# Abstract

An emerging concept in cell signaling is the natural role of reactive oxygen species, such as hydrogen peroxide ( $H_2O_2$ ), as beneficial messengers in redox signaling pathways. Despite growing evidence, the nature of  $H_2O_2$  signaling is confounded by difficulties in tracking it in living systems both spatially and temporally at low concentrations. Here we develop an array of fluorescent single-walled carbon nanotubes that can selectively record in real time the discrete, stochastic quenching events that occur as  $H_2O_2$  molecules are emitted from individual human epidermal carcinoma cells that are stimulated by epidermal growth factor (EGF). We show mathematically that such arrays can distinguish between molecules originating locally on the cell membrane from other contributions. We find that EGF induces 2 nmol  $H_2O_2$  locally over a period of 50 min. This platform promises a new approach to understanding the signaling of reactive oxygen species at the cellular level.

Historically,  $H_2O_2$  is thought to have only a deleterious role in cell biology as a toxic metabolic waste product, or as part of the immune respiratory burst in response to microbial invasion<sup>1</sup>. New findings suggest that it is a messenger in normal signaling pathways:  $H_2O_2$  is produced when cells are stimulated with various growth factors, cytokines and other signaling molecules, and is known to activate specific downstream targets<sup>2</sup>. Understanding the role of  $H_2O_2$  and other reactive oxygen species (ROS) is hampered by their low concentration and short lifetime. This has inspired innovative detection probes<sup>3–7</sup> but many

still cannot map the entire transient signaling response on a single molecule level over its duration with spatial resolution<sup>6-8</sup>.

Our laboratory has pioneered the use of single-walled carbon nanotubes (SWNT) as fluorescent optical sensors for analytical detection from within living cells and tissues. Recent measurements by others<sup>9</sup> and our own laboratory<sup>10–11</sup> have extended the detection limit down to the single-molecule level by analyzing the stochastic quenching of excitons as molecules adsorb to the SWNT surface. Here we develop an array of such single-molecule sensors selective for  $H_2O_2$  that can image the signaling flux emanating from single living A431 human epidermal carcinoma cells in real time with spatial precision. These arrays can resolve several questions about  $H_2O_2$  generation upon growth factor stimulation, including the membrane activity compared to the other contributions, its spatial distribution, and through inhibition experiments, the chemical mechanism of the signal response.

A431 cells over-express the epidermal growth factor receptor (EGFR), which is one of four transmembrane growth factor receptor proteins<sup>12</sup>. EGFR is a 170-kDa glycoprotein with an extracellular receptor domain, a transmembrane domain and an intracellular domain<sup>13</sup>. The extracellular domain is divided into four subdomains: I, II, III and IV, with I and III participating in binding<sup>14</sup> (Fig. 1a). A431 cells express<sup>15</sup> approximately 10<sup>6</sup> EGFRs per cell while only  $4 \times 10^4$  to  $10^5$  receptors occur per non-cancerous cell<sup>16</sup>. Epidermal growth factor<sup>16</sup> (EGF) - a single polypeptide chain of 53 amino acid residues held together by three disulfide bonds in cysteine - stimulates cell growth, proliferation and differentiation upon binding to EGFR (Fig. 1a)<sup>16</sup>. Upon activation by EGR, EGFR undergoes dimerization at the cell membrane<sup>13</sup> and an H<sub>2</sub>O<sub>2</sub> signal is generated<sup>17</sup>. The chemical origin of this H<sub>2</sub>O<sub>2</sub> signal and its relationship to the remaining cascade is largely unknown.

Recent progress in fluorescent probes has confirmed the generation of  $H_2O_2$  signal in A431 in response to EGF, and has also identified a similar mechanism in neuronal cell signaling<sup>6–8</sup>. Our work differs in its single-molecule detection limit, and infinite photoemission lifetime allows continuous detection over the entire response in real time. The array of single-molecule sensors can mathematically discriminate signals generated at the membrane (near-field) from those originating from the cell interior (far field), an important property for cell analysis. Mapping shown before and after EGF stimulation of A431 cells and NIH-3T3 murine fibroblast cells in real time, informs the chemical mechanism of the signaling cascade.

