Order of Authors: Takako Fukazawa, Dr.; George Havenith, Dr.

Abstract: Relevance of local skin wettedness (w_{local}) to general thermal comfort while wearing clothing was investigated in eight males. In the experiments, skin wettedness of the whole body (w_{body}) was controlled to be around the thermal comfort limit, while w_{local} in different target locations of equal area (anterior and dorsal torso, arms, and thighs) was pushed beyond the comfort limit using special test garments. Subjects walked on a treadmill at $4.5 \text{ km}\cdot\text{hr}^{-1}$ under $22 \text{ }^{\circ}\text{C}$ 50% RH. Arms and thighs were thermally in discomfort when their w_{local} exceeded 0.32. On the other hand, discomfort in the anterior and dorsal torso was initiated when their w_{local} arrived at 0.42 and 0.45. That is, the relation of the local comfort limit with w_{local} differed depending upon the location. It was observed however, that general discomfort was not induced when w_{body} remained below 0.36 even if w_{local} was higher than its local comfort limit.

Opposed Reviewers:

Dear Sirs:

Please find our paper entitled

“Differences in comfort perception in relation to local and whole body skin wettedness “.

We would be grateful if you would kindly review our paper for publication in European Journal of Applied Physiology.

Thank you for your kind consideration.

Best regards,

Takako Fukazawa, Ph. D.

4 **Introduction**

5 Temperature sensation and thermal discomfort have a high correlation with skin surface temperature in
6 cold environments. On the other hand, in warm environments or during exercise, thermal discomfort is more
7 highly correlated to sweating than to the skin surface temperature, because the skin temperature is
8 maintained at a favourable level due to evaporative cooling by the sweating. Winslow et al. [1939] suggested
9 that one of the factors for this thermal discomfort was the level of wettedness over the skin surface, which is
10 now widely known as an index (w) for the skin wettedness [Gagge et al. 1937].

11
12 Gagge et al. [1969] found that a state of thermal comfort can be realised when the skin wettedness of the
13 whole body remains below 0.3. This value is called the thermal comfort limit of the whole body. Therefore,
14 the skin wettedness can be recognised to be one of the most convenient indices to predict the thermal
15 comfort level for humans on the warm side [Havenith et al. 2002b].

16
17 Some studies [e.g., Gonzalez et al. 1998] employed the relation between the thermal comfort sensation
18 and the skin wettedness to improve work environments or clothing design for comfort and protection. They
19 studied the relation through the condition in the trunk area due to its high sweat rate and large surface area in
20 the whole body. On the other hand, recent reports [e.g., Toftum et al. 1998; Koshiba and Tamura 1995] have
21 shown that thermal and humid sensitivities in the body depend upon the region. For instance, cold/warm
22 thresholds in the trunk are higher than those in other area [Uchida and Tamura 2007] due to smaller numbers
23 of cold/warm spots on the skin [e.g., Choi and Seol, 2001]. Results of these reports imply that the thermal
24 comfort limit for wettedness of the body may also be different for individual locations. It could also be that,
25 rather than comfort being related to the mean whole body w (w_{body}), it may be dominated by a single zone,
26 most likely the wettest one (w_{local}).

27
28 Furthermore, the production of sweat differs for different body regions [Havenith et al. 2008;
29 Machada-Moreira et al. 2007]. This different production, combined with possible differences in regional
30 evaporation induced by differing convection currents over different skin areas, will in itself lead to different
31 wettedness distributions. As the latter is heavily influenced by clothing design (ventilation openings, wicking
32 etc), knowledge of regional skin wettedness sensitivity is of the utmost importance in the design and
33 optimisation of clothing.

34
35 Thus, in the present study, local thermal comfort limits were investigated through experiments on subject
36 while manipulating the regional skin wettedness. The skin wettedness of the whole body was controlled to be
37 maintained around the comfort limit of the whole body, while that of a selected target region of the body was
38 kept higher than the limit in order to examine relevance of the local skin wettedness to whole body thermal
39 comfort.

