## Abstract

**Introduction:** Transbronchial lung cryobiopsy (TBLC) is increasingly being used as an alternative to video-assisted thoracoscopic surgery (VATS) biopsy to establish the histopathologic pattern in interstitial lung disease (ILD).

**Methods:** A systematic literature search of the PubMed and Embase databases, from October 2010 to October 2020, was conducted to identify studies that reported on diagnostic yield or safety of VATS or TBLC in the diagnosis of ILD.

**Results:** 43 studies were included. 23 evaluated the diagnostic yield of TBLC after multidisciplinary discussion, with a pooled diagnostic yield of 76.8% (95% confidence interval (CI) 70.6–82.1), rising to 80.7% in centres that performed  $\geq 70$  TBLC. 10 studies assessed the use of VATS and the pooled diagnostic yield was 93.5% (95% CI 88.3–96.5). In TBLC, pooled incidences of complications were 9.9% (95% CI 6.8–14.3) for significant bleeding (6.9% for centres with  $\geq 70$  TBLC), 5.6% (95% CI 3.8–8.2) for pneumothorax treated with a chest tube and 1.4% (95% CI 0.9–2.2) for acute exacerbation of ILD after TBLC. The mortality rates were 0.6% and 1.7% for TBLC and VATS, respectively.

**Conclusions:** TBLC has a fairly good diagnostic yield, an acceptable safety profile and a lower mortality rate than VATS. The best results are obtained from more experienced centres.

## Background

Interstitial lung diseases (ILDs) are a group of diseases characterised by inflammation and scarring of the lung parenchyma [1, 2] but differ in aetiology, pathological findings, treatment options and prognosis [1, 3]. In patients with suspected ILD, the clinical and imaging findings of chest radiography and conventional computed tomography are generally nonspecific and performing high-resolution computed tomography (HRCT) is essential to improve diagnostic accuracy [4–6]. Still, in many ILDs, clinical setting and HRCT appearances alone are insufficient to provide a definitive diagnosis [6, 7].

Surgical lung biopsy (SLB) has been considered the gold standard method to establish the histopathologic pattern of a specific type of ILD and better guide the treatment [8–10]. When SLB is deemed necessary, the approach of choice is by video-assisted thoracoscopic surgery (VATS), a less invasive technique that

has largely replaced open lung biopsy (OLB) [11]. Nevertheless, this surgical technique also carries risks and complications, and some subgroups of patients (older subjects, patients with significant comorbidities and/or advanced respiratory disease) have high operative mortality, which explains the need to consider the risk:benefit ratio before performing such biopsy [11, 12].

Transbronchial lung cryobiopsy (TBLC) is an innovative bronchoscopic method for tissue sampling of patients with suspicious diffuse parenchymal lung diseases. A cryoprobe is inserted distally into the bronchus, cooled at  $-79^{\circ}\text{C}$  (using carbon dioxide) or  $-89^{\circ}\text{C}$  (using nitrous oxide) within seconds, and then retrieved with the attached frozen lung tissue [13]. It is increasingly being used for assessing ILDs because it provides tissue samples with a higher percentage of alveolar tissue and fewer crush artefacts, when compared to conventional transbronchial biopsies [14]. Furthermore, this technique has attracted considerable interest in the pulmonology community as a promising and potentially safer alternative to SLB [7, 15, 16].

Therefore, we conducted a systematic review and meta-analysis to evaluate the diagnostic yield and safety of TBLC *versus* VATS lung biopsy in patients with suspected ILD.

## Methods

We followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses statement for the present systematic review [17]. The protocol was registered and allocated the identification number CRD42020213326 in the PROSPERO database.

### Eligibility criteria

Inclusion criteria were as follows: 1) reported at least one of the procedures (SLB by VATS or TBLC) used for the diagnosis of suspected ILD; 2) reported at least one of the study outcomes; 3) written in English or Portuguese; 4) published within the last 10 years.

To be included in the systematic review, studies had to respect all the inclusion criteria. We excluded abstracts, editorials, reviews, comments and case reports. Given the heterogeneity of parenchymal changes from different ILDs, which potentially impact the biopsy results, studies describing the outcomes of procedures in a sole specific ILD subset were also excluded.

