Diffusion Basis Functions Decomposition for Estimating White Matter Intravoxel Fiber Geometry

Alonso Ramirez-Manzanares*, Mariano Rivera, Baba C. Vemuri, *Fellow, IEEE*, Paul Carney, and Thomas Mareci

Abstract—In this paper, we present a new formulation for recovering the fiber tract geometry within a voxel from diffusion weighted magnetic resonance imaging (MRI) data, in the presence of single or multiple neuronal fibers. To this end, we define a discrete set of diffusion basis functions. The intravoxel information is recovered at voxels containing fiber crossings or bifurcations via the use of a linear combination of the above mentioned basis functions. Then, the parametric representation of the intravoxel fiber geometry is a discrete mixture of Gaussians. Our synthetic experiments depict several advantages by using this discrete schema: the approach uses a small number of diffusion weighted images (23) and relatively small b values ($1250 \, \text{s}/\text{mm}^2$), i.e., the intravoxel information can be inferred at a fraction of the acquisition time required for datasets involving a large number of diffusion gradient orientations. Moreover our method is robust in the presence of more than two fibers within a voxel, improving the state-of-the-art of such parametric models. We present two algorithmic solutions to our formulation: by solving a linear program or by minimizing a quadratic cost function (both with non-negativity constraints). Such minimizations are efficiently achieved with standard iterative deterministic algorithms. Finally, we present results of applying the algorithms to synthetic as well as real data.

Index Terms—Axon fiber pathways, basis pursuit, diffusion basis functions, diffusion weighted MRI (dW-MRI), high angular resolution diffusion images (HARDI), intravoxel.

I. Introduction

WATER diffusion estimation has been used extensively in recent years as an indirect way to infer axon fiber pathways and this in turn has made the estimation of fiber connectivity patterns *in vivo*; one of the most challenging goals in

neuroimaging. For this purpose, a special magnetic resonance imaging (MRI) technique named diffusion weighted MRI (DW-MRI) is used. This imaging technique allows one to estimate the preferred orientation of the water diffusion in the brain which, in the white matter case, is usually constrained along the axon orientations. This information is very useful in neuroscience research due to the changes that occur in the neural connectivity patterns with neurological disorders and, in general, with brain development [1], [2].

The water diffusion angular variation has been summarized, in most medical applications, by diffusion tensor MRI (DT-MRI) [3], [4]. In [5], Stejskal–Tanner presented a mono-exponential model of the decayed magnetic resonance (MR) signal. Afterwards, Basser *et al.* [3] developed the DT model

$$S(\mathbf{q}_k, \tau) = S_0 \exp\left(-\mathbf{q}_k^T \mathbf{D} \mathbf{q}_k \tau\right) + \varepsilon_k \tag{1}$$

where the anisotropic diffusion coefficients are summarized by the (3×3) symmetric positive definite tensor $\mathbf{D}$, S_0 is the measured signal in the absent of a diffusion magnetic field gradient (a standard $T2$ image [1]), the attenuation factor on the observed DW-MR signal $S(\mathbf{q}_k, \tau)$ is determined by the gradient diffusion vector $\mathbf{q}_k$, the tensor $\mathbf{D}$ and the effective diffusion time τ. The gradient diffusion vector $\mathbf{q}_k = \gamma \delta G \mathbf{g}_k$, where γ is the gyromagnetic ratio, δ is the duration for which the directional magnetic gradient is applied, G is the magnitude of the applied diffusion magnetic field gradient and the unit vector $\mathbf{g}_k = [g_{kx}, g_{ky}, g_{kz}]_{k=1,\ldots,M}^T$ indicates the kth orientation of the diffusion-encoding gradients. In model (1), ε_k represents noise with Rician distribution, see [6] and Appendix. A standard protocol for indirectly measuring water diffusion consists in acquire M 3-D images along independent orientations $\mathbf{g}_k$. A convention is to let $b = (\gamma \delta G)^2 \tau$ and thus making b (denoted in s/mm^2) a constant directly proportional to the magnitude of the diffusion vectors and the acquisition time.

Given S_0 and at least six measurements $S(\mathbf{q}_k, \tau)_{k=1,\ldots,6}$, the DT is estimated by a least squares (LS) procedure [3], [7]. The DT can be visualized as a 3-D ellipsoid, with the principal axis aligned with the eigen-vectors, $[\hat{e}_1, \hat{e}_2, \hat{e}_3]$, and scaled by the eigen-values, $\lambda_1 \geq \lambda_2 \geq \lambda_3$. Such eigen-values indicates diffusivity along the eigen-vectors. Thus, $\hat{e}_1$ is named the principal diffusion direction (PDD) and is associated with the orientation of the fibers in the case of a single fiber bundle within a voxel. Therefore, the partial volume effect limits the capacity of determining the fiber orientations: the observed DT at voxels where two or more fibers cross, split, or merge is the av-

erage of the diffusion in the constituent fiber orientations. Thus, the DT inadequately represents such an intravoxel information [8]–[10].

On the other hand, the computation of nonparametric diffusivity coefficients with high angular resolution diffusion images (HARDI) fails to estimate correctly two or more fiber orientations (as the apparent diffusion coefficient (ADC) map [11]), as is deeply discussed in [11]–[14].

In this work, we use the Gaussian mixture model (GMM) as a more plausible model for the decayed signal phenomenon [12]

$$S(\mathbf{q}_k, \tau) = S_0 \sum_{j=1}^{L} \beta_j \exp\left(-\mathbf{q}_k^T \mathbf{D}_j \mathbf{q}_k \tau\right) + \varepsilon_k \qquad (2)$$

where the real coefficients $\beta \in [0, 1]$ indicate the contribution of the tensor $\mathbf{D}_j$ (the fiber oriented with $\mathbf{D}_j$) to the total DW signal, i.e., $\left(\sum_j \beta_j = 1\right)$. The GMM explains quite well the diffusion phenomenon for two or more fibers within a voxel under the assumption of no exchange between fibers, i.e., the signals are independently added. The GMM was explored by Basser *et al.* in [15]; they concluded that its solution requires a large number of measurements $S(\mathbf{q}_k, \tau)$, and remarked the numerical problems because of the nonlinearity. Frank [16] expanded his spherical harmonic decomposition (SHD) method to the N-fiber case by using the model (2). Parker and Alexander [17] used the Levenberg–Marquardt algorithm to fit the GMM. Recently, Özarslan *et al.* [14] used the GMM to perform an important refinement in their diffusion orientation transform (DOT) for computing a diffusion displacement probability. See [1] for more details about model in (2).

However, in the best of our knowledge, the GMM has not been efficiently fitted to the DW-MR signals. We describe below the better implementations for this aim. Tuch *et al.* [12], [13], proposed a nonlinear LS method for fitting (2). That approach fixed the eigen-values for the diffusion tensors and solves the GMM for the number of tensors, L, the coefficients, β, and the tensor's orientation angles. The drawbacks of the method are the large number of required diffusion images $\{S\}$ that notably increases the acquisition time (for instance, 126 diffusion 3-D-images are used in [12] and [13] and more recently 54 measurements in [17]) and the algorithmic problems related to the nonlinearity of (2). Thus, multiple restarts of the optimization method are required for preventing the algorithm from settling in a local minimum. Note that it is necessary to choose between fit a single Gaussian or a GMM, or to fit both and then choose the one which explains better the DW-MR signals. Furthermore, no stable solution has been reported for more than two fiber bundles, i.e., for $L > 2$ (see [12] and [13, Ch. 7]).

Another interesting model-based approach is reported in [18], by assuming that the observed diffusion signal results from the hindered (extra-axonal space) and the restricted (intraaxonal space) water diffusion. Although such a model was extended to a multifiber case, the above explained model-selection problem is present.

