right)^{2} R_{v}\left(k_{m i} \rho\right) \sin \left(\frac{m \pi}{2 \theta} \phi\right) \cos \left(\frac{l \pi}{2 b} z\right) \tag{10e}
\end{equation*}
$$

Cavity resonant frequencies $f_{r}$ for each $m l i$ mode are found from the equation

$$
\begin{equation*}
k^{2}=p^{2}+\left(\frac{l \pi}{2 b}\right)^{2} \tag{11}
\end{equation*}
$$

and (2c):

$$
\begin{equation*}
\left(f_{r}\right)_{m l i}=\frac{1}{2 \pi \sqrt{\epsilon \mu}} \sqrt{\left(k_{m i}\right)^{2}+\left(\frac{l \pi}{2 b}\right)^{2}} \tag{12}
\end{equation*}
$$

The TM to $z$ field solution is constructed by choosing $\vec{F}=0$ and $\vec{A}=\hat{u}_{z} \psi$. Using (1) and (2) and applying magnetic wall BC's, $\psi$ can be written as

$$
\begin{equation*}
\psi_{m l i}=B_{m l i} R_{v}\left(k_{m i} p\right) \cos \left(\frac{m \pi}{2 \theta} \phi\right) \sin \left(\frac{l \pi}{2 b} z\right) \tag{13}
\end{equation*}
$$

Here $B_{m l i}$ is a constant for the $m l i t h$ mode, $m=0,1, \cdots$, and $l=$ $1,2, \cdots$, and $R_{v}$ satisfies (4) with $p=k_{m i} \rho$. Equation (5) still applies. Imposing the electric wall BC 's on (5) requires

$$
\begin{equation*}
\left.R_{v}(p)\right|_{p=a, a+h}=0 \tag{14}
\end{equation*}
$$

or

$$
\begin{align*}
& c_{1} J_{v}\left(k_{m i} a\right)+c_{2} N_{v}\left(k_{m i} a\right)=0  \tag{15a}\\
& c_{1} J_{v}\left(k_{m i}[a+h]\right)+c_{2} N_{v}\left(k_{m i}[a+h]\right)=0 \tag{15b}
\end{align*}
$$

In order that $c_{1}, c_{2} \neq 0$,

$$
\begin{align*}
& J_{v}\left(k_{m i} a\right) N_{v}\left(k_{m i}[a+h]\right) \\
& \quad-J_{v}\left(k_{m i}[a+h]\right) N_{v}\left(k_{m i} a\right)=0 \tag{16}
\end{align*}
$$

which is obtained from (15). Equation (16) produces an infinite denumerable set of $k_{m i}$ eigenvalues with $i=1,2, \cdots$. Arbitrarily set $c_{2}=1$ and find $c_{1}$ from (15a):

$$
\begin{equation*}
c_{1}=c_{m i}=-N_{v}\left(k_{m i} a\right) / J_{v}\left(k_{m i} a\right) \tag{17}
\end{equation*}
$$

The field solution is obtained from (4) and (13)

$$
\begin{align*}
E_{\rho}= & \frac{-j}{\omega \epsilon} B_{m l i} k_{m i}\left(\frac{l \pi}{2 b}\right) R_{v}{ }^{\prime}\left(k_{m i} \rho\right) \cos \left(\frac{m \pi}{2 \theta} \phi\right) \cos \left(\frac{l \pi}{2 b} z\right)  \tag{18a}\\
E_{\phi}= & \frac{j}{\omega \epsilon \rho} B_{m l i}\left(\frac{m l \pi^{2}}{4 \theta b}\right) R_{v}\left(k_{m i} \rho\right) \\
& \cdot \sin \left(\frac{m \pi}{2 \theta} \phi\right) \cos \left(\frac{l \pi}{2 b} z\right)  \tag{18b}\\
E_{z}= & \frac{-j}{\omega \epsilon} B_{m l i} k_{m i}^{2} R_{v}\left(k_{m i} \rho\right) \cos \left(\frac{m \pi}{2 \theta} \phi\right) \sin \left(\frac{l \pi}{2 b} z\right)  \tag{18c}\\
H_{\rho}= & -\frac{1}{\rho} B_{m l i}\left(\frac{m \pi}{2 \theta}\right) R_{v}\left(k_{m i} \rho\right) \sin \left(\frac{m \pi}{2 \theta} \phi\right) \sin \left(\frac{l \pi}{2 b} z\right)  \tag{18~d}\\
H_{\phi}= & -B_{m l i} k_{m i} R_{v}^{\prime}\left(k_{m i} \rho\right) \cos \left(\frac{m \pi}{2 \theta} \phi\right) \sin \left(\frac{l \pi}{2 b} z\right) ; H_{z}=0 . \tag{18e}
\end{align*}
$$