Additionally, when multiple publications from the same centre with overlapping recruitment periods were found, we only included the study with the largest sample size to prevent double counting of patients.

### Outcomes evaluated

Two outcomes were defined for this systematic review: diagnostic yield and safety. Diagnostic yield indicates the final clinical diagnosis held by a multidisciplinary team or, when not available, the final histopathological diagnosis. For evaluation of the safety of TBLC, we analysed the incidence of bleeding, pneumothorax and acute exacerbation of ILD. Bleeding was further divided into four categories: “none”; “mild bleeding” (self-limiting bleeding, managed with suction); “moderate bleeding” (controlled with cold saline, vasoconstrictive drugs or by endobronchial blocker); and “severe bleeding” (any bleeding causing hemodynamic or respiratory instability, requiring tamponade or other surgical interventions, transfusions, or admission to the intensive care unit) [7, 18].

As for VATS, we recorded the incidence of recurrent pneumothorax, persistent air leak (defined as an air leak that lasts longer than 5–7 days), pneumonia/empyema, haemothorax, thoracic pain and ILD acute exacerbation. Data from 30-day mortality was collected from both techniques.

### Search and selection of the studies

We performed a systematic search of the literature from October 2010 to October 2020 to check all studies that reported relevant information on the diagnostic yield or safety of VATS lung biopsy or TBLC in the diagnosis of ILD. The search was performed in PubMed/MEDLINE and Embase, and the following search terms were used (both as free text and appropriate subject indexing terms): “interstitial lung disease” OR “diffuse parenchymal lung disease” AND “video-assisted thoracic surgery” OR “VATS” OR “cryobiopsy” OR “cryo-transbronchial”. The search did not include the terms “diagnostic yield” or “safety” to maximise the number of research results.

For the selection of the studies to be included in the systematic review, titles and abstracts were independently reviewed for eligibility by two authors (I.R. and R.E.G.). Disagreement on any study selection

was resolved by an independent review of a third author (H.N.B.). After the first selection, the nonexcluded studies underwent a full-text review, and data was collected from the studies that were considered eligible.

### **Data extraction**

Before the beginning of the reading of the selected articles, a set of items were established to be extracted: 1) publication details (authors, year of publication and country of origin); 2) study design (cross-sectional, cohort or randomised clinical trial); 3) sample size and population demographics (mean age and sex distribution); 4) details of the procedure (number of biopsies per patient; cryoprobe used and cooling time for TBLC studies); 5) characteristics of biopsy specimens (number, surface area, and largest diameter); 6) diagnostic yield (final clinical-pathologic diagnosis); 7) complications associated to the procedure (severe bleeding, pneumothorax and others); and 8) mortality associated with the procedure.

### **Quality assessment**

The quality and validity of each article were assessed using the CASP (Critical Appraisal Skills Programme) checklists by two reviewers independently. The CASP checklists are a commonly used tool to evaluate the quality appraisal in various types of studies. Based on study design, the CASP cohort study checklist [19], the CASP randomised controlled trial checklist [20] or the CASP diagnostic study checklist [21] were used.

### **Data analysis**

Extracted data were pooled and weighted proportionately to its sample size for all outcomes of interest. The pooled proportions were calculated using the Freeman–Tukey transformation, using a DerSimonian random effects model in the presence of significant heterogeneity. Forest plot graphs were used to illustrate the weighted outcomes as well as the pooled estimation with the 95% confidence interval (CI). Heterogeneity of results was assessed by the  $I^2$  statistic, and an  $I^2 > 40\%$  was considered indicative of significant heterogeneity [22]. The statistical analysis was performed using the Comprehensive Meta-Analysis Package version 2.2.064 (Biostat, Englewood, NJ, USA) statistical software.

## **Results**

### **Search results**

The initial search identified 1320 citations, and 933 titles and abstracts were review after the removal of duplicates (figure 1). Of these, 68 publications were full text reviewed and 43 studies were included in the final systematic review.