Q-space method is an alternative nonparametric representation. This method is based on the diffusion spectrum imaging (DSI) [19]–[21], by exploiting the Fourier transform (FT) rela-

tionship from which an ensemble average probability (EAP) is computed. The EAP [13], [22] is defined as

$$P(\mathbf{r}) = S_0^{-1} \int S(\mathbf{q}, \tau) e^{-i\mathbf{q}^T \mathbf{r}} d\mathbf{q} = \mathcal{F}^{-1}\left[E(\mathbf{q}, \boldsymbol{\tau})\right] \qquad (3)$$

where the displacement vector $\mathbf{r} = \mathbf{r}_e - \mathbf{r}_0$ defines the particle displacement (located at $\mathbf{r}_0$ at the beginning and at $\mathbf{r}_e$ at the end of the experiment), $\mathcal{F}^{-1}$ denotes the inverse FT with respect to the diffusion vector $\mathbf{q}$, and $E(\mathbf{q}, \tau) = S(\mathbf{q}, \tau)/S_0$. The nonparametric DSI can represent several fibers within the voxel, although the large number of required DW images makes the method impractical for medical purposes. Recent methods for recovering EAP, as Q-ball [23], persistent angular structure (PAS) [24] or DOT [14] have demonstrated good results with a smaller number of diffusion images; for instance, in [24] are used 54 measurements. However, it is desirable to diminish this number for practical purposes. A drawback in the previous methods is that, for estimating the intrafiber orientations, the maxima of the EAP need be computed as a postprocessing [13], [14], [22], [23].

Recently, spherical-deconvolution techniques explain DW-MR signals as the convolution of a single fiber response with the fiber orientation distribution (FOD). FOD is represented with a linear basis for spherical functions in [25] and [26], and in [27] was proposed a maximum-entropy formulation of the spherical deconvolution (MESD) problem with a nonlinear deconvolution kernel (a generalization of PAS method). Although [27] presented better results, the method does not guarantee the attainment of the global minimum and requires a significant computational effort. In [28], it is proposed a simple axial symmetric model of diffusion, where the angular distribution of fibers is computed by a deconvolution process and by assuming constant, both, mean diffusivity and perpendicular diffusivity in all the white matter (a similar assumption was used in [26]).

In most previous works [12], [14], [23], [25], [26], [28], large b-values (larger than $2000 \, \text{s/mm}^2$) or large datasets are required for recovering good angular resolution, which is somewhat impractical in a clinical setting. In a recent article [10], a regularization-based approach was proposed for recovering the underlying fiber geometry within a voxel. That approach reconstructs the observed tensors as a linear combination of a given tensor basis. However, the multitensor model is computed from previously fitted DTs [instead of the raw measurements $S(\mathbf{q}_k, \tau)$] and thereby important information is lost.

In this paper, a novel method for reconstructing the intravoxel information is presented. We note that present work extends previous conference papers [29], [30]. The method is based on the solution of a discrete version of the parametric model in (2). Synthetic experiments for a realistic situation demonstrate the advantages of our method: the intravoxel information for more than two axon fibers can be inferred at a fraction of the acquisition time with respect to methods that require a larger set of DW-MR images ($M \geq 54$) or large b values ($b \geq 2000 \, \text{s/mm}^2$). We present two variants of our method: one based on the minimization of a linear programming (LP) problem (which is computationally more efficient) and another based on the minimization of a regularized quadratic cost

function (which improves the quality of the results for noise corrupted data), both with nonnegativity constraints.

II. DIFFUSION BASIS FUNCTIONS

In this section, we propose a discrete diffusion model based on the GMM in (2). In order to simplify the solution of such a model, we propose to use a set of diffusion basis functions (DBF) $\{\phi\}$, which are generated from a tensorial basis as the one used in [10]. Such a tensor basis is defined as a fixed set of tensors $\bar{\mathbf{T}}$ with cardinality equal to N. The individual basis tensors $\bar{\mathbf{T}}_j$ are chosen, such that, they are distributed as uniformly as possible in the 3-D space of orientations, and their anisotropy is chosen according to prior information about longitudinal and transversal fiber diffusion. For the human brain, it is reasonable to assume that the anisotropy and magnitude of the water diffusion for a single fiber in white matter is almost constant in all the volume [12], [26], [28], we will discuss this topic in Section VIII. For instance, one could expect that longitudinal fiber diffusion is about five times the transversal one $[\lambda_1, \lambda_2, \lambda_3] \approx [1 \times 10^{-3} \text{ mm}^2/\text{s}, 2 \times 10^{-4} \text{ mm}^2/\text{s}, 2 \times 10^{-4} \text{ mm}^2/\text{s}]$ [1], [13]. However, these values could change among patients, so that, we instead recommend setting the basis eigen-values according to the procedure described in Section IV-A-2. By fixing the basis eigen-values, we reduce the degrees of freedom for the problem. Thus, we propose to model the DW-MR signal, at each voxel, with

$$S(\mathbf{q}_k, \tau) = \sum_{j=1}^{N} \alpha_j \phi_j(\mathbf{q}_k, \tau) + \eta_{\mathbf{q}_k} + \varepsilon_k \qquad (4)$$

with $\alpha_j \geq 0$; where we define the jth DBF by

$$\phi_j(\mathbf{q}_k, \tau) = S_0 \exp(\mathbf{q}_k^T \bar{\mathbf{T}}_j \mathbf{q}_k \tau) \qquad (5)$$

where $\phi_j(\mathbf{q}_k, \tau)$ is understood as the coefficient of the diffusion weighted signal for the diffusion vector $\mathbf{q}_k$ due to a single fiber modelled by the basis tensor $\bar{\mathbf{T}}_j$. The nonnegative α_j denotes the contribution of the jth DBF $\{\phi_j(\mathbf{q}_k, \tau)\}_{k=1,\dots,M}$. Note that the basis $\{\phi\}$ is incomplete, because the available orientations are a discretization of the 3-D space (see Section VIII). So that a residual $\eta_{\mathbf{q}_k}$ in the signal representation is observed. By choosing a basis with a large cardinality, we can diminish $\eta_{\mathbf{q}_k}$, until it becomes insignificant enough, and then neglected for practical purposes. As can be noted, an advantage in our model (4) is that the unknowns are the α-coefficients because the $\phi_j(\mathbf{q}_k, \tau)$ coefficients can be precomputed. In fact, we need to compute the best linear combination of DBFs that reproduce the signal S. This is illustrated in the 2-D schema shown in Fig. 1. Fig. 1(a) shows a single fiber case where we compute the α_j values that, given a set of five DBFs (continuous-blue lines) reproduce the $S(\mathbf{q}_k, \tau)_{k=1,\dots,M}$ measurements (dotted-red line) as accurately as possible; for this particular case, we expect $\alpha_3 \approx 1$. On the other hand, for the two fiber case [Fig. 1(b)], the α coefficients should reproduce the addition (cross-marked black line); in this case, we expect $\alpha_3 \approx \alpha_5 \approx 0.5$. Note that in our approach, we do not work with the schematized continuous measurements in Fig. 1, but with a discrete set of M samples (measurements).

Fig. 1. Two-dimensional schema of DBFs. (a) Continuous-blue line shows the DBFs generated by an uniformly distributed tensor basis with cardinality $N = 5$; the doted-red line shows the signal $S(\mathbf{q})$ generated by an arbitrary DT. (b) Schema for a two fiber case, the dotted-red line shows the $S(\mathbf{q}, \tau)$ measured signals for the two arbitrary tensors, the half-addition of both signals are shown in the cross-marked black line. See text for details.