Cavity resonant frequencies are found from (12).
Inspection of the cavity field solutions in (10) for the TE to $z$ modes and (18) for the TM to $z$ modes shows that the complex power density (Poynting vector) $\vec{P}=\vec{E} \times \vec{H}^{*}$ is purely imaginary. Thus the time average power flow $P_{\mathrm{av}}$ out of the walls is zero. This result is expected, however, some comments are in order. For applications where the cavity is used to model a microstrip antenna radiator, the following procedure can be used to obtain radiation. First the cavity field solutions are obtained as it has been done here. Next the field solutions are used as Huygens sources at the open wall (formed by perpendiculars dropped from the antenna patch edges to the conducting surface below) boundaries. These wall fields allow for actual radiation (with the dropping at this stage of the magnetic wall conditions). Finally the radiation problem may be simplified by using the equivalence principle to express the boundary fields alternatively as radiating electric current $\vec{J}=\hat{n} \times \vec{H}_{b}$ and magnetic current $\vec{M}=\vec{E}_{b} \times \hat{n}$ sources ( $b$ subscript denotes boundary and $\hat{n}$ is normal to wall which points outward from cavity).

Consider the limiting case of the cavity where $h \rightarrow 0$. First examine the $\mathrm{TM}_{z}$ modal field solution. Equation (16) can be written as

$$
\begin{equation*}
E(p)=J_{v}(p) N_{v}(p+\Delta p)-J_{v}(p+\Delta p) N_{v}(p)=0 \tag{19}
\end{equation*}
$$

by letting $p=a k_{m i}$ and $\Delta p=h k_{m i}$. Using Taylor series expansions of the Bessel functions about $p$ and retaining only first order terms in $\Delta p$, the left side of (19) can be simplified to read

$$
\begin{align*}
E(p) & =\left[J_{v}(p) N_{v}^{\prime}(p)-J_{v}(p) N_{v}(p)\right] \Delta p  \tag{20a}\\
& =\frac{2}{\pi p} \Delta p \tag{20b}
\end{align*}
$$

Equation (20b) was obtained from (20a) by identifying the term in brackets as the Wronskian of $J_{v}$ and $N_{v}$. Combining (19) and (20) require that $p \rightarrow \infty$. That is, a finite $k_{m i}$ solution to the radial Bessel equation cannot be found for the limiting case of $\Delta p / p \rightarrow$ 0 or $h / a \rightarrow 0$. Thus for physical reasons the TM to $z$ field solution would not be used to obtain the general field solution. For completeness, however, the TM to $z$ field solution will be given for this limiting case. Referring to (17) and (18), and setting $\beta=l \pi / 2 b$

$$
\begin{align*}
& E_{\rho}=\frac{j}{\omega \epsilon} B_{m l i} l^{\prime} \beta \cos (v \phi) \cos (\beta z) ; \quad E_{\phi}=E_{z}=0  \tag{21a}\\
& H_{\phi}=B_{m l i} \cos (v \phi) \sin (\beta z) ; \quad H_{\rho}=H_{z}=0 \tag{21~b}
\end{align*}
$$

where $B_{m l i}$ is related to $B_{m l i}$ by

$$
\begin{equation*}
B_{m l i}^{\prime}=-k_{m i} B_{m l i} R_{v}^{\prime}\left(k_{m i} a\right) \tag{22}
\end{equation*}
$$

Next examine the $\mathrm{TE}_{z}$ modal field case. Equation (8) can be expressed as

$$
\begin{equation*}
D(p)=J_{v}^{\prime}(p) N_{v}^{\prime}(p+\Delta p)-J_{v}^{\prime}(p+\Delta p) N_{v}^{\prime}(p)=0 \tag{23}
\end{equation*}
$$

Following the same procedure in going from (19) to (20a), the left side of (23) becomes

$$
\begin{equation*}
D(p)=\left[J_{v}^{\prime}(p) N_{v}^{\prime \prime}(p)-J_{v}^{\prime \prime}(p) N_{v}^{\prime}(p)\right] \Delta p \tag{24}
\end{equation*}
$$