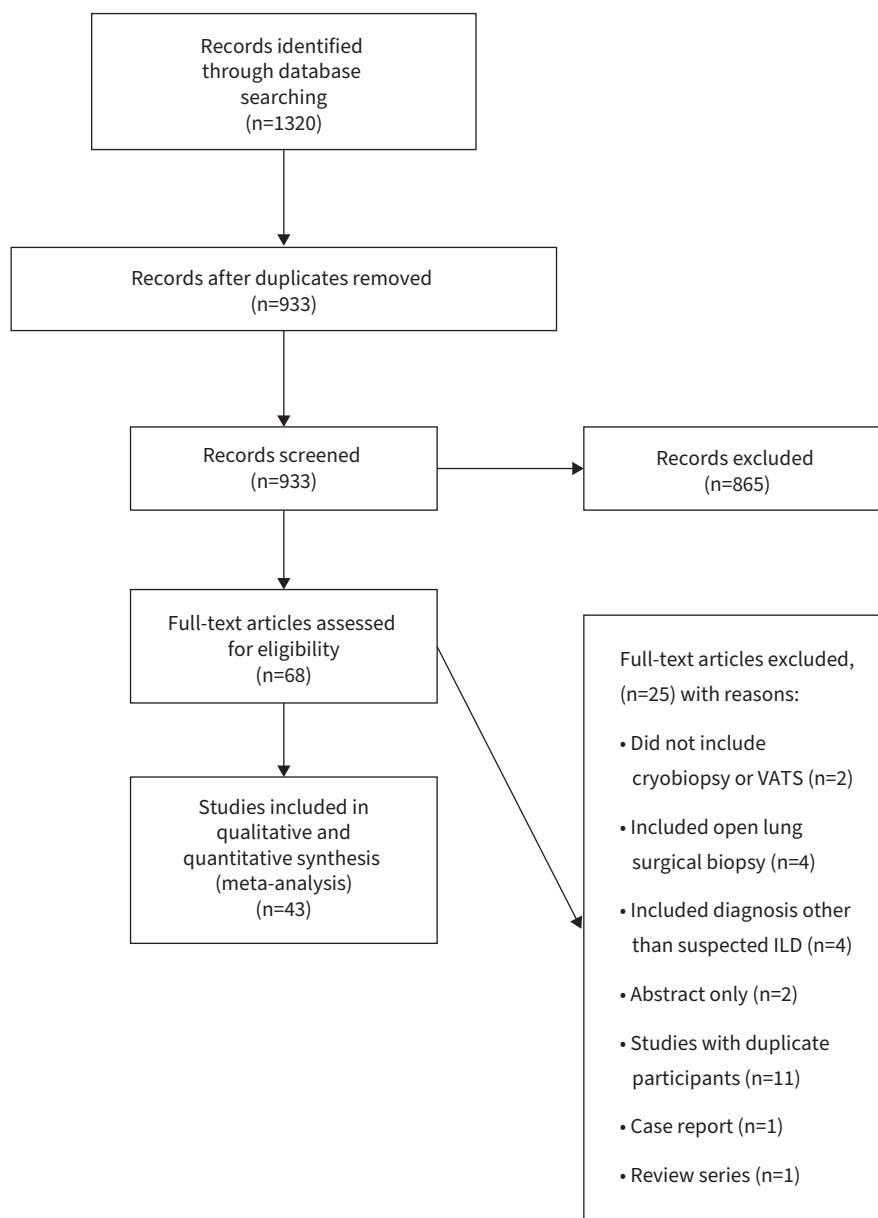

### **Study characteristics**

The 43 studies included 4550 patients (sample size range 12–359). TBLC was performed in 2824 patients and SLB (by VATS) in 1814. From the included studies (supplementary table S1), 27 [15, 18, 23–47] evaluated the use of TBLC in the diagnosis of suspected ILDs, 13 [2, 48–59] assessed the use of SLB, and three [60–62] compared the use of TBLC and SLB. In two studies [61, 62], both TBLC and SLB were performed sequentially on the same patient. There were 24 retrospective cohorts, 14 prospective cohorts, three cross-sectional studies and two randomised controlled trials comparing TBLC with conventional forceps sampling (supplementary table S2). 41 studies reported mean or median age, ranging from 45.6 to 66.6 years, and 42 studies reported sex distribution, ranging from 33% to 73% male. The number of tissue samples per subject was reported in 33 studies, ranging from one to eight biopsies in the TBLC group and one to three in the SLB group (supplementary table S3). The mean biopsy area was described in eight studies of TBLC, varying from 9 mm<sup>2</sup> to 44.4 mm<sup>2</sup>.