Fig. 2. Normalized diffusion weighted signal $E(q)$ for a basis Tensor $\bar{\mathbf{T}}_j$ and its corresponding EAP. Black axis denotes the PDD.

Although in this work we use the free-diffusion model in (5) for setting the DBF, it is possible to use another diffusion model as the cylinder restricted diffusion model proposed in [31], see discussion in Section VIII.

By substituting our observation model (4) in the EAP in (3), we obtain

$$P(\mathbf{r}) = S_0^{-1} \sum_{j=1}^{N} \alpha_j \mathcal{F}^{-1} [\phi_j(\mathbf{q}, \tau)]. \qquad (6)$$

As the DBF is a Gaussian (according to the free-diffusion model) and the FT of a Gaussian results in a Gaussian $\left(\mathcal{F}[g((x), \Sigma)](\mathbf{w}) \propto g(\mathbf{w}, \Sigma^{-1})\right)$, then in our case, the EAP is a GMM with peaks oriented along the PDDs of the corresponding basis tensors. Moreover, the peaks in $P(\mathbf{r})$ are determined by the largest α_j and, therefore, also the fiber orientations. This is illustrated in Fig. 2 where we show for a given basis tensor the synthetic DW signal and the EAP computed with (3). As can be seen, the maxima of a single EAP in the GMM corresponds with the PDD of the associated basis tensor.

III. NUMERICAL SOLUTIONS FOR DBF MODEL

In this section, we present two procedures for estimating the coefficients α in (4). We first introduce the notation that will be useful in the following. The observation model (4) can be written in matrix form as

$$S = \mathbf{\Phi}\alpha + \eta \qquad (7)$$

with $\alpha_j \geq 0, \forall j$; $\boldsymbol{\Phi}$ is an $M \times N$ matrix where the jth column corresponds to the jth DBF ($\boldsymbol{\Phi}_j = [\phi_j(\mathbf{q}_k, \tau)]_{k=1,\dots,M}$) and $S \in \Re^M$ is the vector composed by all the DW signals. Note that because of our requirements, the matrix $\boldsymbol{\Phi}$ is rectangular: we want to acquire as few as possible S signals and to recover solutions with a high angular resolution; for instance we use $N = 129$ DBFs and $M = 23$ DW-MR images. Consequently, we have more unknowns, α's, than data, S's; the problem (7) is ill-posed and should be constrained or regularized in order to compute a meaningful solution.

In the following subsections, we introduce two algorithms for computing the best α vector by means of introducing prior information about desired features in the solution.

A. Basis Pursuit Algorithm

Compact signal representation is a well studied problem by signal processing researchers [32]–[34]. In that context, it is convenient to represent a given signal by a set of coefficients associated with elements of a dictionary (or base) of functions. The elements of such a dictionary are called *atoms* (or basis functions). The idea is to select from the dictionary the *atom* decomposition that best match the signal structure, using a criterion for choosing among equivalent decompositions. A commonly used criterion is the basic principle of sparsity, i.e., to represent the signal with fewest *atoms* as possible. Additionally, a desirable feature is to achieve the decomposition in a computationally efficient way.

In our notation, (7) is the mathematical model for representing the decomposition of the signal $S \in \Re^M$ as a linear combination of *atoms* $\boldsymbol{\Phi}_j$ in the dictionary $\boldsymbol{\Phi}$.

In [32], the basis pursuit (BP) technique was proposed for solving the problem (7), i.e., for computing the α coefficients. Based on the BP framework, we propose to compute a solution to (7) by means of an LP problem of the form

$$\min \quad \|\alpha\|_1 = \sum_j \alpha_j = \hat{e}^T \alpha$$

$$\text{subject to} \quad \boldsymbol{\Phi}\alpha = S, \quad \alpha_j \geq 0, \ \forall j \tag{8}$$

where $\hat{e}$ is a vector with all its components equal to one (we can use just $\hat{e}^T \alpha$ instead of $\|\alpha\|_1$ since the sign of the components of α is already constrained). Because of the noise and given that $\boldsymbol{\Phi}$ is an uncomplete dictionary, the signal reconstruction constraint in (8) could not to be fully accomplished, resulting in an over-constrained LP problem. Therefore, an appropriate minimization procedure is required: an interior-point method which tries to minimize the magnitude of the residual vector $\eta_\alpha = \boldsymbol{\Phi}\alpha - S$ (see [35]). In our experiments, we used the powerful primal-dual predictor-corrector algorithm by Merhotra (see [35] and [36]) that computes the results in a fraction of the computational effort required by other less-sophisticated interior point methods. The BP method has shown, in general, a better performance with respect to other pursuit techniques as, for instance, matching pursuit (MP) [34]. The BP method represents with few α coefficients the *atoms* that best fit the local structures.

B. Spatial and Coefficient-Contrast Regularization

The adverse effect of noise or a limited number of measurements $S(\mathbf{q}_k, \tau)$ could possibly lead most methods to miss the

original fiber directions. In such situations, the BP method could erroneously estimate the α coefficients: they may do not correspond to the correct axonal fiber orientations or may not indicate the right number of fibers within each voxel. In such a case, the use of a spatial regularization diminishes the noxious noise effect [37], [38]. In this work, in order to reduce such an adverse effect, we propose to filter the α coefficients and therefore to introduce prior knowledge about the piecewise smoothness assumption on the axon fibers orientation and for promoting high contrast in the α-coefficients.

In our notation, a voxel position is denoted by $r = [x, y, z]$, such that α_{jr} is the α_j-th coefficient at the r voxel position and $\mathcal{N}_r$ denotes the second-order spatial neighborhood of r: $\mathcal{N}_r = \{s : |r - s| < 2\}$. Therefore, the α_{jr} coefficient is implicitly associated with the fraction diffusion in a given orientation (i.e., along the PDD of the associated basis tensor $\bar{\mathbf{T}}_j$), and the spatial smoothness of the α_j layer ($\forall r$) is intimately related with the fiber's spatial smoothness. Moreover, if an axon bundle has a trajectory closely parallel to the jth PDD, then we expect a large value for the α_j coefficient. Thus, by smoothness, the neighbor voxels along the orientation of the fiber should have its α_j coefficient large too. Similarly, such a behavior is expected for the close-to-zero coefficients too: if a fiber is not present in a position, then it is not likely to detect its prolongation along its orientation. The above prior knowledge is coded in the regularization term [10]

$$U_s(\alpha, r) = \sum_{s:s\in\mathcal{N}_r} \sum_j w_{jrs} (\alpha_{jr} - \alpha_{js})^2$$

which penalizes the difference between neighboring coefficients along the underlying fiber orientations. Such a process is controlled with the anisotropic weight factors $w_{jrs} = (s - r)^T \bar{\mathbf{T}}_j (s - r) / \|s - r\|^4$.