Utilizing (4) to eliminate $J_{U}{ }^{\prime \prime}$ and $N_{v}{ }^{\prime \prime}$ in (24) transforms $D(p)$ into

$$
\begin{equation*}
D(p)=\frac{v^{2}-p^{2}}{p^{2}}\left[J_{v}^{\prime}(p) N_{v}(p)-J_{v}(p) N_{v}^{\prime}(p)\right] \Delta p \tag{25}
\end{equation*}
$$

which by (20) becomes

$$
\begin{equation*}
D(p)=\frac{2}{\pi} \frac{p^{2}-v^{2}}{p^{3}} \Delta p \tag{26}
\end{equation*}
$$

From (23) $D(p)=0$. Imposing this constraint on (26) produces solutions $p= \pm v= \pm m \pi / 2$, if $p \neq 0$. Since $m$ is an integer on the domain $(-\infty, \infty), p=v$ is a complete solution statement. For $p=0$, application of L'Hôpital's rule shows that $\mathrm{D}(0)=0$ and (26) is automatically satisfied. Since $p=0$ corresponds to $m=0$, $p=v$ for all $m$ on the integer domain.

The TE to $z$ field solution for the limiting case $\Delta p / p \rightarrow 0$ or $h / a \rightarrow 0$, referring to (9) and (10), is given by

$$
\begin{align*}
& E_{\rho}=-\frac{1}{a} A_{m} l^{\prime} \cos (v \phi) \cos (\beta z) ; \quad E_{\phi}=E_{z}=0  \tag{27a}\\
& H_{\phi}=\frac{j}{\omega \mu a} A_{m l^{\prime} \beta \cos (v \phi) \sin (\beta z) ; \quad H_{\rho}=0}^{H_{z}}=\frac{-j}{\omega \mu a^{2}} A_{m l} l^{\prime} v \sin (v \phi) \cos (\beta z) \tag{27b}
\end{align*}
$$

Here we have used $k_{m i}=m \pi / 2 \theta a, c_{m i}=c_{m}$, and

$$
A_{m l}{ }^{\prime}=A_{m i i} v R_{v}(v)
$$

Resonant frequencies using (12) are given by

$$
\begin{equation*}
\left(f_{r}\right)_{m l}=\frac{1}{2 \pi \sqrt{\epsilon \mu}} \sqrt{\left(\frac{m \pi}{2 \theta a}\right)^{2}+\left(\frac{l \pi}{2 b}\right)^{2}} \tag{29}
\end{equation*}
$$

The modal $\left(f_{r}\right)_{m l}$ are the same form as found for a planar rectangular cavity with $k_{x}=n \pi / h=0$ (i.e., $n=0$ giving no field variation in the $x$ coordinate direction) for the TE to $z$ modes. This $k_{x}$ choice produces the same planar rectangular field solution functional form as we found in (27), the correspondence being obvious if the limit $a \rightarrow \infty$ is applied and the identifications $a \phi \rightarrow y, 2 \theta a \rightarrow 2 c$, and $\rho \rightarrow x$ made ( $2 c$ is the extent in the rectangular coordinate $y$ direction).

It is interesting to note that the correct field solutions for thin cavities seen in (27) are obtained by solving the electromagnetic problem subject to the constraint that all variation with $\rho$ goes to zero; i.e., $\partial / \partial \rho \rightarrow 0$. The procedure of taking $\partial / \partial n \rightarrow 0$ where $\hat{n}$ is a unit vector normal to the conformal conducting surface is often applied to microstrip antenna problems and leads to good agreement between theory and experiment [4].

## NUMERICAL RESULTS

For illustrative purposes the dimensions of the cylindricalrectangular cavity will be chosen to be $a=2 \mathrm{~cm}, b=1 \mathrm{~cm}, \theta=$ $24^{\circ}$. The filling relative dielectric constant is set to $\epsilon_{r}=5.0$. From the $k_{m i}$ eigenvalue solutions as determined by (16), the $\mathrm{TM}_{m l i}$ cylindrical-rectangular frequency eigenvalues $f_{r} C$ are found using (12) and are shown in Table I for $m=0-4, i=1-$ 5 , and $l=1$. The $\mathrm{TE}_{m l i}$ frequency eigenvalues $f_{r C}$ are found in a similar manner using (8) and (12) and are given in Table II for $m=1-5, i=1-5$, and $l=0$. Both tables provide $f_{r C}$ for $h / a=$ $0.1,0.25,0.50,0.75$, and 1.00 .