# Selective SWNT sensors detect and map H<sub>2</sub>O<sub>2</sub> efflux spatially

The SWNT array is ideally suited for imaging  $H_2O_2$  fluxes from living cells because  $H_2O_2$  binds with a forward (77.8 M<sup>-1</sup>s<sup>-1</sup>) and reverse (0.0006 s<sup>-1</sup>) rate constant<sup>10</sup> that allows sensitive detection and that excludes other ROS with long lifetimes. Previously<sup>10</sup>, we showed that Hidden Markov Modeling can determine forward and reverse rate constants from single-molecule adsorbates on SWNT. Figure 1c is the application of the technique to several species of interest in this work. Except for nitric oxide (NO),  $H_2O_2$  has the largest forward rate constant of all, meaning its capture probability is the highest. Protons (H<sup>+</sup>) can be detected with a forward rate of 8.1 M<sup>-1</sup>s<sup>-1</sup>, but their reverse rate constant is high (0.0011)

 $s^{-1}$ ) such that, at physiological pH (7.4) their contribution is negligible. Likewise, interfering nitrites and nitrates have small rate constants and there is no contribution from components of cell media. NO has a high forward binding rate of  $80.0 \text{ M}^{-1}\text{s}^{-1}$ , however its reverse rate is almost immeasurable under these experimental conditions. This means that its presence can be easily distinguished, as it irreversibly deactivates the SWNT single-molecule sensor that it encounters. Excluding such signals can subtract the contribution of NO, however no such events were measured in this work, indicating NO was not detected. In addition, our sensor is inert to singlet oxygen ( ${}^{1}O_{2}$ ) and superoxide ( $O_{2}^{\bullet}$ <sup>-</sup>) (Fig. 1c).

Our single-molecule detector array is embedded in a thin film, with 2 nm roughness (Fig. S1) and open porosity (average pore size = 30 nm) towards the SWNT. Therefore, only the most stable species emanating from the cell are detected. For example,  ${}^{1}O_{2}$ ,  $O_{2}^{\bullet}$  and OH-have lifetimes of 4  $\mu$ s<sup>18</sup>, 1  $\mu$ s and 1 ns respectively<sup>19</sup>. These species are not likely to diffuse into the film and interfere with SWNT. The selectivity of our film, together with the diffusion calculation, result in an array of sensors specifically designed to detect single H<sub>2</sub>O<sub>2</sub> molecules in real time. We note that this does not limit the approach exclusively to H<sub>2</sub>O<sub>2</sub>. We recently showed that by varying the chemistry of the encapsulating matrix<sup>20</sup>, or by utilizing multiple orthogonal optical responses (multi-modality)<sup>11</sup>, it is possible to selectively detect virtually any single-molecule analyte emanating from the cell. Future work will underscore this point.

The detection limit for this class of single-molecule sensor is exchanged for observation time (Fig. S2). For instance, an array of SWNT can detect a concentration of 1  $\mu$ M (10  $\mu$ M) provided an acquisition time of 14 min (3 min).

When no cells are plated onto the collagen-SWNT array, the result is a photoluminescence intensity of constant root mean square value. A Hidden Markov algorithm finds no quenched states outside of the noise floor as expected. SWNT sensors near or underneath plated A431 cells show discrete quenching transitions of the type observed previously<sup>9–10</sup>. Stepwise quenching and dequenching reactions are clearly observable (Fig. 1e), compared to the control experiment (Fig. 1d). Because the collagen-SWNT array has such high selectivity towards  $H_2O_2$ , we assign this flux as single  $H_2O_2$  originating from cellular metabolic activity<sup>2</sup> and also non-specific receptor-ligand binding<sup>21</sup>. To further support this assignment, we use manganese oxide (MnO<sub>2</sub>) to selectively catalyze the decomposition of  $H_2O_2$  around the A431 cells both with and without EGF stimulation, to show that the quenching reverses significantly (Fig. S3) as  $H_2O_2$  is depleted.

Hidden Markov algorithm was applied to each SWNT signal in the array, yielding the spatial and temporal detection of single molecules emitted from the cell in real time. The typical observation time was 3000s and Figure 2a–d describes the spatial distribution of detection frequencies for both live (Fig. 2a, b) and fixed (Fig. 2c,d) A431 cells after the addition of EGF (500ng/mL) at t = 0 using a Matlab program written by us. Each sensor was binned according to its number of quenching transitions within the 3000s observation window into one of 16 color categories between 0 and 150 counts for Fig 2a–d and between 2 and 70 counts for Fig 2e. Note that the control array, exposed to 10  $\mu$ M H<sub>2</sub>O<sub>2</sub> in the absence of

cells, demonstrates a spatially random distribution of transition frequencies (Fig. 2e). However, when instead A431 cells are present, the frequency distribution possesses a sharp mode invariably confined to the region immediately under the cell. The behavior is seen for both live and fixed cells. The locations of these "hot spots" do not remain invariant over the course of the 3000 s experiment, but shift to alternate regions. The EGFR lifetime<sup>15</sup> is approximately 30 min, long enough to prevent spatial averaging of the membrane signal. Example fluorescence traces from a nanotube right under the cell (green star, highlighted in pink circle, Fig. 2a) and nanotube far away from the cell (dark blue star, highlighted in pink circle, Fig. 2a) is shown in Fig. 2f and g. It is clear from these examples that the dominant contribution of the H<sub>2</sub>O<sub>2</sub> flux comes from the A431 cells, and the data suggests that at any given time it is concentrated at specific locations on the array, unlike the case of a uniformly exposed control.