Additionally, we promote high contrast in the α-coefficients for distinguishing the representative α-coefficients (orientations) from the noisy ones and for computing a sparse solution. Thus, we force each α_{jr} coefficient to be different from the arithmetic mean $\bar{\alpha}_r = \sum_j \alpha_{jr}/N$, by minimizing $U_c(\alpha, r) = -\sum_j (\alpha_{jr} - \bar{\alpha}_r)^2$, see [10]. Finally, the cost function that we propose to minimize is

$$U(\alpha, r) = \|S - \boldsymbol{\Phi}\alpha_r\|_2^2 + \mu_s U_s(\alpha, r) + \mu_c U_c(\alpha, r) \tag{9}$$

subject to $\alpha_{jr} \geq 0$, where the nonnegative control parameters μ_s and μ_c allow us to tune the amount of regularization. The potentials were chosen in order to keep the cost function (9) quadratic. Thus, by equaling to zero the partial derivative with respect to each α_{jr} results in a constrained linear system. It can easily be solved by using a Gauss–Seidel (GS) scheme [29], [39] (used in our experiments because of its efficient use of memory) or a conjugate gradient technique which is time efficient [35]. The nonnegativity constraint over the α coefficients is accomplished along with the minimization with a particular case of the well-known gradient projection: the negative α_{jr} values are projected to zero in each iteration [35]. The tuning of the spatial regularization parameter is quite simple: the large μ_s value

eliminates noise but a too large value over smooths the recovered solution. We found that, in our experiments, $\mu_s \in [0.5, 3.0]$ produces an adequate noise reduction. As it was explained in [10], the μ_c value is gradually introduced because it is important to perform the coefficient-contrast regularization once we have an intermediate regularized solution: for each iteration $k = 1, 2, \ldots, n$, we set $\mu_c^{(k)} = \mu_c \left(1.0 - 0.95^{100k/n}\right)$ that increases to μ_c in the approximately 90% of the total number of iterations n, with $\mu_c \in [0.1, 0.5]$ for all our experiments.

IV. IMPLEMENTATION DETAILS

In this section, we describe important implementation details to be taken into account for obtaining high quality results.

A. Designing the Tensor Basis

There are two main aspects: 1) the eigen-vector orientations and 2) the eigen-values.

1) Orientations: The basis orientation set depends on a compromise between the desired resolution of the results and the computational effort. The procedure for obtaining the 3-D balanced orientations is exactly the same as that of selecting the acquisition DW orientations in the MR machine [40], i.e., one can use the almost uniformly distributed directions given by the n-fold tessellated icosahedron hemispheres, or by using an electrostatic repulsion model [41]. In particular, we used recursive tessellations of a square pyramid (having equilateral triangles as sides) that results in $\{3, 9, 33, 129, 513, 2049, \ldots\}$ almost uniform orientations for $\{0, 1, 2, 3, 4, 5, \ldots\}$ successive tessellations, respectively. We used $N = 129$ orientations in all our experiments. Note that in our approach, the high angular resolution is in the tensor basis but not in the acquired signals $S(\mathbf{q}, \tau)$.

2) Eigen-Values: As it was mentioned in Section II, we can make use of prior information about longitudinal and transversal diffusion. As the diffusion parameters may change between patients or by scale-factor effects in the signal, then it is important to determine the best set of parameters for each experiment. In present work we perform experiments using rat brain data. The optimal parameters were determined by fitting the standard DT model to the voxels in the *corpus callosum*, a well-known region with high generalized anisotropy (GA) [42] and relatively free of crossing fibers. Then, the mean values of the fitted DTs are used for designing the base; in particular we found $[\lambda_1, \lambda_2, \lambda_3] = [6 \times 10^{-4} \text{ mm}^2/\text{s}, 2 \times 10^{-4} \text{ mm}^2/\text{s}, 2 \times 10^{-4} \text{ mm}^2/\text{s}]$.

We do not constrain $\sum_j \alpha_j = 1$ because (assuming that S_0 is accurate enough) a well-designed basis will automatically satisfy it. A summation different enough from 1 indicates error in the DBF design; in our experiments, for such a voxelwise summation, we obtained a mean value equal to 0.96.

B. Computation of a Continuous Solution

The formulation presented in Section II produces a discrete set of PDDs that can be conveniently postprocessed for obtaining refined continuous orientations with smaller angular errors. Assuming the 2-D example shown in Fig. 3, the BP approach gives us a solution with minimum $\|\alpha\|_1$ and minimum magnitude of the error $r_\alpha = \mathbf{\Phi}\alpha - S$ [as shown in the Fig. 3(b)], the maximum diffusion orientation (plotted in a dotted-red line), lies at an intermediate value between the orientation of the two

Fig. 3. Example of a single fiber case. (a) Discrete solution (*cluster*) composed with two DBFs. (b) Level curves of $\|\mathbf{\Phi}\alpha - S\|_2$ for α_i (X axis) and α_{i+1} (Y-axis) coefficients, with $\alpha_k = 0, \forall\, k \neq i, j$. See text for details.

closest basis tensors $\bar{\mathbf{T}}_i$ and $\bar{\mathbf{T}}_{i+1}$ (continuous-lines). For computing the continuous solution we group the orientations in *clusters* and we assign an unique orientation to each *cluster*. A *cluster* $\mathbf{\Omega} = \{v_l\}$ is a set of vectors associated with the basis tensors that contribute to the GMM (their corresponding coefficients are $\alpha_l > 1 \times 10^{-2}$) and with a transitive neighborhood relationship. We denote by

$$\mathcal{N}_{v_l} = \{v_j = PDD(\bar{\mathbf{T}}_j) : e_{lj} \in \mathcal{E}\}$$
$$\cup \left\{v_j = -PDD(\bar{\mathbf{T}}_j) : v_j^T v_l \leq \max_{e_{lk} \in \mathcal{E}} v_k^T v_l\right\}$$

the set of neighbor vectors to v_l; where $\mathcal{E}$ is the set of edges in the tessellation structure and $PDD(\bar{\mathbf{T}}_l)$ is the first eigen-vector of the basis tensor $\bar{\mathbf{T}}_l$. The *cluster* centroid $\bar{Q} \in \Re^3$ is then computed by the weighted summation

$$\bar{Q} = \sum_{v_l \in \mathbf{\Omega}} \alpha_l v_l. \tag{10}$$

Therefore, we obtain a new GMM with continuous DTs (with eigen-values $[\lambda_1, \lambda_2, \lambda_3]$ and oriented along $\bar{Q}$) and mixture coefficients equal to $|\bar{Q}|$.

Due to the high sparsity in the α vector for the discrete solutions, the processed *clusters* were composed in most cases of two or three vectors.

C. Avoiding Ill-Conditioning in Merhotra's Algorithm

Last iterations of Merhotra's algorithm could involve to compute the solution of an ill-conditioned problem of the form $\mathbf{A}\mathbf{x} = \mathbf{b}$, see [35]. To avoid such a problem, we modify $\mathbf{A}$ by adding the value $\kappa = 5 \times 10^{-6}$ to the diagonal when its smallest eigen-value is less than 1×10^{-3}: we solve instead $(\mathbf{A} + \kappa\mathbf{I})\mathbf{x} = \mathbf{b}$.

D. Fast Convergence

In order to speed up the GS solver for (9), we use the BP solution as the initial guess for α. Then we eliminate noise by means of a spatial integration performed by a small number of iterations of the GS approach.