40
41
42
43
44
45
46
47
48
49 **Experimental design**

50 In this study, skin wettedness for both the whole and individual regions were simultaneously controlled at

1
2
3
4 the desired level by means of a combination of custom made over-all garments, the exercise level and the
5 environmental condition.
6

7 ***Design of the test garment for the study***

8
9 Four regions in the body, front trunk (Front: chest and belly), back trunk (Back: back and buttock), arms
10 (Arms: forearm and upper arm), and thighs (Thighs) were selected as target locations, all with similar surface
11 areas as shown in Table 1.
12

13
14 In the experiment, the skin wettednesses in both the whole body and a target location was manipulated
15 simultaneously by means of 5 types of test garments shown in Fig. 1; four of them were designed to increase
16 the skin wettedness in a specific region above the comfort limit of the whole body, while the last one was for
17 control.
18

19
20 All of the test garments were basically made of polyester fleece material with a high permeability for both air
21 and water vapour (intrinsic local thermal resistance= $0.14 \text{ m}^2\text{K}\cdot\text{W}^{-1}$; intrinsic local water vapour resistance=
22 $554 \text{ s}\cdot\text{m}^{-1}$ hereafter, permeable). For the individual target location in the each test garment, however, the same
23 fleece as used elsewhere was laminated externally with polytetrafluoroethylene (PTFE) membrane to reduce
24 the local vapour permeability (intrinsic local thermal resistance= $0.15 \text{ m}^2\text{K}\cdot\text{W}^{-1}$; intrinsic local water vapour
25 resistance= $1,056 \text{ s}\cdot\text{m}^{-1}$; hereafter, impermeable). The employed test garments provided an almost identical
26 thermal resistance of about $0.14 \text{ m}^2\text{K}\cdot\text{W}^{-1}$, while they showed larger water vapour resistances in the
27 individual target location than in the remaining parts.
28
29
30
31
32
33

34 ***Experimental design for the study***

35
36 Although thermal comfort can be realised when the skin wettedness is kept below 0.3, target mean skin
37 wettedness in the whole body (w_{body} , henceforth) was selected as 0.4 in the experiment, as participants may
38 not provide accurate information about thermal comfort sensations if they are in the near neutral state
39 [Toftum et al., 1998]. In order to detect the change from comfort to discomfort with sufficient sensitivity, the
40 experiment was designed to slowly raise w_{body} over time, achieving a value of 0.4 by the end of the exposure.
41 If loaded too lightly, discomfort may not occur. If loaded too heavily, the transition to discomfort may go too
42 fast and not provide the information desired. In order to induce the desired w_{body} at around 0.4, the subject
43 must generate a specific level of energy, which is equivalent to 3 METs of metabolic heat production
44 according to Nishi and Gagge [1977]. In the study, the desired w_{body} was attained by sweating through
45 walking at $4.5 \text{ km}\cdot\text{hr}^{-1}$, equivalent to a heat production of 314 watts for the standard person [ISO 8996 1990].
46
47
48
49
50
51
52
53

54 Environmental conditions were decided upon based on the interaction between metabolism, air velocity
55 [ISO 7730 1995], heat and water vapour transfer from the clothed body and thermal and water vapour
56 resistances of clothing [Havenith 2002; Havenith et al. 2002; Nishi and Gagge 1970; Lotens 1993].
57

58 Humidity or stuffiness sensations are perceived when water vapour pressure at the skin exceeds a particular
59 value ranging from 15 mmHg to 22 mmHg [e.g. Tamura and Koshiba 1995; Ushioda et al. 1995]. According
60
61
62
63
64
65

1
2
3
4 to numerous papers dealing with clothing thermal comfort [e.g. Harada1996; Suzuki 1932], we can stay in
5 neutral or comfort condition thermally when the microclimate is maintained at a condition of 32 °C with
6 50 %RH (= 18 mmHg) under any external environmental conditions. Under these conditions, the mean skin
7 temperature becomes 33 °C. Thus, mean skin temperature during the experiments should be kept at around
8 33 °C, because the thermal comfort cannot be accomplished if the mean skin temperature is above 35 °C
9 [Mochida 1994].
10
11