# Real-time quantitative analysis of EGF stimulation

First, we analyze the total dynamic count rate of each single cell in response to EGF to measure the duration of the induced efflux. The quenching rate was calculated in real time for EGF stimulation (500ng/mL EGF was added at t=0) on live and fixed 3T3 (Fig. 3a) and A431 cells (Fig. 3b). Compared to the no cell control and unstimulated cell data, the quenching rate of both A431 and 3T3 cells were increased by EGF stimulation. A431 cells with a higher EGFR density have a much higher quenching rate than 3T3 cells. As can be seen from Fig. 3a-b, the behaviors of single A431 cells after EGF stimulation are similar: the quenching rate increased rapidly right after stimulation. However, the time point of maximal response ranges from 600s to 1800s after stimulation. There is no significant difference between live and fixed A431 cells. Removal of EGF decreases the quenching (Fig. S4). Compared to ensemble measurements on thousands of cells, our platform allows real-time quantification on single isolated cells for the first time. To confirm that the above results correlated with overexpression of EGFR, we then compared the EGFR density in 3T3 cells and A431 cells via immunostaining (Methods). As can been seen in the confocal images (Fig. 3c, d), A431 cells express much more EGFR than 3T3 cells (see Fig. S5 for more immunostaining images). From a calculation on the immunostaining images of 100 cells, the EGFR density of A431 cells is approximately 10 times that of 3T3 cells, consistent with the literature 15-16.

# Near-field generation from the membrane

Rank ordering the sensor responses from lowest to highest capture rate constructs the cumulative distribution (supplement). Let x be the number of sensors having a response less than y, so that  $\frac{x(y)}{n}$  is then the probability of finding a sensor with a number of counts less

than y. For the case of equal capture probabilities, the rank-ordered response is a modified Gamma distribution (Fig. S6a–b):

$$x = \frac{n \int_0^y e^{-t} t^{a-1} dt}{\int_0^\infty e^{-t} t^{a-1} dt} = \frac{n \Upsilon(a, y)}{\Gamma(a)} = n P(a, y) \quad (\text{Eq. 1})$$

Where  $\Upsilon$ ,  $\Gamma$  and P represents the lower incomplete, ordinary and regularized Gamma functions respectively with *a* as the mean value of y.

A kinetic Monte Carlo simulation of  $10^4 \text{ H}_2\text{O}_2$  molecules randomly binned into a sensor array consists of 300 sensors (n=300) is well-described by Eq. 1 after rank ordering (Fig. S6a–b). Note that all simulations (no fit parameters) utilized Matlab and were repeated 100 times with the average reported unless specified otherwise.

An array of sensors capable of detecting discrete, single molecules has the following unique property: it is possible to distinguish between those near-field component generated at the interface and those comprising a far-field component with no memory of origination.

On top of the far-field component described by Eq. 1, molecules generated near the array surface (i.e. at the cell membrane surface) are easily distinguished. The algorithm for extracting this interfacial generation at the interface simply accounts for non-binomial contributions to the frequency distribution. The local response,  $y_{local}(x)$ , is:

$$y_{Local}(x) = y(x) - P^{-1}(a, \frac{x}{n})$$
 (Eq. 2)

The mean value *a* can be found by computing the slope of the experimental data in the  $x \rightarrow 0$  limit:

$$\frac{\partial y}{\partial x} = \frac{\Gamma(a)}{ny^a - 1e^{-y}} \quad \left( \text{from } \frac{\partial \Gamma(a, y)}{\partial y} = -y^a - 1e^{-y} \right)$$