The effect of curvature on a patch antenna's $f_{r}$ can be ascertained by considering the inner radial surface of the cylindricalrectangular patch antenna to be equal to the patch area of a planar rectangular patch antenna. The radial thickness $h$ is set equal to the planar patch antenna's dielectric substrate thickness. The rectangular dimensions are therefore $x=h, y=2 \theta a$, and $z=2 b$. Tables III and V give $f_{r R}$ for the rectangular patch for, respectively, $h / a=0.1$ and 1.0 ,

$$
\begin{equation*}
f_{r R}=6.703563 \sqrt{\left(\frac{m}{g}\right)^{2}+(5 i)^{2}+\left(\frac{l}{2}\right)^{2}} \tag{30}
\end{equation*}
$$

with $g=1.675516$. Equation (30) gives $f_{r R}$ in GHz . For nontrivial $\mathrm{TM}_{z}$ rectangular patch field solutions $i=1,2, \cdots, m=0,1$, $\cdots$, and $l=1,2, \cdots$. These eigennumbers correspond exactly to those in Table I. Comparison of the $f_{r C}$ and $f_{r R}$ eigenvalues in Table I and Table III for $h / a=0.1$ shows the largest difference being 0.87 percent. As $i$ increases the difference is reduced, but as $m$ increases, the difference is increased. This same $f_{r}$ behavior with varying $i$ and $m$ occurs for $h / a=1.0$ in Tables I and V with the largest difference being 4.4 percent. For the $\mathrm{TE}_{z}$ rectangular patch fields, having nontrivial solutions at $i=0,1, \cdots, m=1,2$, $\cdots, l=0,1, \cdots$, the difference is about an order of magnitude larger. Tables II and VII for $h / a=0.1$ demonstrate that the largest $f_{r}$ difference is 5.2 percent, and Tables II and IX for $h / a=1.0$ that this value is enlarged to 79.2 percent.

The $\mathrm{TE}_{m i 0}$ cylindrical-rectangular eigenvalues correspond to the two-dimensional resonating modes of the planar rectangular patch antenna which have no field variation normal to the patch surface. These modes are often utilized in planar microstrip antenna analysis, and have $f_{r R}$ and $f_{r C}$ differing by less than 5 percent for $h / a=0.1$.

Tables IV, VI, VIII, and X provide $f_{r R}$ calculated using (30) with $g=1.759292(h / a=0.1)$ or $2.513274(h / a=1.0)$. Using these $g$ values means that an equivalent rectangular cavity (to the cylindrical-rectangular cavity) has been found because an average radius $r=a+h / 2$ has been chosen for one side of the cylindrical-rectangular cavity. One might expect $f_{r R}$ to be extremely close to $f_{r C}$. Agreement is within 0.011 percent for

## CONCLUSION

The field distribution within a cylindrical-rectangular micro strip antenna has been determined using a cavity modal mode
for the $\mathrm{TE}_{z}$ and $\mathrm{TM}_{z}$ modes. Resonant frequency eigenvalue equations for these modes were used to calculate the eigenfrequencies $\left(f_{r}\right)_{m l l}$ for some of the lowest order modes.

Comparison of $\left(f_{r}\right)_{m l i}$ for the cylindrical-rectangular case $f_{r C}$, and $\left(f_{r}\right)_{m i i}$ for a planar rectangular microstrip antenna $f_{r R}$, allows an assessment of the effect curvature has on resonant frequency. Numerical results show that curvature changes $f_{r}$ by less than about 5 percent for a substrate dielectric thickness equal to one tenth of the radius of curvature. The exact effect of curvature on $f_{r}$ will be dependent on the particular choice of antenna parameters, but the results found in this communication should be a useful guide when designing conformal microstrip antennas.

An equivalent rectangular microstrip planar antenna to the cylindrical-rectangular microstrip antenna had been defined. Agreement between $f_{r R}$ and $f_{r C}$ is better than 0.035 percent.

## Combined $E$ - and $H$-Plane Phase Centers of Antenna Feeds

PER-SIMON KILDAL, MEMBER, IEEE

#### Abstract

The feed efficiency, a first approximation to the aperture efficiency of a paraboloid or a conventional Cassegrain antenna, is used to define uniquely a combined $E$ - and $H$-plane phase center of the feed pattern. A formula for numerical calculation of the combined phase center is presented, as well as theoretical results of the feed position tolerances and the efficiency loss due to differences in the principal plane phase patterns.