12
13
14 To achieve the desired w_{body} (pilot studies), the environmental condition was regulated at 22 °C air and
15 wall temperatures and 10 mmHg in absolute water vapour pressure (50.5 %RH). Air velocities of, 0.1 and
16 0.2 m·s⁻¹ were chosen at rest and during the exercise periods, respectively.
17
18
19

20 **Experiment**

21 ***Subjects***

22
23
24 Eight healthy un-acclimatized Europeans male university students (age 22.4 ± 4.2 years, height 178.8 ±
25 6.2 cm, weight 74.7 ± 8.8 kg, and BMI 23.4 ± 2.7 kg·m⁻²) served as test volunteers in the experiment. All
26 subjects were given full information about the purpose, procedure, and risks prior to the experiment. They all
27 expressed an understanding of the experiments by signing a statement of informed consent.
28
29

30 ***Procedure and Measurements***

31
32 The experiments were conducted in a climate chamber for 65 min in total, in which air and wall
33 temperatures, relative humidity, and air velocity were maintained at the targeted conditions. In the first 15
34 min, the subject rested and then they started the exercise of walking on a treadmill (Tunturi,
35 T-treck-gamma-300, Finland) till the end of the experiment. During the experiment, aural canal temperature
36 was measured using a thermistor (Grant, UK) as core temperature. Eight skin temperatures (forehead,
37 scapula, chest, upper arm, forearm, hand, thigh, and calf) were measured by Thermocouples (T-type, Omega,
38 UK). A mean skin surface temperature was calculated from the obtained skin temperatures and the mean
39 saturated water vapour pressure at the skin as well [Nishi and Gagge 1970; ISO 9886 2004]. Hygrometers
40 (Sensirion, Switzerland) were placed on 4 locations of scapula, chest, upper arm, and thigh. These
41 parameters were recorded in data loggers (Grant Squirrel, UK and MSR, Switzerland) continuously with an
42 interval of 1 min. A subjective questionnaire was also completed for the thermal comfort sensations of the
43 whole body and the individual target location using a seven-point Likert scale (very comfortable to very
44 uncomfortable).
45
46
47
48
49
50
51
52
53

54 Before the commencement of the first experiment, the subjects were instructed how to answer the
55 psychological thermal sensations and how to fill the questionnaire. The subject arrived at the laboratory at
56 least 30 min before starting the measurement. Upon arrival, the subject was equipped with the temperature
57 sensors and the hygrometers. After the application of all instrumentation, the subject dressed in the test
58 clothing, and socks and shoes and was then weighed, fully clothed, by an electronic balance (Sartorius,
59
60
61
62
63
64
65

Germany, 150 kg; resolution 1g).

Skin wettedness

Skin wettedness (w , dimensionless) is defined as

$$w = \frac{q_{sw}}{q_{e\max}} + 0.06, \quad (1)$$

where q_{sw} is the evaporated heat flux from the clothed body caused by regulatory sweating ($\text{W}\cdot\text{m}^{-2}$), $q_{e\max}$ the maximal evaporative heat flux from the body with the actual clothing and skin surface temperatures for a totally wet skin ($\text{W}\cdot\text{m}^{-2}$), and 0.06 the minimal skin wettedness by skin diffusion (dimensionless). The rate of $q_{e\max}$ can be obtained by the following equation:

$$q_{e\max} = \frac{C_{sk,s} - C_e}{R_D} \cdot L, \quad (2)$$

where $C_{sk,s}$ is the saturated water vapour concentration of the skin surface ($\text{kg}\cdot\text{m}^{-3}$), C_e the water vapour concentration of the environment ($\text{kg}\cdot\text{m}^{-3}$), R_D the over-all water vapour resistance from the skin surface to the environment ($\text{s}\cdot\text{m}^{-1}$), L the latent heat coefficient ($2,430 \text{ kJ}\cdot\text{kg}^{-1}$). The actual evaporated heat flux from the body with the clothing, q_{sk} , can be obtained by:

$$q_{sk} = \frac{C_{sk} - C_e}{R_D} \cdot L, \quad (3)$$

where C_{sk} is the water vapour concentration of the skin surface ($\text{kg}\cdot\text{m}^{-3}$). In Eq. 3, q_{sk} consists of the evaporated heat fluxes by the regulatory sweat and by the skin diffusion. Accordingly, it can be also expressed as

$$q_{sk} = q_{sw} + q_{diff}, \quad (4)$$

where q_{diff} is the evaporated heat flux by the skin diffusion ($\text{W}\cdot\text{m}^{-2}$). This q_{diff} can be obtained using Eq. 1 as

$$q_{diff} = 0.06 \cdot q_{e\max}. \quad (5)$$

Thus, from Eqs. 1, 3, 4, and 5, we can obtain the following equation for calculating the skin wettedness simply using C_{sk} , $C_{sk,s}$ and C_e

$$w = \frac{q_{sk}}{q_{e\max}} = \frac{C_{sk} - C_e}{C_{sk,s} - C_e}. \quad (6)$$

Statistics

In the present study, the primary independent variable is the test garment (5 levels), or in other words, the individual target location. Dependent variables are aural canal and skin surface temperatures, skin wettedness, and thermal comfort sensations. These measured data over time are analysed by a two-way analysis of variance with repeated-measures (ANOVA) using the data taken every 5 min. The effect of the w_{local} upon thermal comfort of the whole body is rated by means of one-way ANOVA. In all analyses, $p < 0.05$ is used to

1
2
3
4 establish a significant difference. Regression analysis is performed to assess the correlations among thermal
5 comfort sensations, the aural canal temperature, and the skin wettedness. Data in figures and tables are given
6 in terms of the mean values and their standard deviation (SD).
7
8
9

10 **Results**

11 ***Confirmation of the obtained data***

12
13
14 Figure 2 shows the variation of the skin wettedness of the whole body (w_{body}) over time. A main effect of
15 time is observed ($p < 0.001$). However, no significant difference in w_{body} between garments is observed ($p =$
16 0.50), indicating that w_{body} was successfully kept at a similar level during the whole period of the experiment
17 for all test garments. In the experiment, w_{body} stayed around 0.15 during the rest period. Then w_{body} gradually
18 increased from about 10 min after starting the exercise, rising to 0.38-0.40 at end of the experiment. Table 2
19 shows the obtained experimental data of temperature, water vapour concentration, wettedness of the skin
20 surface in the individual target locations during the first and the last 15 min. Results of one-way ANOVA
21 indicate that in all the locations, both the initial and the last w 's in the individual target location show
22 significantly higher values than the other zones because of the significantly high water vapour concentration
23 of the skin due to the impermeable fabric. In general, there is, however, no difference in the skin surface
24 temperature in the individual target location.
25
26
27
28
29
30
31

32 Figure 3 indicates the w 's in the 4 target locations during wearing the test garments of Types A to D for the
33 last 15 min in the experiment. Results of the one-way ANOVA for w on the individual target locations in
34 different test garments show that w_{local} for the target locations was always significantly higher when that area
35 was covered with the low permeability fabric than for the all the other garments: Front trunk, garment of
36 Type A: ($p < 0.001$); Back trunk, Type B: ($p < 0.001$); Arms, Type C: ($p < 0.01$) and Thighs, Type D: ($p <$
37 0.001).
38
39
40
41

42 Thus, we confirmed that the w 's in both the whole body and the target locations were maintained
43 simultaneously at the aimed levels (equal for w_{body} , and raised w_{local} for targeted area) according to the results
44 mentioned above.
45
46
47
48