V. RESULTS ON SYNTHETIC DATA

To show important features of the signals, all previous figures were generated using $b = 5000 \text{ s/mm}^2$ and a high angular resolution (so that, the $S(\mathbf{q}_k, \tau)$ signal generates contrasted plots).
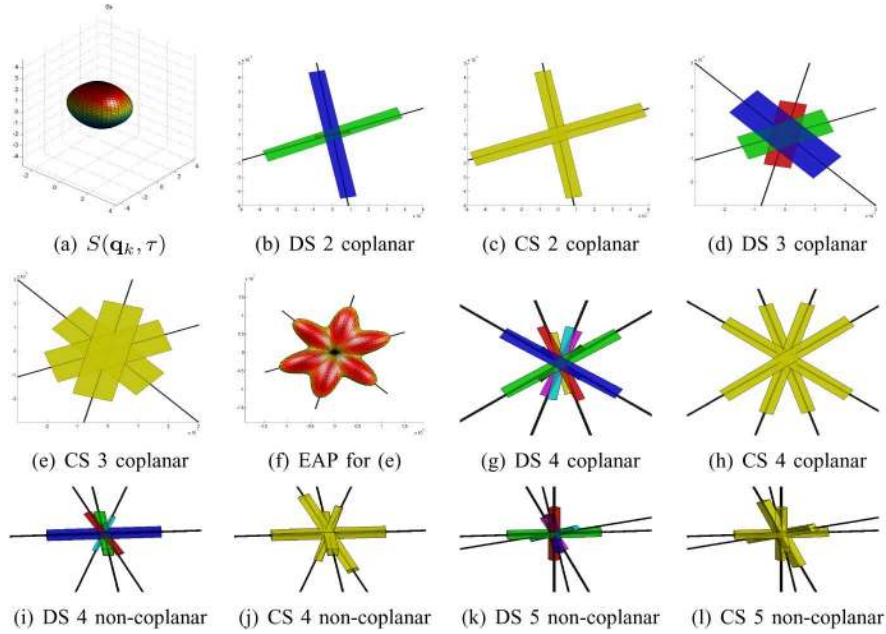

Fig. 4. Results of noise-free synthetic experiments. Fiber axis are plotted in black. (a) DW signal for four noncoplanar fiber orientations, $b = 1200\ \mathrm{s/mm^2}$, $D_{al} = 1 \times 10^{-3}$, $D_{tr} = 2 \times 10^{-4}$. (b), (c) Discrete solution (DS) and refined continuous solution (CS) for two coplanar fibers, $b = 800\ \mathrm{s/mm^2}$, $D_{al} = 6 \times 10^{-4}$, $D_{tr} = 2 \times 10^{-4}$ (these diffusion parameters are similar to those obtained from the rat brain white matter). (d)–(f) DS, CS, and EAP for three coplanar fibers, $b = 800\ \mathrm{s/mm^2}$, $D_{al} = 6 \times 10^{-4}$, $D_{tr} = 2 \times 10^{-4}$. (g), (h) DS and CS for four coplanar fibers, $b = 1350\ \mathrm{s/mm^2}$, $D_{al} = 1 \times 10^{-3}$, $D_{tr} = 2 \times 10^{-4}$. (i), (j) DS and CS for four noncoplanar fibers, $b = 1200\ \mathrm{s/mm^2}$, $D_{al} = 1 \times 10^{-3}$, $D_{tr} = 2 \times 10^{-4}$. (k), (l) DS and CS for five noncoplanar fibers, $b = 1000\ \mathrm{s/mm^2}$, $D_{al} = 1 \times 10^{-3}$, $D_{tr} = 2 \times 10^{-4}$.

In real imaging protocols lower values for previous parameters are preferred. In this section, we show synthetic results obtained by using only 23 diffusion encoding orientations, relatively small b values and small ratios between the longitudinal diffusion (D_{al}) and the transversal diffusion (D_{tr}), see Fig. 4. An example of a realistic $S(\mathbf{q}_k, \tau)$ is shown in Fig. 4(a). Same figure shows synthetic noise-free experiments and demonstrates the capability of our method for resolving multiple fiber orientations (in yellow parallelepiped) with a small error. We show the discrete solution and the continuous solution computed according to the procedure described in Section IV-B. The real axis for the maximum diffusion orientations are plotted as black lines. In Fig. 4(f) we show, for illustrative aims, the EAP for the recovered multi-DT in Fig. 4(e), computed with inverse FT of the GMM as indicated in [8]. We note that the peaks of the EAP (aligned, as expected, with the PDDs of the recovered multi-DTs) correspond with the axes for the maximum diffusion orientations. Such EAP peaks are directly determined by the orientation of DBF with significant α values. Thus, in our approach, for bunch fiber detection we look for large α values and the computation of the EAP is not needed. For computing previous solutions, the BP solver requires approximately 35 ms per voxel, implemented in C language, on a modest PC Pentium IV, 2.8 Mhz.

In order to analyze the expected error in real conditions, we performed 3-D synthetic experiments simulating three noncoplanar fibers within the voxel, oriented with azimuthal and elevation angles equal to $[\pi/4, \pi/4]$, $[3\pi/4, \pi/4]$ and $[3\pi/2, \pi/4]$, respectively. In Tables I–III and Fig. 6, we show the computed mean angular error, $\bar{\theta}$, of 100 experimental out-

Fig. 5. Simulated crossing fibers, the signals were corrupted with Rician noise, $\mathrm{SNR} = 2.0$ (6.02 dB). (a) Solution without regularization (BP based method). (b)–(d) Noise removal effect with the quadratic formulation and the mean angular errors $\bar{\theta}$. Solution in (d) is over-smoothed because of a too large μ_s value. See text for details.

comes taking into account four important variables that directly affect the solution quality.

1) Noise robustness. The $S(\mathbf{q}, \tau)$ signals were corrupted with Rician noise with a signal-to-noise ratio (SNR) (see the Appendix for SNR definition) range from 2 (6.02 dB) to 16 (24.08 dB), see Table I.

TABLE I

MEAN ANGULAR ERROR $\bar{\theta}$ VERSUS SNR. $M = 23$ MEASUREMENTS, $b = 1250\,\mathrm{s/mm^2}$, DBF PARAMETERS $[\lambda_1, \lambda_{2,3}, N] = [9 \times 10^{-4}, 1 \times 10^{-4}, 129]$, DIFFUSION PARAMETERS $[D_{al}, D_{tr}] = [1 \times 10^{-3}, 2 \times 10^{-4}]$, COMPARTMENT SIZES $\beta_i = 1/3, (i = 1, 2, 3)$

SNR	$\bar{\theta}$
2 (6.02 dB)	15.21
4 (12.04 dB)	7.75
6 (15.56 dB)	5.29
8 (18.06 dB)	3.68
10 (20.00 dB)	3.66
12 (21.58 dB)	2.74
14 (22.92 dB)	2.15
16 (24.08 dB)	1.85

TABLE II

MEAN ANGULAR ERROR $\bar{\theta}$ VS. BASIS PARAMETERS. $N = 129$, $M = 23$ DIFFUSION MEASUREMENTS, $b = 1250\,\mathrm{s/mm^2}$, SNR $= 6$ (15.56DB), DIFFUSION PARAMETERS $[D_{al}, D_{tr}] = [1 \times 10^{-3}, 2 \times 10^{-4}]$, COMPARTMENT SIZES $\beta_i = 1/3, (i = 1, 2, 3)$

9.00×10^{-4}	1.0×10^{-4}	1.0×10^{-4}	5.77
9.50×10^{-4}	1.5×10^{-4}	5.0×10^{-5}	5.02
1.00×10^{-3}	2.0×10^{-4}	0.0	5.46
1.05×10^{-3}	2.5×10^{-4}	5.0×10^{-5}	5.11
1.10×10^{-3}	3.0×10^{-4}	1.0×10^{-4}	4.96
1.15×10^{-3}	3.5×10^{-4}	1.5×10^{-4}	5.60

TABLE III

MEAN ANGULAR ERROR $\bar{\theta}$ VERSUS COMPARTMENT SIZES $([\beta_1, \beta_2, \beta_3])$. $M = 23$ DIFFUSION MEASUREMENTS, $b = 1250\,\mathrm{s/mm^2}$, SNR $= 8$ (18.06DB), TENSOR BASIS PARAMETERS $[\lambda_1, \lambda_{2,3}, N] = [9 \times 10^{-4}, 1 \times 10^{-4}, 129]$, DIFFUSION PARAMETERS $[D_{al}, D_{tr}] = [1 \times 10^{-3}, 2 \times 10^{-4}]$

compartment sizes	$\bar{\theta}$	Mean Recovered $[\bar{\beta}_1, \bar{\beta}_2, \bar{\beta}_3]$
[0.333, 0.333, 0.333]	3.90	[0.279, 0.283, 0.279]
[0.433, 0.283, 0.283]	7.15	[0.363, 0.220, 0.221]
[0.533, 0.233, 0.233]	14.16	[0.439, 0.186, 0.183]
[0.633, 0.183, 0.183]	19.27	[0.510, 0.150, 0.159]

2) Error in the diffusion basis with respect to the diffusion parameters in the data. The purpose of this set of experiments is to evaluate the sensitivity of the method to deviations in the prefixed DBFs with respect to the real diffusion parameters which change between voxels, see Table II.