It can be shown from Monte Carlo simulation that membrane generation near the array interface of sufficient activity always biases the rank-ordered response to the highest activity sensors (Fig. 4a–b, Fig. S6e–i). As a result, a small number of data points at  $x \rightarrow 0$  are enough to extract the far-field component (Eq. 1) from any experimental curve with the membrane generation recovered from Eq. 2. A practical sensor array constructed as described above has a distribution of sensor capture probabilities as each sensor varies slightly in length and orientation. A beta distribution is a generic, empirical function that can describe this variation. It has the advantage that the far-field component then becomes a cumulative beta binomial distribution (see simulation and fit in Fig. S6c–d), and an analogous deconvolution can be derived (Fig. 4c–d). The rank-ordered sensor responses of SWNT-collagen arrays exposed to constant (uniform) concentrations of H<sub>2</sub>O<sub>2</sub> from 10 to 100  $\mu$ M are described by beta binomial distributions with parameters  $a = 1.2 \pm 0.15$  and  $\beta = 3.0 \pm 0.12$  (Fig. S7a–d). These parameters were used to correct the measured responses for the variation of capture sensitivities of each SWNT.

Membrane activities on single live, fixed A431 cells and live 3T3 cells before and after EGF stimulation over 3000s were extracted from the above algorithm (Fig. 4e–g, see Fig. S8 for the whole data set). Before stimulation, the local activity is negligible. After stimulation, the membrane generation observed for both live and fixed A431 cells, however not for live 3T3 cells. The increased activities after stimulation in the unit of number of quenching transitions

per sensor are summarized in Table 1. For A431 cells after simulation, the local  $H_2O_2$  concentration is determined through calibration to be  $2\mu M$  using control experiments in the cell-free system (Fig. S7e). The local generation rate from each membrane source is then 0.04 nmol  $H_2O_2$ /min after correcting for diffusion from Eq. S3.

# A consistent H<sub>2</sub>O<sub>2</sub> signal generation mechanism

The spontaneous or catalytic breakdown of  $O_2^{\bullet}$  <sup>-</sup> is considered to be the source of H<sub>2</sub>O<sub>2</sub> in many biological pathways, not only for immune cells, but also in a variety of eukaryotic cells<sup>2</sup>.  $O_2^{\bullet}$  - can be produced by the partial reduction of oxygen by cytochrome c oxidase in mitochondria<sup>2</sup> or by membrane-associated NAD(P)H oxidase<sup>6</sup>. Extensive literature has shown that EGF stimulated H<sub>2</sub>O<sub>2</sub> generation originates from NAD(P)H oxidase instead of mitochondria for various nonphagocytes, including A431 cells<sup>6, 22-23</sup>. Growth factors like EGF induce the formation of a complex on NAD(P)H oxidase to promote the electron transfer from NAD(P)H to molecular oxygen<sup>23</sup>. Fixation of A431 cells using 4% paraformaldehyde were designed to remove the influence of the mitochondria<sup>24</sup> in our experiments, as has been used in the literature to kill the cells without affecting the binding abilities of EGFR $^{21}$ . The fact that we see no quantitative difference between live and fixed A431 cells in their EGF inducible membrane generation (Table 1) is consistent with the all existing literature where mitochondria do not affect the EGF-induced H<sub>2</sub>O<sub>2</sub> generation. In addition, our single-molecule sensor array allows the membrane signaling flux to be differentiated from a diffuse far-field component for the first time, and can therefore inform the discussion of the nature of the  $H_2O_2$  signal. Our analysis above confirms the  $H_2O_2$  that increases in response to EGF binding is generated at the membrane and not in the cell interior (Fig. 4e–g). Recently, DeYulia and co-workers demonstrated that the H<sub>2</sub>O<sub>2</sub> production is EGFR-ligand-dependent in A431 cells<sup>21</sup>, where the inhibition of EGFR phosphorylation did not affect the H<sub>2</sub>O<sub>2</sub> generation. At this point, both the signaling network post-NAD(P)H oxidation, and the connection between activation of NAD(P)H oxidase and EGFR-ligand-dependent generation, are unclear from the literature. We further performed inhibition experiment using NAD(P)H oxidase inhibitors(Fig. S9a-b) and EGFR inhibitor (Fig. S9c) and found that consistent with our speculation, NAD(P)H oxidase inhibitors prevent H<sub>2</sub>O<sub>2</sub> from forming while EGFR inhibitor has no effect on the H<sub>2</sub>O<sub>2</sub> produced.