Outcomes of included studies for each technique are summarised in tables 1 and 2. 25 studies reported histopathological diagnostic and 33 reported final diagnostic yield after histopathologic results were combined with clinical and radiological features in a multidisciplinary team discussion. 41 studies reported procedure-related complications.

### **Study quality**

The quality of full-text studies included in this revision was variable (supplementary tables S4, S5 and S6). Most cohort studies (n=38) were considered to have selected the cohort in an acceptable way, but in relation to the outcomes, only 14 studies (36.8%) had precise results. Two of the three diagnostic studies described the methodology well and had reliable results. Regarding the randomised clinical trials included (n=2), both had nonblinded randomisation and, although the results were not considered totally precise, all important outcomes were evaluated.

**FIGURE 1** Flowchart of study selection. ILD: interstitial lung disease; VATS: video-assisted thoracoscopic surgery.

### Diagnostic accuracy and yield

28 studies evaluated the diagnostic yield of TBLC, and a subanalysis was performed based on the criteria applied by each study to define the diagnostic yield (histopathological pattern alone *versus* final multidisciplinary diagnosis). 17 studies reported diagnostic yield from histopathologic assessment (figure 2a), with a pooled diagnostic yield of 77.1% (95% CI 70.1–82.8;  $I^2=88.7\%$ ,  $p<0.001$ ); 23 studies reported diagnostic yield after multidisciplinary team discussion, with a pooled diagnostic yield of 76.8% (95% CI 70.6–82.1;  $I^2=86.3\%$ ,  $p<0.001$ ). When looking solely at centres that performed  $\geq 70$  TBLCs, which has been suggested as the minimum number to achieve proficiency in the technique [63], the diagnostic yield after multidisciplinary team discussion rises to 80.7% (95% CI 71.6–87.4;  $I^2=92.1\%$ ,  $p<0.001$ ).

16 studies analysed the use of SLB in the diagnosis of ILD. Eight studies reported histopathologic diagnosis (figure 2b), with a pooled diagnostic yield of 95.3% (95% CI 84.7–98.7;  $I^2=87.5\%$ ,  $p<0.001$ ); 10 studies reported the diagnostic yield after multidisciplinary team discussion, with a pooled estimate of 93.5% (95% CI 88.3–96.5;  $I^2=81.1\%$ ,  $p<0.001$ ).

ILD: interstitial lung disease; MDD: multidisciplinary discussion; NA: not available; OLB: open lung biopsy.										

**FIGURE 2** Meta-analysis of the diagnostic yield of a) transbronchial lung cryobiopsy (TBLC) and b) video-assisted thoracoscopic surgery, according to diagnostic criteria. The diamonds indicate the pooled effects. CI: confidence interval; MDD: multidisciplinary discussion.

Only three studies compared TBLC diagnostic accuracy with the gold standard of SLB, in which two studies [61, 62] compared sequential TBLC followed by SLB performed on the same patient. ROMAGNOLI *et al.* [62] evaluated sequential TLBC and SLB in 21 patients. A histopathological pattern was obtained in 81% of the TBLCs. However, it was concordant with the SLB histopathological pattern in only 38% of cases ( $\kappa=0.22$ ), and with the final diagnosis after multidisciplinary team discussion in 48% ( $\kappa=0.31$ ). In the same study, SLB was considered the gold-standard procedure and a histopathological diagnosis was achieved in all cases, which was concordant with the definitive diagnosis after multidisciplinary discussion in 62% of cases ( $\kappa=0.51$ ). TROY *et al.* [61] also performed both techniques sequentially but achieved different results. Agreement between TBLC and SLB on histopathological assessment was present in 70.8% cases ( $\kappa=0.7$ ) and, for multidisciplinary discussion final diagnosis, raw agreement between TBLC and SLB was 76.9% ( $\kappa=0.62$ ). The final diagnostic yield after multidisciplinary discussion was reached in 60% of the TBLC and 74% of SLB. RAVAGLIA *et al.* [60] compared TBLC against SLB performed in different patients. A total of 297 patients were submitted to TLBC and 150 to SLB. Only the histopathological diagnostic rate was described for both techniques, with 82.8% and 98.7% for TBLC and SLB, respectively.