3) Method capability for recovering intravoxel geometry with different b-values, see Fig. 6.

4) Sensitivity to changes in the fibers compartment size, see Table III.

As one can see, the mean angular error, $\bar{\theta}$, is small enough for a large set of parameter variations. These results improve the methods of the state-of-the-art. The multisensor method in [43] is restricted to recover only one or two fibers orientations within a voxel, and reports a mean angular error smaller than $10°$ for simulated fibers with an $\overline{\mathrm{SNR}} = 80$ (We note that the $\overline{\mathrm{SNR}}$ is not defined in [43], so it can not be directly compared with our SNR definition). In our work, we obtained $\bar{\theta} \approx 5°$ for $\mathrm{SNR} = 6$ (15.56 dB), for the three fibers case, see

Table I. For $\mathrm{SNR} \geq 6$, our algorithm is capable of yielding high quality results ($\bar{\theta} \leq 6°$) with realistic b values, see Fig. 6. Fig. 5 demonstrate the spatial and contrast regularization performance, introduced in Section III-B. We simulate a crossing of two fibers with $b = 1250\,\mathrm{s/mm^2}$, $D_{al} = 1 \times 10^{-3}\,\mathrm{mm^2/s}$, $D_{tr} = 2 \times 10^{-4}\,\mathrm{mm^2/s}$, SNR $= 2$ (6.02 dB) and a 2-D tensor basis composed of $N = 30$ orientations. Fig. 5(a) shows the noise corrupted recovered solution with the BP procedure (i.e., without regularization). The resultant orientation errors are similar to the ones reported by Perrin *et al.* [44], where $\bar{\theta} \approx 30°$ was reported in a crossing zone for a realistic phantom and, in our opinion, reveals the need of introducing a regularization mechanism for dealing with highly noise data. Fig. 5(b)–(d) shows the noise removal effect when our proposed quadratic regularized method is used. The regularization parameters used in the experiments were $[\mu_s, \mu_c] = [1.0, 0.5]$, $[\mu_s, \mu_c] = [2.0, 0.5]$ and $[\mu_s, \mu_c] = [3.0, 0.5]$, for in Fig. 5(b)–(d), respectively.

VI. RESULTS ON RAT BRAIN DW-MR DATA

Under deep anesthesia, a Sprague Dawley rat was transcardially exsanguinated then perfused with a fixative solution of 4% paraformaldehyde in phosphate buffered saline (PBS). The corpse is stored in a refrigerator overnight then the brain was extracted and stored in the fixative solution. For MR measurements, the brain was removed from the fixative solution then soaked in PBS, without fixative, for about 12 h (overnight). Prior to MR imaging, the brain was removed from the saline solution and placed in a 20-mm tube with fluorinated oil (Fluorinert FC-43, 3M Corporation, St. Paul, MN) and held in place with plugs. Extra care was taken to remove any air bubbles in the sample preparation.

The multiple-slice diffusion weighted image data were measured at 750 MHz using a 17.6 T, 89-mm bore magnet with Bruker Avance console (Bruker NMR Instruments, Billerica, MA). A spin-echo, pulsed-field-gradient sequence was used for data acquisition with a repetition time of 1400 ms and an echo time of 28 ms. The diffusion weighted gradient pulses were 1.5 ms long and separated by 17.5 ms. A total of 32 slices, with a thickness of 0.3 mm, were measured with an orientation parallel to the long-axis of the brain (slices progressed in the dorsal-ventral direction). These slices have a field-of-view $30\,\mathrm{mm} \times 15\,\mathrm{mm}$ in a matrix of 200×100. The diffusion weighted images were interpolated to a matrix of 400×200 for each slice. Each image was measured with two diffusion b weights: 100 and $1250\,\mathrm{s/mm^2}$. Diffusion-weighted images with $100\,\mathrm{s/mm^2}$ were measured in six gradient directions determined by a tetrahedral based tessellation on a hemisphere. The images with a diffusion-weighting of $1250\,\mathrm{s/mm^2}$ were measured in 46 gradient-directions, which are also determined by the tessellation on a hemisphere. The $100\,\mathrm{s/mm^2}$ images were acquired with 20 signal averages and the $1250\,\mathrm{s/mm^2}$ images were acquired with five signal averages in a total measurement time of approximately 14 h. In our DBF based reconstruction, we used only the DW images with $b = 1250\,\mathrm{s/mm^2}$.

Representative results for this rat brain data are shown in Fig. 7. The GMM model is computed for each position plotted and shown as overlapped ellipsoids. The processed brain regions are indicated by the highlighted boxes in the GA map.
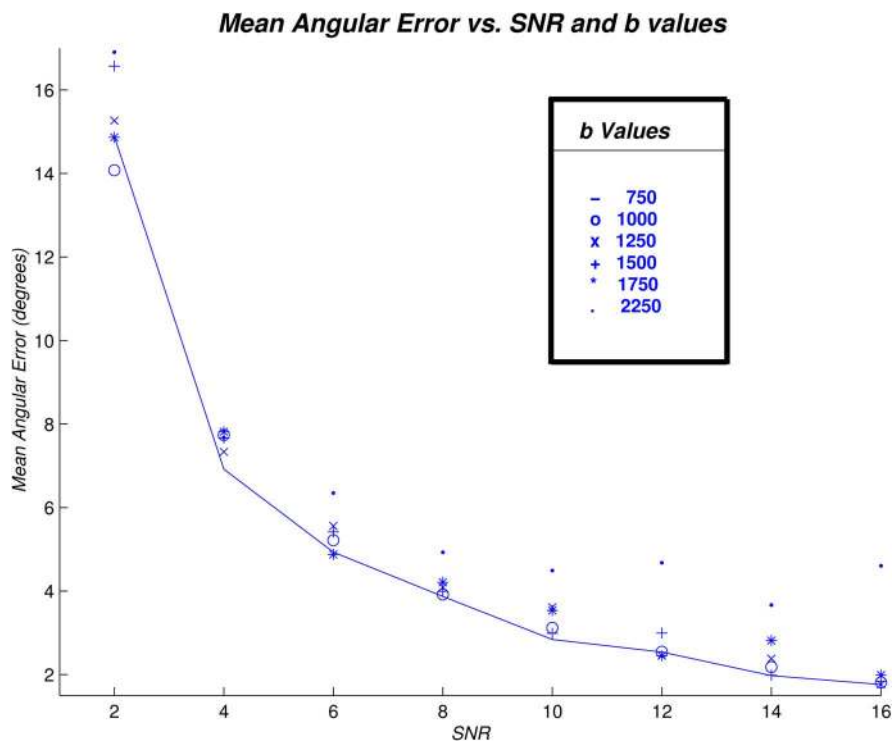

Fig. 6. Mean angular error $\bar{\theta}$ versus SNR and b-values. $M = 23$ diffusion measurements, tensor basis parameters $[\lambda_1, \lambda_{2,3}, N] = [9 \times 10^{-4}, 1 \times 10^{-4}, 129]$, diffusion parameters $[D_{al}, D_{tr}] = [1 \times 10^{-3}, 2 \times 10^{-4}]$, compartment sizes $\beta_i = 1/3, (i = 1, 2, 3)$. See text for details.