It is also not clear what catalytic portion of EGFR may be responsible for membrane  $H_2O_2$  generation from previous work<sup>21</sup>. Tryptophan (Trp) is proposed to be responsible for the conversion of  ${}^{1}O_{2}$  to  $H_2O_2$  in antibodies<sup>25</sup>. This antibody-mediated process is triggered upon binding of  ${}^{1}O_2$  to conserved binding sites within the antibody fold<sup>26</sup>, where the antibody serves as the catalyst, stabilizing the intermediate ( $H_2O_3$ ) and directing its conversion to  $H_2O_2$ . Trp is present in both EGF<sup>16</sup> (Trp 49, Trp 50) and EGFR<sup>27</sup> (Trp 140, 176, 453, 492) (Fig. 1a). If lacking these Trp residues, EGFR does not bind ligand with high affinity<sup>27</sup>. It is possible that EGFR, upon binding with EGF, allows greater access to sites on the receptor itself that catalyze the conversion of  ${}^{1}O_2$  to  $H_2O_2$ . To explore this, 1 mM sodium azide (NaN<sub>3</sub>), a scavenger of  ${}^{1}O_2{}^{28}$ , was added to fixed A431 cells with and without the presence of EGF and the single-molecule efflux of  $H_2O_2$  was again recorded. Compared to the un-stimulated control (green curve, Fig. 4h), NaN<sub>3</sub> greatly diminished both the near

and far-field portions of the  $H_2O_2$  response to EGF (black and red curve, Fig. 4h). Further, we observed an increase in  $H_2O_2$  after we exchanged water with  $D_2O$  (the lifetime of  ${}^1O_2$  in  $D_2O$  is 67  $\mu$ s<sup>29</sup>, a factor of 16 times greater than that in water) for the EGF stimulation experiment on fixed A431 cell (purple curve, Fig. 4h), compared to the parallel experiment conducted with water (blue curve, Fig. 4h). In previous studies, the level of  $H_2O_2$  before and after EGF stimulation is not affected when shutting down the mitochondria<sup>22–23</sup>. The fact that we were able to observe an obvious decrease in  $H_2O_2$  level even below the basal level when adding NaN<sub>3</sub> before and after EGF stimulation, and an increase in  $H_2O_2$  level when extending the lifetime of  ${}^1O_2$ , supports a complex pathway involving  ${}^1O_2$ .

One possible signaling network that may explain this more complex response starts from  $O_2^{\bullet}$ , which is produced from the reduction of molecular oxygen by NAD(P)H oxidase in A431 cells (Fig. 4k)<sup>22, 26</sup>.

$$NAD(P)H + 2O_2 \xrightarrow{NAD(P)H \text{ oxidase}} NAD(P)^+ + H^+ + 2O_2^{\bullet} - \text{(Reaction. 1)}$$

EGF was found to increase the production of  $O_2^{\bullet}$  <sup>-</sup> in A431 cells while an inhibitor of NAD(P)H oxidase halts this mechanism in a manner that was also mitochondria independent<sup>22</sup>. This observation, together with the previous known EGF-EGFR induced NAD(P)H oxidase activation mechanism for EGF stimulated A431 cells from numerous literature<sup>6, 22–23</sup>, and our inhibition experiment results (Fig. S9a–b), supports Reaction 1.  $O_2^{\bullet}$  <sup>-</sup> can then be decomposed by superoxide dismutase (SOD). It has been found that SOD is a master regulator of growth factor signaling and the inhibition on SOD1, which is an abundant copper/zinc enzyme found in the cytoplasm, increases the steady-state levels of  $O_2^{\bullet}$  <sup>-</sup> and decreases the levels of H<sub>2</sub>O<sub>2</sub> in A431 cells<sup>30</sup>. These reactions are rapid and occur with a diffusion limited reaction rate.

$$2O_2^{\bullet} \xrightarrow{-} + 2H^+ \xrightarrow{SOD} {}^1O_2 + H_2O_2^{31}$$
 (Reaction. 2)

$$2O_2^{\bullet} \xrightarrow{-} + 2H_2O \xrightarrow{SOD} O_2 + H_2O_2 + 2\overline{OH^{32}} \quad (\text{Reaction. 3})$$

Transition metal ions such as iron or copper can catalyze the reduction of  $H_2O_2$  by  $O_2^{\bullet}$  -33-35

$$O_2^{\bullet} \xrightarrow{-} + H_2 O_2 \xrightarrow{\text{transition metal ions}} {}^1O_2 + {}^{\bullet}OH + OH^{-}$$
 (Reaction. 4)

Nat Nanotechnol. Author manuscript; available in PMC 2019 March 28.

.....

 ${}^{1}O_{2}$  can decay to the ground state oxygen. It has been shown that the decay of  ${}^{1}O_{2}$  is determined by its interactions with water in the cell and not by interactions with other cell constituents with a decay rate constant of  $3 \times 10^{5} \text{ s}^{-1} \text{ }^{36}$ .

$${}^{1}O_2 \xrightarrow{water} O_2$$
 (Reaction. 5)

Ferrous also reacts with  $H_2O_2$ , known as the Fenton reaction<sup>37</sup>.