### Procedure-related complications

41 studies reported procedure-related complications. In relation to TBLC, 26 studies described the occurrence of bleeding. The mean reported frequency for mild bleeding was 29.9% (range 0–96%), moderate bleeding 9.1% (range 0–56.4%) and severe bleeding 1.6% (range 0–13.1%). Pooled incidence of significant bleeding (data available for moderate to severe degrees) was 9.9% (95% CI 6.8–14.3) (figure 3a). There was significant heterogeneity between studies ( $I^2=85.2\%$ ;  $p<0.001$ ). When analysing studies that performed  $\geq 70$  TBLCs, the incidence of significant bleeding falls to 6.9% (95% CI 4.2–11.2;  $I^2=86.5\%$ ,  $p<0.001$ ).

Pneumothorax was reported in 30 TBLC studies. It was present in 261 patients, with a mean occurrence rate of 9.2% (range 0–26%). From the studies that reported the need for chest drain, the pooled incidence of patients with pneumothorax that required drainage was 5.6% (95% CI 3.8–8.2) (figure 3b) and significant heterogeneity was observed ( $I^2=71.5\%$ ;  $p<0.001$ ). The incidence of pneumothorax requiring chest drain for studies that performed  $\geq 70$  TBLC was 5.3% (95% CI 3.3–8.6;  $I^2=79.2\%$ ,  $p<0.001$ ). Finally, acute exacerbation of ILD after TBLC was reported in 18 studies, with a pooled incidence rate of 1.4% (95% CI 0.9–2.2%), with an  $I^2$  of 0% ( $p=0.851$ ) (supplementary figure S1).