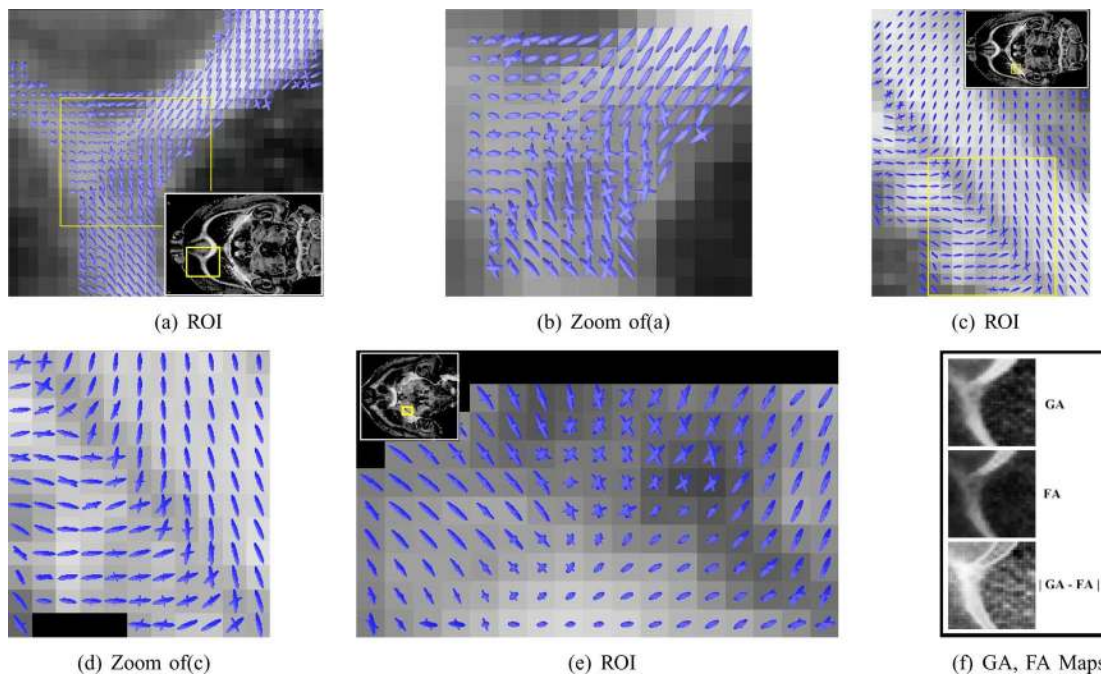

Fig. 7. Computed DTs of the GMM from a real rat brain DW-MR set superimposed over the GA axial map. Note several fiber crossings and splits. (f) GA map, FA map and their difference for the ROI in (a).

The intersecting fibers of cingulum and corpus callosum are seen in Fig. 7(a) and (b) (Paxinos and Watson [45, Plate 111 and Fig. 111]). In Fig. 7(c) and (d), the detailed fiber structure of the fimbria of the hippocampus can be seen, that illustrates the entry of fibers into the fimbria from surrounding structures. This detailed analysis shows that the computed fiber orientations appear to be congruent with the prior anatomical knowledge for those regions. Note that according to Fig. 7(d), a significant difference between the GA (computed from a six-rank tensor [46]) and FA map are found in the crossing zone, the same region where we detected more than one fiber per voxel (as noted in [47]).

The capabilities of the regularization presented in Section III-B are shown in Fig. 8, note how the noise effect is eliminated and the obtained results with $M = 23$
Fig. 8. Results of regularization in the rat corpus callosum. (a) ROI in axial GA map. (b) Without spatial regularization (BP based method) by using $M = 23$ measurements, the yellow circle indicates a voxel where the noise and the reduced number of measurements produces an inaccurate result. (c) With $M = 23$ measurements and quadratic regularization: $\mu_s = 0.50$, $\mu_c = 0.18$. (d) With $M = 46$ measurements with the BP method. Note that the result obtained in (c) and (d) are equivalent for all practical purposes.

Fig. 9. Real three fiber crossing in a rat cerebellum. (a) ROI GA map. (b) Region in which three fibers are present. The diffusion along **X** axis were plotted in red, along **Y** axis in green and along **Z** axis in blue. Note that the region contains an intersection of 3 fiber bundles. (c) Zoom in a voxel where the 3 bundles are crossing.

measurements are equivalent to the ones obtained with $M = 46$ measurements without regularization.

Finally, we show in Fig. 9 a region of decussation in the cerebellum, in which we recovered voxels with three fiber bundles using the BP approach (i.e., without spatial regularization). Note that the region is composed of voxels with two and three maximum diffusion orientations; in particular, in the center we can observe voxels with three spatially congruent fiber orientations.

VII. COMPARISONS WITH Q-BALL METHODOLOGY

In this section, we compare the performance of the proposal method with respect to Q-ball, a well-known nonparametric method [23]. For all Q-ball results, we compute the EAP for the 129 orientations defined in Section IV-A-I (the same orientations that we use for building the DBFs) and the integration over the equators was performed over 36 interpolated uniformly spaced points. In the kernel regression stage, we used the following parameters: cutoff $\alpha_c = 20°$ and $\sigma_{Q\text{-Ball}} = 10°$. A peak in the computed EAP was defined as the maximum value in a radius of $20°$.

Fig. 10 shows a comparison, given the same signal S for a three fiber crossing with Rician noise and in realistic acquisition conditions. Note that our proposed method reports smaller mean angular error, $\bar{\theta}$, than Q-ball.

Fig. 10. Synthetic S signal generated for a three fiber crossing with compartment sizes $\beta_i = 1/3$, $(i = 1, 2, 3)$, tensor basis parameters $[\lambda_1, \lambda_{2,3}, N] = [9 \times 10^{-4}, 3 \times 10^{-4}, 129]$, diffusion parameters $[D_{al}, D_{tr}] = [1 \times 10^{-3}, 2 \times 10^{-4}]$, $M = 46$ measurements, $b = 1250 \text{ s/mm}^2$ and $\text{SNR} = 5$ (13.97 dB). (a) Result for Q-ball, mean angle error (for the three fibers) $\bar{\theta} = 10.90°$ (b) Result for DBF approach, $\bar{\theta} = 3.78°$.

Fig. 11. Q-ball results for the rat brain DW-MRI, confront with the DBF results in Fig. 7(b) and (d).

TABLE IV
MEAN ANGULAR ERROR FOR DBF $(\bar{\theta}_{DBF})$ AND Q-BALL $(\bar{\theta}_Q)$ RECONSTRUCTIONS. THREE FIBER CROSSING WITH COMPARTMENT SIZES $\beta_i = 1/3$, $(i = 1, 2, 3)$, TENSOR BASIS PARAMETERS $[\lambda_1, \lambda_{2,3}, N] = [9 \times 10^{-4}, 3 \times 10^{-4}, 129]$, DIFFUSION PARAMETERS $[D_{al}, D_{tr}] = [1 \times 10^{-3}, 2 \times 10^{-4}]$. WHEN THE PARAMETER WAS NOT UNDER ANALYSIS WE SET $M = 46$ MEASUREMENTS, $b = 1250 \text{ s/mm}^2$ AND $\text{SNR} = 6$ (15.56 DB)

SNR→[$\bar{\theta}_Q$, $\bar{\theta}_{DBF}$]	M→[$\bar{\theta}_Q$, $\bar{\theta}_{DBF}$]	b→[$\bar{\theta}_Q$, $\bar{\theta}_{DBF}$]
10→[8.70 , *2.48*]	513→[7.57 , *1.70*]	3000→[9.23 , *3.37*]
6→[9.41 , *4.81*]	129→[8.03 , *3.78*]	2000→[9.48 , *3.61*]
4→[11.02 , *5.82*]	46→[9.57 , *3.97*]	1250→[9.42 , *3.77*]
2→[24.24 , *11.41*]	23→[27.57 , *5.43*]	900→[9.18 , *3.48*]

In Fig. 11, we show the Q-ball solution for the rat DW-MR images. Confronting Fig. 11(a) and (b) with Fig. 7(b) and (d), respectively, (both results without spatial regularization), the Q-ball results presents poor performance for such conditions, i.e., low spatial coherence in the crossing zone in Fig. 11(a) and inability in resolving the intravoxel information (dark region) in the crossing zone in Fig. 11(b).