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\bullet}OH + OH^-$$
 (Reaction. 6)

$$Fe^{3+} + O_2^{\bullet-} \rightarrow Fe^{2+} + O_2$$
 (Reaction. 7)

Upon EGF stimulation, <sup>1</sup>O<sub>2</sub> is converted into H<sub>2</sub>O<sub>2</sub> catalyzed by EGF-EGFR<sup>38–39</sup>.

$$2^{1}O_{2} + 2H_{2}O \xleftarrow{EGF - EGFR}{2H_{2}O_{2} + O_{2}}$$
 (Reaction. 8)

From solving the proposed pathway numerically (with the initial values for *in vitro* ROS obtained from the literature<sup>40</sup>: superoxide, ~1nM, H<sub>2</sub>O<sub>2</sub>, 1 $\mu$ M, <sup>1</sup>O<sub>2</sub>, ~1nM) assuming a well-mixed condition and using the methods in previous work<sup>41–42</sup>, the concentration of  $O_2^{\bullet}$  <sup>-</sup> and H<sub>2</sub>O<sub>2</sub> increases with the addition of EGF (Fig. 4i), consistent with the experimental observations by us and others<sup>6, 17, 22</sup>. The addition of NaN<sub>3</sub> causes decrease of H<sub>2</sub>O<sub>2</sub> (Fig. 4j), even below the initial value, consistent with our observations in Fig. 4h. While the pathway that we proposed here is compelling, future work is necessary in order to conclusively rule out alternate mechanisms.

# Conclusions

In conclusion, an array of SWNT sensors has been used to image, for the first time, the incident flux of  $H_2O_2$  molecules that stochastically absorb and quench the emission with spatial and temporal resolution. Notably, arrays of this type can distinguish between molecules originating near an interface and those with no memory of origination, attributed as the far-field component. The signaling activity of EGFR on single A431 cells has been successfully measured using this sensor array. We find that the EGF stimulation induces on average 2 nmol  $H_2O_2$  over a period of 50 min in A431 cells. Corresponding inhibition experiments suggest a mechanism whereby water oxidizes  ${}^1O_2$  at a catalytic site on the receptor itself, generating  $H_2O_2$  in response to receptor binding. An EGFR-mediated  $H_2O_2$ 

generation pathway that is consistent with all current and previous findings has been proposed and numerically tested for consistency.

# Methods

# Suspension of SWNT in Collagen

Single-walled HiPco carbon nanotubes (Rice University) were suspended in type 1 collagen (BD Biosciences) via 1min probe-tip sonication (1/4" tip, 40% amplitude). One mg of SWNT was used per mL of 3.41 mg/mL collagen stock in 0.02 N acetic acid for sonication. The mixture was centrifuged for 270min at 16300g and the pellet discarded, retaining the supernatant for future experiments.

# **Collagen-SWNT Thin Films**

Collagen-SWNT was diluted with stock collagen (3.41 mg/mL) to make 272 mg/L SWNT concentration. This solution was diluted to 50 µg/mL collagen with 0.02 N acetic acid with a final concentration of SWNT of 8mg/L for imaging purposes (the concentration of SWNT is found by trial and error to achieve a desirable coverage of SWNT on the film) and pipetted onto glass bottom 35mm Petri dishes (MatTek Corp., P35G-1.5–14-C) in 500 µL aliquots to completely cover the glass region in the center of the dish. The collagen was dried at room temperature in a laminar flow hood. The dried film was rinsed well with PBS to remove the remaining acid. Everything was done under a sterilized environment.

#### Singlet Oxygen and Superoxide Generation

Rose bengal was used to generated singlet oxygen and superoxide in real time using a procedure described from a previous study<sup>43</sup>. Briefly, 50 nM of rose Bengal was illuminated at 561 nm at 200mW for 30 min and the fluorescence of nanotubes upon this illumination was recorded in real time. It is reported that this procedure will generate both singlet oxygen and superoxide. MnO<sub>2</sub> was added to the solution to prevent any interference from H<sub>2</sub>O<sub>2</sub>.