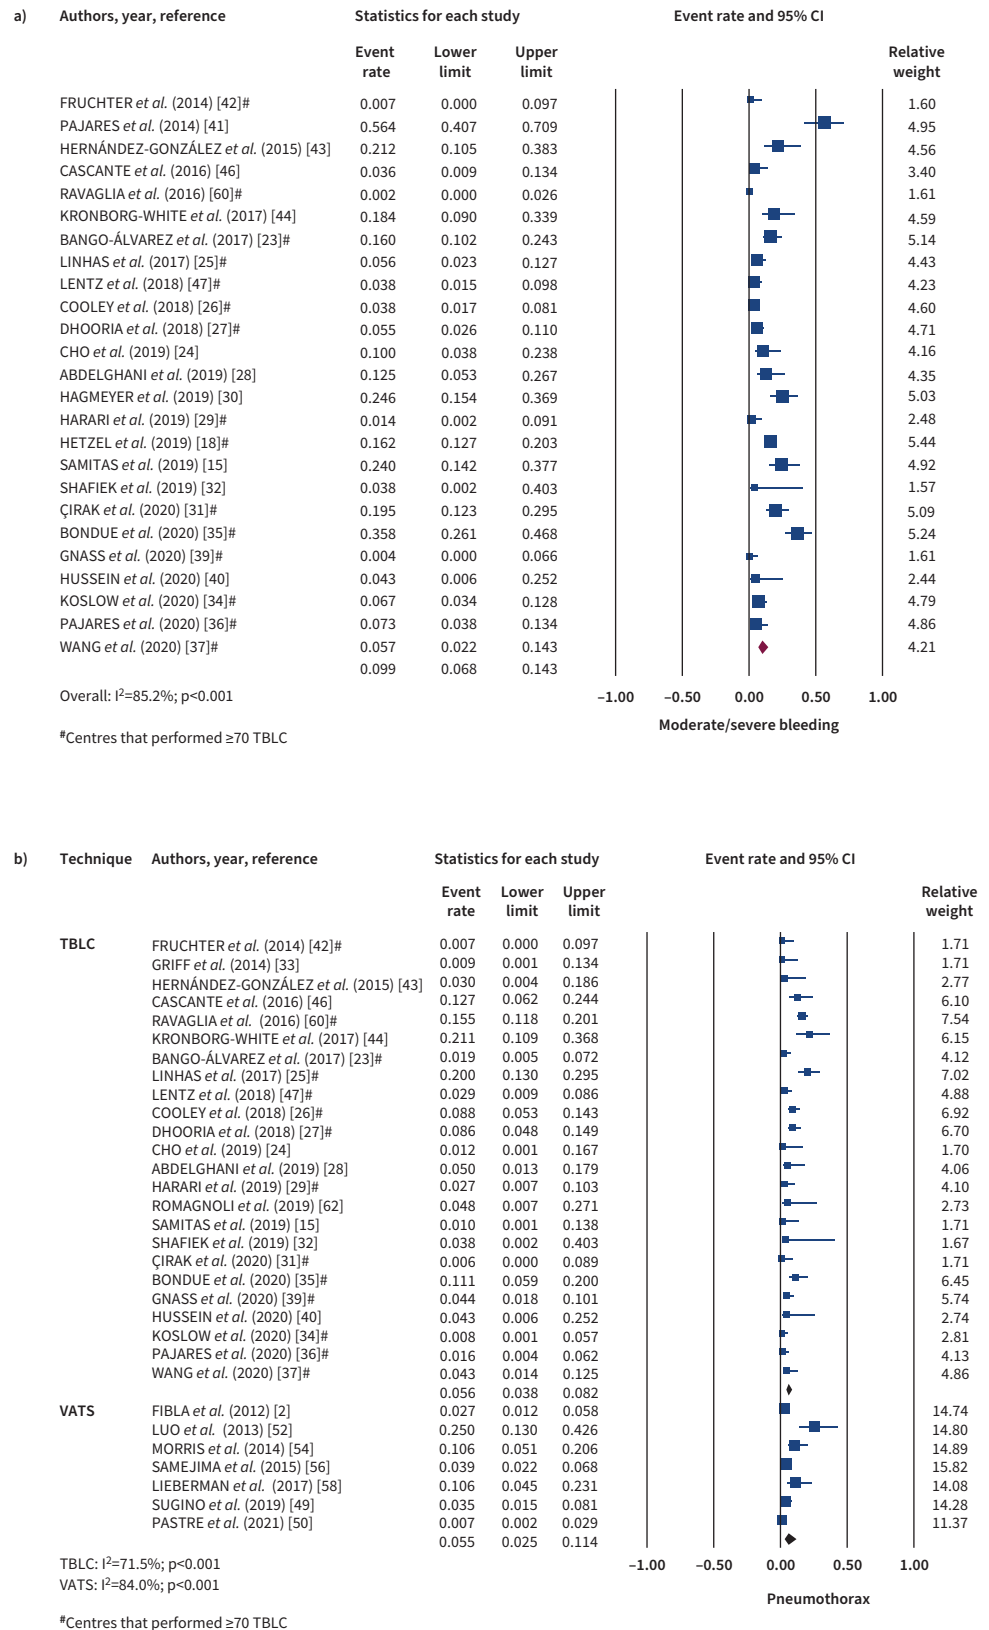

Considering SLB, 13 studies reported procedure-related complications. The pooled incidence rate of recurrent or persistent pneumothorax (figure 3b) was 5.5% (95% CI 2.5–11.4) with significant heterogeneity ( $I^2=84.0\%$ ;  $p<0.001$ ); 2.1% (95% CI 0.3–13.9) for pneumonia or empyema (supplementary figure S2a), with significant heterogeneity ( $I^2=93.3\%$ ;  $p<0.001$ ); 3.4% (95% CI 2.0–5.8%) for thoracic pain (figure S2b), with no significant heterogeneity ( $I^2=0\%$ ;  $p=0.763$ ); 1.8% (95% CI 0.8–4.0) for persistent air leak (figure S2c), with significant heterogeneity ( $I^2=54.5\%$ ;  $p=0.003$ ); and 2.0% (95% CI 1.3–3.1%) for acute ILD exacerbation (figure S2d), with no significant heterogeneity ( $I^2=0\%$ ;  $p=0.635$ ).

30-day mortality was reported in 29 studies. The mortality rate was 0.6% (range 0–3.2%) and 1.7% (range 0–6.7%) in TBLC and SLB, respectively.