49 ***Thermal comfort sensation in the whole body***

50 In Fig. 4, w_{body} is plotted against thermal comfort sensation. This figure includes all the data from the
51 whole period of the experiment and shows the mean values of every 5 min for each test garment. The thermal
52 comfort of the whole body is in inverse proportion to the w_{body} for all the tested garments. A high, significant,
53 correlation is found between the thermal comfort sensation and w_{body} ($r = 0.92$; $p < 0.001$). Based on these
54 data, the thermal comfort limit for the whole body in the experimental conditions is found to be 0.36 (SD
55 0.05) in terms of the w_{body} . The thermal comfort sensation for the whole body can be given by
56
57
58
59

$$60 \text{ Thermal comfort sensation} = -7.30 \cdot w_{body} + 2.60 \quad (7)$$

61
62
63
64
65

1
2
3
4
5
6 *Local thermal comfort sensation*

7 The local thermal comfort sensations in the 4 target locations are illustrated as a function of their w_{local} 's
8 in Figs. 5-1 to 5-4. The plotted data are results obtained on all the 5 test garments during the whole period of
9 the experiment. The individual local thermal comfort decreases with the increasing w_{local} and is inversely
10 proportional to the w_{local} expressed by their regression lines.
11
12

13
14 @ Front Local thermal comfort sensation = $-5.15 \cdot w_{Front} + 2.06$ (8)

15 @ Back Local thermal comfort sensation = $-3.88 \cdot w_{Back} + 1.75$ (9)

16 @ Arms Local thermal comfort sensation = $-7.73 \cdot w_{Arms} + 2.47$ (10)

17 @ Thighs Local thermal comfort sensation = $-6.48 \cdot w_{Thighs} + 2.08$ (11)

18
19 Their correlation coefficients are found to be higher than 0.7 with a high significance of $p < 0.001$ in all the 4
20 target locations.
21
22

23
24
25 ***Correlation among comfort sensation, temperature, and wettedness of the skin surface***

26 Results of correlation analysis between the thermal comfort sensation in the whole body and temperature
27 and wettedness of the skin surface are summarised in Table 3. Significant correlations have been observed
28 between comfort sensation of the whole body and wettednesses of the four target locations, though these
29 correlations are lower. Correlations of the comfort sensation with the local skin surface temperatures are only
30 significant for the Back and Arms, not for the Front and Thighs.
31
32

33 Table 4 presents correlation coefficients of local comfort sensation and local skin surface temperatures
34 and local wettedness in the individual target location. Correlations of the local thermal comfort are found to
35 be significant with both the local skin temperature and wettedness in the Back and Arms. For the Front and
36 Back only the correlation of the local comfort with the local skin wettedness was significant, the correlation
37 with skin temperature was not.
38
39
40
41
42
43
44

45 **Discussion**

46 ***Correlation of the thermal comfort and the skin wettedness***

47 When we are in warm environments or during exercise, thermal comfort sensation is more strongly
48 related to the level of skin wettedness than to the temperature of the skin surface [Winslow et al., 1939]. In
49 the present study indeed, the obtained results indicate that the whole body thermal comfort sensation is
50 mainly caused by the skin wettedness. This conclusion can be deduced from Tables 3 and 4. That is, in
51 Tables 3 and 4, absolute values of the correlation coefficients of thermal comfort with skin wettedness (w)
52 are larger than those with the skin surface temperature both for the whole body and for the target locations,
53 except for the Arms. Accordingly, the thermal comfort sensation depends mainly upon the w in the present
54 experimental conditions.

59
60
61
62
63
64
65

1
2
3
4
5
6 ***Relevance of local skin wettedness to thermal comfort in the whole body***

7
8 According to the obtained results and the derived Eq. 7, the thermal comfort limit of the whole body is
9 found to be 0.36 (SD 0.05) in terms of w_{body} . This comfort limit is slightly higher than often quoted value of
10 0.25 – 0.3 [Gagge et al. 1969; Takanokura 1997] but is still close to the usual range. (This reason will be
11 discussed later). It is important to note that this comfort limit for the whole body is obtained under conditions,
12 in which w_{local} in the target different locations is considerably higher than in the rest of the body. This
13 indicates that the local thermal comfort does not influence significantly the general thermal comfort within
14 the present experimental condition (see Fig. 2).
15
16
17
18