#### Fluorescence Microscopy on Live and Fixed Cell

Human epidermoid carcinoma A431 cells and murine NIH-3T3 cells were cultured with Dulbecco's Modified Eagle's Medium (DMEM, ATCC) supplemented with 10% fetal bovine serum (FBS, Gemini Bio-Products) and 1% Pen-Strep Solution (10,000 U/mL Penicillin-G 10,000 µg/mL Streptomycin Penicillin-Streptomycin Solution, Gemini Bio-Products) at 37 °C with 5% CO<sub>2</sub> on a collagen film<sup>10</sup> in a glass bottom 35mm Petri dish (MatTek Corp., P35G-1.5–14-C) after serum starvation<sup>17</sup>. Right before imaging, the cell medium was changed into Leibovitz's L-15 medium, which buffers the pH in the atmosphere. The nanotubes in the collagen film beneath the cells are then imaged using a fluorescence microscope (Carl Zeiss, Axiovert 200), with a CCD camera (Carl Zeiss, ZxioCam MRm) and 2D InGaAs array (Princeton Instruments OMA 2D). Movies were acquired using the WinSpec data acquisition program (Princeton Instruments). The nanotubes were excited by a 658 nm laser (LDM-OPT-A6–13, Newport Corp) at 35mW. After a stable fluorescence intensity was observed (Fig. S1), 500 µL of each reagent was added to reach the desirable final concentration. For experiment with fixed cells, A431 cells

were washed with PBS, fixed in 4% paraformaldehyde (pH 7.4) for 10 min, washed 3 times and ready for imaging.

#### Fluorescent Staining of Cells

Cells were incubated with 4% PFA/PBS (USB Corporation) at 4 °C for 5 min, at room temperature for 10 min, then with 100% methanol (Sigma) at -20 °C for 10 min. The fixed cells were washed 3 times with PBS (Hyclone), permeabilize with 0.1% Triton X 100 (Sigma)/PBS for 20 min at room temperature followed by another washing with PBS. The cells were then incubated in 1% FBS/0.05% Tween (Sigma)-20/PBS for 20 min at room temperature, after which they were incubated with the primary antibody (rabbit polyclonal to EGFR, ABCAM Inc) in 1% FBS/0.05% Tween-20/PBS for 1h at room temperature. Washing and blocking were repeated. In the dark, the secondary antibody (Alexa Fluor 568 donkey anti-rabbit IgG, Invitrogen) was added in 1% FBS/0.05% Tween-20/PBS for 1h at room temperature (Alexa 1:500), after which 4',6-diamidino-2-phenylindole (DAPI, Sigma Aldrich Co.) was added with a final concentration of 1µg/L. The washing step was repeated. The sample was then mounted in Moviol (Shandon Immu-Mount, Thermo Fisher Scientific). The samples were then analyzed in Zeiss LSM 510 Meta confocal microscope using the same configuration and processed in LSM image Browser software from Zeiss.

#### Atomic Force Microscope (AFM)

MFP-3D (Asylum Research) was used for tapping mode atomic force microscopy (AFM) imaging. Samples were directly deposited on a 75 mm × 25 mm glass slide (VWR International) and imaged using rectangular silicon tips (Olympus AC240TS) with a nominal spring constant of 2 N/m. Both topographic and height images were recorded during AFM analysis. Height analysis was performed using Igor Pro software.

# Figure 1.

Nanotube sensing platform. a, A431 cell cultured on collagen-SWNT film. Zoom in on red circle: EGFR domains spanning the cell membrane. Domains I and III bind to EGF (red) and generate  $H_2O_2$ . b, NIR image of SWNT underneath A431 (left) and phase contrast image of A431 cell (right) cultured on SWNT sensors (658 nm excitation, 1mW, Alpha Plan-Apo 100x/1.46 oil emersion objective). c, Forward and reverse binding rate of SWNT sensor for various analytes show selectivity for  $H_2O_2$ . d, Fluorescence trace for control (no cells) show no steps. e, Trace for SWNT in the red circle in (b) show reversible, stepwise quenching (green trace), modeled by HMM (red).

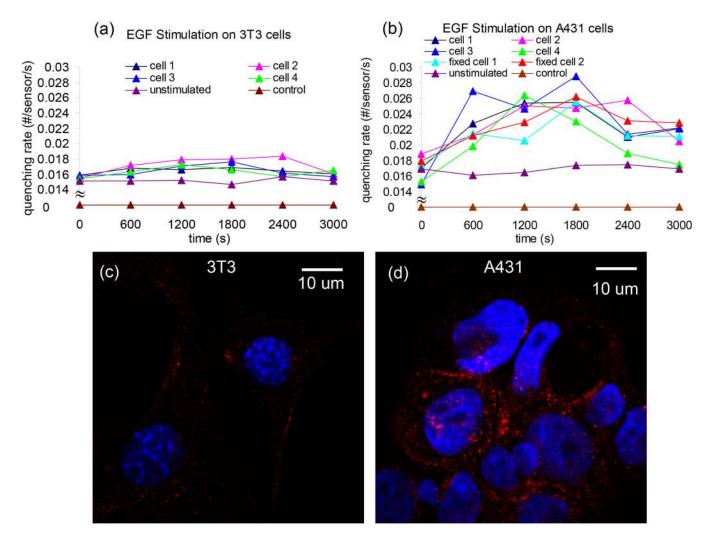

Jin et al.