### Discussion

In this meta-analysis, TBLC was shown to have a pooled diagnostic yield after multidisciplinary discussion of 76.8%, which raises to 80.7% in experienced centres, while SLB had 93.5%. This means that around eight in every 10 cases may achieve confident diagnosis without undergoing surgery. A difference of similar magnitude was observed for histopathological diagnosis with TBLC, compared to SLB. While histopathological diagnostic yield is a simple measure of biopsy efficacy, evaluating specimen adequacy and the presence of a characteristic histological pattern, which could arguably be considered a more direct measure of comparison between biopsy techniques, the contribution to the final ILD diagnosis must be harmonised with other variables in the context of multidisciplinary team discussion. Therefore, we believe that the real impact of the biopsy technique should be discerned within the frame of a multidisciplinary evaluation of the clinical case.

Conversely, the safety profile analysis benefits TBLC, especially when considering the post-procedural 30-day mortality rate, which is 0.6% for TBLC and more than double, 1.7%, in SLB. This figure is in line with a previous meta-analysis that included both VATS and OLB, where the pooled 30-day mortality rate was 2.2%, but could be as high as 7.8% in studies containing mechanically ventilated patients [3]. Possible explanations for the higher mortality in SLB may be the risk of pneumonia, empyema or ILD acute

**FIGURE 3** Complications related to the technique: a) moderate/severe bleeding after transbronchial lung cryobiopsy (TBLC); b) pneumothorax after TBLC and video-assisted thoracoscopic surgery (VATS). The diamonds indicate the pooled effects. CI: confidence interval.

exacerbation in the post-operative period. Additionally, the collapse induced to the lung that will be biopsied during VATS, which is necessary for visualisation of the pleural cavity, may also be deleterious to the patients undergoing SLB. Previous research has linked repetitive alveolar collapse to epithelial cell injury and idiopathic pulmonary fibrosis (IPF) progression [64, 65], and clinical studies have shown that pneumothorax in IPF patients is associated to dismal prognosis, with high in-hospital mortality rate [66, 67]. Although pneumothorax requiring chest drainage after TBLC may also occur, with a pooled incidence rate of 5.6% in our meta-analysis, we found a surprisingly identical rate of recurrent or persistent pneumothorax after SLB, with a pooled frequency of 5.5% of cases, which provides a second hit with lung collapse and potentially drives clinical worsening in susceptible patients.

Clearly, mortality rate and complications associated with SLB can also be influenced by comorbidities, including immunocompromised status and low baseline lung function [3], especially in elderly patients. In a large cohort study of TBLC cases, impaired lung function was also associated with increased rate of post-procedural pneumothorax, but, conversely, was not related with higher mortality [68]. Moreover, we show in our review that TBLC has been performed safely in patients with a wide range of age, further reinforcing its role to diagnose advanced cases of fibrotic ILDs. On the other hand, the most common complication related to TBLC is moderate to severe bleeding (9.9%), although less frequently in the most experienced centres (6.9%) and often manageable with local endoscopic measures. In a previous meta-analysis, the pooled incidence of moderate to severe bleeding differed widely (4.9–39.0%) [60, 69–71]. This difference may be associated with variability in the reporting of this complication and the absence of a prophylactic endobronchial balloon in some studies, which has been associated with lower rate of significant bleeding [27]. Studies suggest that bleeding risk is independent of baseline functional status, probe size, number of samples or multiple site sampling [68].