19 In the present study, the thermal comfort limit for the whole body was found to be 0.36 in terms of w_{body} .
20 Gagge et al. [1969] reported that the general thermal comfort state was maintained when the w_{body} was less
21 than 0.25 - 0.3 through their experiment using subjects without clothing at rest. Takanokura [1997]
22 performed a series of experiments with clothed young females to examine influence of water vapour
23 adsorbability of clothing upon the thermal comfort sensation. In her study, the subjects at rest were kept in
24 thermally comfort state till w_{body} reached 0.25 - 0.3. These reported values of the thermal comfort limit are
25 smaller than the ones obtained in the present study. However, Nishi and Gagge [1977] have found that the
26 thermal comfort limit depends upon metabolism due to exercise e.g.; the comfort limit increases with the
27 increasing metabolic heat production. In case the body produced heat energy of 1 Met, comfort was if w_{body}
28 was less than 0.22, but the comfort limits for 2 and 3 Mets were observed to be 0.29 and 0.36, respectively.
29 In the present study, the employed exercise condition was 4.5 km·hr⁻¹ walking, equivalent to a metabolic heat
30 production of 3 Mets [ISO 8996 1990]. Thus, the observed thermal comfort limit in the present study of 0.36
31 shows excellent agreement with the prediction given by Nishi and Gagge [1977] and the differences with
32 earlier studies can be attributed to the difference in the metabolism [Gagge et al. 1969; Takanokura 1997].
33
34
35
36
37
38
39
40
41

42 In the present study, head as well as face and hands were exposed to the environment. Those regions
43 remained in a comfortable state during the whole period of the experiment. This may be one of the reasons
44 why the thermal comfort state of the whole body was not affected by the local thermal comfort sensation of
45 the target zones, because head, face, and hands are predominant regions for the general thermal comfort as
46 reported by Zhang et al. [2004]. According to Boutcher et al. [1995] and Kato et al. [2001], face and head are
47 so sensitive against the thermal stimulus that the thermal sensation in the whole body is effectively
48 dominated by their local thermal sensations. They have shown that the body in warm discomfort can be
49 changed to comfort condition when face and head were given a cooling treatment. Mori et al. [2004] found
50 experimentally and theoretically that the increased core temperature dropped when a cooling treatment was
51 given to the head. Okada and Fukai [2003] demonstrated that a treatment of cooling/warming for hands
52 brings the body into thermal comfort, while the core temperature stays higher/lower than the appropriate
53 level. Accordingly we can conclude that, in case when the effective parts such as head, face, and hands on
54

65

1
2
3
4 the thermal comfort sensation are kept in comfort state, the thermal comfort in the whole body does not
5 depend upon w_{local} , but links to w of the clothed areas within the limits of this study ($w_{body} < 0.4$).
6
7

8 9 ***Local thermal comfort limit and local thermal comfort sensitivity***

10 It is found in Fig. 5 that each correlation coefficient is so high that the obtained individual correlation line
11 is reliable and thus it is useful to discuss the relation between the w_{local} and that area's thermal comfort
12 sensation. Slopes of the regression lines in the 4 target locations are shown in Fig. 6, which indicates the rate
13 of change in the thermal comfort due to the increase in the w_{local} . In other words, this slope represents
14 'thermal comfort sensitivity'. According to the comparison of the local thermal comfort sensitivity among
15 the target locations, it is found that the slope of the Front is remarkably gentler than that of the Arms, while it
16 is steeper than that of the Back. The thermal comfort sensitivity of the Back is significantly lower than that of
17 the Arms (all $p < 0.05$). No significant difference is found between the Thighs and the other locations
18 because of the large SD, though the difference between Thighs and Front approaches significance ($p = 0.052$).
19 In addition, there is a tendency in thermal comfort sensitivity of Thighs to be different from those of the
20 Back and Arms (both $p = 0.19$). The general picture is that of a higher sensitivity in the periphery compared
21 to the torso.
22
23