Statistical values for the performance of both methods are shown in Table IV. Each experiment consist of 50 Monte-Carlo outcomes with variations of the acquisition parameters. The $\bar{\theta}$ value reported by the DBF method is about half of the one obtained by the Q-ball approach. This behavior agrees with the results on rat DW-MRI: For $M = 46$ and $b = 1250 \text{ s/mm}^2$, we expect a significant large value $\bar{\theta}$ for Q-ball, about twice the one obtained by the DBF approach.

VIII. Discussion and Conclusion

The use of basis functions (for instance radial or kernel basis functions) that span a subspace of smooth functions is a common and successful strategy for noise reduction in signal and image processing problems. Such a strategy can be seen as an implicit regularization procedure where prior knowledge is introduced by selecting the correct form of the basis function. In our case, the chosen basis functions are directly related with the signal observation model. Thus, besides promoting noise reduction, our formulation reconstructs the signal by estimating the control parameters of the diffusion process (the α-coefficients). An important characteristic of the proposed DBFs is that they are over-complete for spanning the subspace of smooth functions: Some reconstructions can be computed with different combination of α-coefficients; for instance, because of the sparsity constraint, an isotropic diffusion can be approximated with several triads of DBFs with self-orthogonal PDD; similarly a flat (2-D-isotropic) diffusion with different possible pairs of DBFs. This could be seen as a limitation of our model that makes the restoration process ill-posed. However, it only means that if the $S(q_k)$ signal does not exhibit preferential diffusion directions the DBF representation, then our proposal, like others methods as DT, Q-space or deconvolution methods will be unable to recover the intravoxel geometry.

Undefined diffusion directions can be caused by noise or tissue properties, as in gray matter or cerebral spinal fluid. In this work, we assume that white matter has previously been segmented from other tissues and thus the proposed model can recover the intravoxel fiber structure for the case of low level of noise. In other cases, for relatively high level noise, a regularization process that codifies the prior knowledge about smooth fiber trajectories is proposed. Sections III-A and B presented our approaches for the two noise level cases above discussed.

The present work is based on the assumption that the MR signals for a single fiber orientation are sufficiently homogeneous in the white matter tissue (as in [12], [26], and [28]), so that, for each voxel, the MR signal could be explained as a linear combination of DBFs that takes into account changes only in orientation. In [26], it was noted that if the diffusion parameters change by different myelination levels, axonal diameters and axonal densities, then the diffusion parameters violate the homogeneity assumption and the relative volume fractions will not be exactly recovered. However, such errors are small and do not significantly alter the estimated fiber orientations (the most important data in axon fiber tracking). The later conclusion is congruent with our experimental results shown in Table II.

We have presented a new representation for directly obtaining the local nerve fiber geometry from DW-MR measurements. Our proposal, by means of a discrete approximation of the GMM dubbed DBF, overcomes the well-known difficulties of fitting a GMM to DW-MR data, i.e., our proposal.

1) Automatically computes the number of fibers and the compartment sizes within each voxel, avoiding the need of prior knowledge about the number of Gaussians.

2) Is capable of detecting more than two fibers within a voxel, which improves the state-of-the-art for methods based on parametric GMM.

3) Allows us to infer complicated local fiber geometry with DWIs collected along a sparse set of diffusion encoding directions (46, or 23 by using quadratic regularization) as opposed to techniques that use a large number of directions in HARDI data sets.

4) Yields small angular errors for relatively small b values (1250 s/mm^2); as demonstrated by experiments.

5) Has the additional advantage of being formulated as a constrained LP or constrained quadratic optimization problem, that are solved efficiently by a parallelizable interior point method or by the solution of a bounded linear system, respectively.

To the best of our knowledge, the aforementioned properties considerably advance the state-of-the-art.

It is important to note that (8) uses an L-1 norm instead of an L-2 norm. In this sense, we know that the L-1 norm belongs to the robust potential category, distinct from the L2-norm. From an ill-posed problem the BP schema allows us to introduce prior information about the desired solution namely: to select the sparcest solution among all the possible solutions that minimizes the magnitude of the residual vector $r_\alpha = \Phi\alpha - S$. This could be translated in the DW-MR framework as, "to explain the voxel's DW signal with as few as possible DBFs."

Because the solution is given in a parametric form, the fiber orientations are computed by basis PDDs weighted by the recovered α coefficients, so that the probability of displacement is achieved without the need of looking for peaks in nonparametric models as in [48] and [49]. Moreover, in our case for fiber pathway tracking one can use the simple method reported in [10] (no modifications are needed).

Distinct from the model-free methods (as Q-ball, DOT, etc.), our method implicitly incorporates prior knowledge on axonal water diffusion models for the reconstruction of the diffusion signals. In particular, we use the free diffusion model because the parameters (the DT) can be easily estimated from the corpus callosum for each patient (see Section IV-A2). However, the proposed method can be adapted to use others axonal water diffusion models, as the cylindrical confined diffusion model [31]. In such a case, it is necessary to compute the diffusion coefficient, cylindrical radius and length for the Söderman's *et al.* model.

Model based methods (as presented here) have the additional advantage over model-free methods of being more robust to noise because one can discard unreasonable fiber topologies; see experimental comparisons for an unique fiber region of DT-MRI versus Q-ball results in the fiber phantom by Perrin *et al.* [44]. In many cases, the selection among different mathematical models is based on algorithmic (numerical and algebraic) advantages. This is the case with our approach.

Finally, the proposed method is very efficient as the DBF used in the GMM can be precomputed by using the acquisition parameters. We demonstrated via experiments, the performance of our algorithm on synthetic and real data sets, and in the former case, the results were validated.

APPENDIX
NOISE GENERATION AND SNR DEFINITION

For the MR images, the Rician noise distribution results in the magnitude of the complex number such that the real and imaginary parts were corrupted with additive independent Gaussian noise with $\mathcal{N}(0, \sigma^2)$. Thus, one can simulate signals $S_\sigma(\mathbf{q}_k, \tau)$ corrupted with Rician noise [50] as $S_\sigma(\mathbf{q}_k, \tau) = \sqrt{(S(\mathbf{q}_k, \tau) + \varepsilon_1)^2 + \varepsilon_2^2}$; where $\varepsilon_1 \sim \mathcal{N}(0, \sigma)$, $\varepsilon_2 \sim \mathcal{N}(0, \sigma)$. SNR was computed according to the ratio of the peak-to-peak distance in the signal to the root mean square of the noise signal (that as convention is equal to σ [51]) as: $\mathrm{SNR}(S, \sigma) = (\max(S) - \min(S)/\sigma)$. With the aim of correct experiment reproducibility, we prefer the above SNR convention that avoids dependency on the direct current component in the signal (differently to one that depends on the mean value of S). For the decibel standard, we use $\mathrm{SNR}_{dB}(S, \sigma) = 20 \log_{10}(\mathrm{SNR}(S, \sigma))$.