## I. INTRODUCTION

For designing a reflector antenna system, it is important to know the feed phase center since it determines the location of the feed relative to the focal point of the reflector. Too large a deviation between the two points causes severe defocusing of the secondary radiation pattern. The phase center of an antenna is ideally the center of a portion of a sphere on which the radiation field of the antenna has a constant phase [1], [2]. However,

Manuscript received March 29, 1982; revised June 29, 1982. This work was supported by the Norwegian Council for Scientific and Industrial Research.

The author is with Electronics Research Laboratory, The Norwegian Institute of Technology, O. S. Bragstads Plass 6, N-7034, TrondheimNTH, Norway.
in many cases the phase patterns are oscillatory, so that an ideal phase center does not exist. A more practical definition of the phase center has been given by Rusch and Potter [3, p. 147], as the center of the "best" nearly constant-phase spheres in a least squares sense. Although the definition given by Rusch and Potter is general enough to obtain a combined $E$ - and $H$-plane phase center within a given solid angle, practical formulas were given only for numerical calculation of a phase center in a single principal plane. This communication presents a practical formula for calculation of a combined $E$ - and $H$-plane phase center, and is therefore an important supplement to Rusch and Potter's work.

The results in this communication are obtained by a slightly different general definition. The feed for a paraboloid or a conventional Cassegrain reflector system is located in such a way that the phase reference point of the feed pattern coincides with the focal point of the reflector system. The phase center is then defined as the phase reference point which maximizes the feed efficiency, the latter being the first-order approximation to the aperture efficiency of the paraboloid or the Cassegrain system. This definition is equivalent to that of Rusch and Potter [3] for a proper choice of weighting functions in the least-squares calculation. The resulting calculation formula for the overall phase center is therefore also very similar to the formula for the principal plane phase center. The tolerances on the phase-center position (corresponding to the axial tolerances on the position of the feed in the reflector antenna) and the efficiency losses due to differences in the principal plane phase patterns are also discussed.

## II. MATHEMATICAL FORMULATION

We assume a far-field feed pattern, which is linearly polarized and determined by its $E$-plane pattern $A(\psi)$ and $H$-plane pattern $C(\psi)$, according to

$$
\begin{equation*}
\vec{E}(\psi, \xi, \rho)=\left[A(\psi) \sin \xi \vec{a}_{\psi}+C(\psi) \cos \xi \vec{a}_{\xi}\right] \frac{1}{\rho} e^{-j k \rho} \tag{1}
\end{equation*}
$$

where $\vec{a}_{\psi}$ and $\vec{a}_{\xi}$ are unit vectors in the direction of increasing polar angle $\psi$ and azimuth angle $\xi$, respectively. Equation (1) assumes that $A(\psi)$ and $C(\psi)$ are given with respect to the same phase reference point 0 , positioned at $z=0$ and that $\rho$ is the distance from 0 to the far-field point (Fig. 1). $A(\psi)$ and $C(\psi)$ can be transformed to a new phase reference point $P$ positioned at $z=\delta$, by the relations

$$
\begin{equation*}
A_{\delta}(\psi)=A(\psi) e^{-j k \delta \cos \psi}, \quad C_{\delta}(\psi)=C(\psi) e^{-j k \delta \cos \psi} . \tag{2}
\end{equation*}
$$

Then the far field is given by (1) if $A_{\delta}(\psi)$ and $C_{\delta}(\psi)$ replace $A(\psi)$ and $C(\psi)$, respectively, and if $\rho$ now is the distance from $P$ to the far-field point.

We consider the feed to be located in the primary focus of a paraboloidal antenna or in the secondary focus of a conventional Cassegrain antenna (hyperboloid-paraboloid configuration) in such a way that the point $P$ coincides with the proper focal point. Then the first approximation to the aperture efficiency of the reflector antenna, excluding the effects of blockage and subreflector diffraction in the Cassegrain, is

$$
\begin{equation*}
\eta_{f}=\cot ^{2}\left(\frac{\psi_{0}}{2}\right) \frac{\left|\int_{0}^{\psi_{o}}\left[A_{\delta}(\psi)+C_{\delta}(\psi)\right] \tan \frac{\psi}{2} d \psi\right|^{2}}{\int_{0}^{\pi}\left[\left|A_{\delta}(\psi)\right|^{2}+\left|C_{\delta}(\psi)\right|^{2}\right] \sin \psi d \psi} \tag{3}
\end{equation*}
$$