24 The thermal comfort limits can be obtained for the individual target location using the regression lines
25 from Figs. 5-1 to 5-4, as statistical significances have been confirmed in the thermal comfort sensitivity as
26 shown in Fig. 6. According to these regression lines, the subjects sensed their skin surface humidity as
27 negative in the Arms and the Thighs around $w_{local} = 0.32$. On the other hand, comfort limits in the Front and
28 the Back are 0.40 and 0.45, respectively.
29

30 The comfort limits in the Arms and the Thighs are thus lower than those in the Front and the Back, consistent
31 with a higher sensitivity, and consistent with Toftum et al.'s data [1998]. Following a different technique,
32 they have reported that perception of arms against humidity is more sensitive than those of chest and back. It
33 can be inferred through the present study that the local thermal comfort sensitivity has a great deal of
34 relevance to the humidity sensation because the w becomes a predominant factor in the thermal comfort
35 under warm environments or during exercise. This fact was firstly pointed out qualitatively by Winslow et al.
36 [1939] 70 years ago. The present study confirmed this tendency based on the quantitative statistical treatment
37 for the individual locations.

40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 ***Relation between the evaporative heat flux and thermal comfort sensation***

55 In order to discuss the influence of magnitude of the released evaporated heat flux from the skin surface
56 (q_{sk}) upon the thermal comfort sensation, q_{sk} from the individual location within the test garments of type A
57 to D were calculated employing Eq. 3. The water vapour resistance R_D in the equation was determined on a
58 thermal manikin (Measurement Technology Northwest, USA, Newton). According to the manikin
59
60
61
62
63
64
65

1
2
3
4 measurement, the water vapour resistances of the permeable and the impermeable zones in the test garment
5 were obtained as 691 and 1,192 s·m⁻¹, respectively.
6

7 Figs. 7-1 to 7-4 show the calculated q_{sk} from the body surface in the individual location. No difference is
8 observed in q_{sk} for a specific location caused by the suits. It seems that transferred mass fluxes are almost
9 unchanged by the difference in resistance. Considering Eq. 3, it is thus obvious that the increased resistance
10 of the impermeable fabrics is fully compensated for by an increased vapour pressure at the skin, compared to
11 the permeable fabric condition. On the other hand, magnitude of q_{emax} , which can be calculated through Eq. 2,
12 is considerably different in the individual target locations. In the target location of Front, the q_{emax} in type A
13 indicates a steady rate of 52 to 57 W·m⁻² for the whole test period, while those in types B to D show a larger
14 rate of 76 to 94 W·m⁻². Therefore, in the present study, the magnitude of the q_{emax} directly dominates the level
15 of the skin wettedness, as no difference is found in the skin surface temperature (see Table 2) and q_{sk} for each
16 location. It should be noted that there is a limit to the compensation of higher vapour resistance by increased
17 vapour pressure at the skin. These areas' vapour pressure will reach saturation earlier than in the case of
18 permeable clothing, and once that happens q_{sk} will fall behind for the impermeable fabric area.
19

20 It is of practical importance to improve clothing design for comfort and protection in terms of the heat
21 and water vapour transfer through the clothing. In order to maintain the human body totally in thermal
22 comfort under warm conditions and during exercise, q_{emax} must be kept at a high level especially in
23 extremities such as arms and thighs.
24
25
26

27 **Conclusion**

28 Local thermal comfort limits for local skin wettedness differ between different skin locations of the body.
29 Sensitivity of thermal comfort sensation to skin wettedness is more sensitive in extremities than on the trunk.
30 The thermal comfort of the whole body however, is not so much influenced by that of individual locations in
31 the present experimental conditions. Although locally thermal discomfort is sensed based on local skin
32 wettedness, the thermal comfort limit of the whole body is found to be 0.36 in terms of the whole body skin
33 wettedness, independent of the location where skin wettedness was raised above normal. That is; the whole
34 body can remain in thermally comfortable condition even when the local skin wettedness stays higher than
35 the comfort limit.
36