There are two features that distinguish the present systematic review and meta-analysis from the previous ones. First, we focus on the final diagnostic yield after the multidisciplinary team discussion, as we believe that a simple histopathological yield is not the most clinically informative outcome. Second, our research included two recent trials comparing TBLC with SLB performed sequentially on the same patients [61, 62], which were absent in former meta-analyses. Interestingly, these trials presented contradicting results, with ROMAGNOLI *et al.* [62] showing poor concordance between TBLC and SLB for the histologic diagnosis and TROY *et al.* [61] showing that histopathologic agreement between TBLC and SLB was 70.8%, with the concordance increasing to 94.9% in cases of TBLC with high or definite diagnostic confidence at multidisciplinary discussion. Given these conflicting outcomes, an updated meta-analysis was deemed necessary. SHARP *et al.* [69] reported a pooled diagnostic yield of 84% (based on 10 studies and abstracts) without specifying their diagnostic criteria; JOHANSSON *et al.* [70] reported 83% (based on five studies) considering histopathological assessment alone and 79% (based on six studies) when TBLC was incorporated into a multidisciplinary discussion; RAVAGLIA *et al.* [60] reported 80% (based on eight studies) referring to the identification of a characteristic histological pattern and 81% (based on seven studies) considering multidisciplinary discussion as the final diagnosis; and IFTIKHAR *et al.* [71] reported an overall pooled diagnostic yield of 83.7% (based on 16 studies) considering both diagnostic criteria. Here, we calculated a relatively lower diagnostic yield, which may be related to the higher number of studies included in this analysis (23 studies, excluding abstracts), reporting a wide range of diagnostic yield, from 44.2% to 95.6%, possibly explained by technical differences, such as cryoprobe size, number of biopsies and sampling site, duration of freezing time, use of fluoroscopy, method of sedation (moderate/deep), and use of flexible *versus* rigid bronchoscopy. Both cryoprobe diameters (1.9 mm and 2.4 mm) were shown to perform similarly in terms of diagnostic performance, although associated with significantly lower pneumothorax rate for the 1.9 mm cryoprobe compared with the 2.4 mm (2.7% *versus* 21.2%) [68]. A prospective study [72] has shown that two samples taken from two different segments significantly increases the diagnostic rate, compared to two biopsies taken from the same segment alone (78% *versus* 96%). These results were confirmed by a retrospective cohort, in which both histopathological and multidisciplinary team discussion diagnostic yield were significantly better when samples were obtained from two different sites (either different segments in the same lobe or different lobes) [68]. Finally, the incidence for pneumothorax needing drainage in former analyses was similar to ours, with 3% (1–8%) [60], as was the 30-day mortality (0.3–0.7%) [60, 69, 71].

In summary, our results support the clinical use of TBLC, considering its lower invasiveness over SLB, with less morbi-mortality, shorter hospitalisation stay and better cost-effectiveness profile [43]. In fact, the use of TBLC in the diagnostic algorithm of ILD whose differential diagnosis includes fibrotic hypersensitivity pneumonitis has been already suggested [73]. Another strength of the study is that we compared TBLC with SLB performed through VATS, rather than OLB, since the latter has become less recommended due to higher post-operative complications and longer hospital stays [74].

Although we restricted our analysis to studies written in English or Portuguese, a selection bias is unlikely given that only a minority of manuscripts (<2%) were excluded due to language restrictions, and the present review included studies from 21 different countries. Yet, the heterogeneity found between studies for diagnostic accuracy, occurrence of bleeding and pneumothorax, may be pointed out as a potential drawback of our analysis. Heterogeneity may be explained by technical differences in the TBLC procedure between studies and putative selection bias in studies. Overall, better results are found in the most experienced centres. We have previously shown that approximately 70 procedures are needed to achieve technical proficiency in TBLC, which is associated with significant improvement in sample quality and fewer pneumothorax events, and better diagnostic yield, that reflect both proficiency in technical performance and histopathological sample interpretation [63]. Our meta-analysis confirms that the pooled diagnostic yield was higher and complication rates were lower in studies including 70 or more procedures. However, significant heterogeneity was still observed in this subgroup analysis. In order to standardise procedures, HETZEL *et al.* [16] have published an expert statement on TBLC proposing recommendations in patient selection, contraindications, risks and technical performance. More recently, MALDONADO *et al.* [7] published the first guidelines on the technical aspects of the TBLC procedure. The latter is expected to homogenise the TBLC procedure between centres, which would result in more reliable results in future studies.

### Conclusion

In conclusion, our meta-analysis demonstrates that TBLC contributes to the diagnosis in a great number of patients under study for ILD, with a reasonable safety profile, particularly in centres with more experience. Therefore, it should be considered as an alternative to SLB or at least as a first-line procedure for lung tissue sampling. Guidelines on TBLC techniques should improve the diagnostic yield and reduce the risk of complications.