# Figure 2.

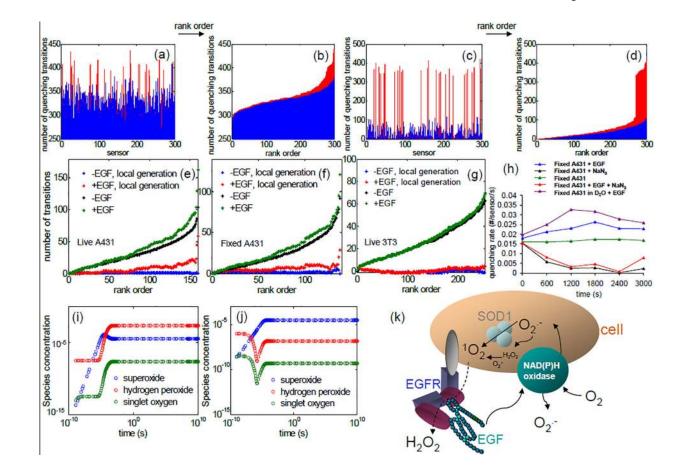

Spatial mapping of quenching transitions over single A431 cells. a-d, Quenching activity (unit of counts) over the 3000s observation window of each sensor was binned into sixteen categories represented by 16 different color bars with red having the highest quenching activity and black the lowest for live (a, b) and fixed (c, d) A431 cells. e, Control experiment where  $10\mu M H_2O_2$  was present in the absence of a cell. Left panels show phase contrast images without the overlap of quenching activities. Fluorescence trace of green star (f) and dark blue star (g) from (a) are shown.

Jin et al.

# Figure 3.

SWNT quenching depends of EGFR density. a, b, Real time quenching rate for live 3T3 cells (a) and live/fixed A431 cells (b). The number of sensors under each single cell is 255, 200, 250, 150, 255, 200 respectively for cell 1, 2, 3, 4, unstimulated and control in (a); 160, 110, 126, 174, 140, 180, 180, 200 respectively for cell 1, 2, 3, 4, fixed cell 1, 2, unstimulated and control in (b). Representative confocal images for 3T3 cells (c) and A431 cells (d) with EGFR (red) labeled with rabbit polyclonal antibody against EGFR and Alexa Fluor 568 donkey anti-rabbit IgG. Nuclei (blue) is stained with 4',6-diamidino-2-phenylindole (DAPI).

#### Figure 4.

Quantitative analysis of results from SWNT sensor array. a-d, Simulation of sensor response (a), rank-ordered sensor response from a (b), sensor response following beta distribution (c) and rank-ordered sensor response from c (d) of  $10^5 \text{ H}_2\text{O}_2$  randomly falling onto 300 sensors (blue), with additional response to local generation (red). After far-field component subtraction from the rank-ordered sensor response (black, -EGF; green, +EGF), the local generation before (blue, star) and after (red, star) EGF stimulation for live (e), fixed (f) A431 cell and live 3T3 cell (g). h, Real-time quenching rate for fixed A431, before (green) and after (blue) EGF stimulation. Sodium azide decreases the quenching, with (red) and without (black) EGF. Extending the singlet oxygen lifetime using D<sub>2</sub>O increases the quenching (purple). Concentration profiles on log-log scale for different species from solving Reaction 1–8 (i) and from considering the effect of NaN<sub>3</sub> when solving the reaction network (j). k, Scheme of the proposed pathway for H<sub>2</sub>O<sub>2</sub> generation.

# Table 1

Number of quenching transitions per sensor from receptors alone calculated for live, fixed A431 cells and live 3T3 cells.

Cell type	Number of quenching transitions per sensor
Live A431 cell #1	6.6
Live A431 cell #2	4.0
Live A431 cell #3	5.0
Live A431 cell #4	7.5
Fixed A431 cell #1	4.5
Fixed A431 cell #2	7.8
A431 cells average	6.0
Live 3T3 cell #1	1.0
Live 3T3 cell #2	1.1
Live 3T3 cell #3	1.1
Live 3T3 cell #4	1.0
3T3 cells average	1.1
