#### Abstract

We present a modification of the Mumford-Shah functional and its cartoon limit which facilitates the incorporation of a statistical prior on the shape of the segmenting contour. By minimizing a single energy functional, we obtain a segmentation process which maximizes both the grey value homogeneity in the separated regions and the similarity of the contour with respect to a set of training shapes. We propose a closed-form, parameter-free solution for incorporating invariance with respect to similarity transformations in the variational framework. We show segmentation results on artificial and real-world images with and without prior shape information. In the cases of noise, occlusion or strongly cluttered background the shape prior significantly improves segmentation. Finally we compare our results to those obtained by a level set implementation of geodesic active contours.

Keywords: image segmentation, shape recognition, statistical learning, variational methods, diffusion snake, geodesic active contours

## 1. Introduction

Over the last years many variational approaches to image segmentation have been proposed. They make use of image information such as edges (Kass et al., 1988; Caselles et al., 1995; Kichenassamy et al., 1995), homogeneity requirements on the statistics of the regions being segmented (Mumford and Shah, 1989; Zhu and Yuille, 1996; Chan and Vese, 2001; Yezzi et al., 2002) or a combination of both (Paragios and Dériche, 2000). However, given large amounts of noise, clutter and

[^0]occlusion, the information contained in the image may not be sufficient to define a desired segmentation. Various efforts have been made to include prior information about the shape of the objects of interest in segmentation approaches (Grenander et al., 1991; Zhu and Mumford, 1997; Wang and Staib, 1998; Kervrann and Heitz, 1999).

Recently, statistical shape knowledge has been introduced in a level set implementation of geodesic active contours (Leventon et al., 2000): A shape model is built over the distribution of surfaces which are obtained by embedding the training curves as zero level sets by the signed distance function. The surfaces are sampled at regular intervals and a principal component analysis is performed in this high-dimensional vector space of
sampled surfaces. During segmentation the surfaces are evolved by the level set equation. An additional term is included which causes a relaxation towards the most probable shape. The latter is determined by a separate maximum a posteriori optimization of shape and pose parameters. Numerical results show very promising segmentation properties for 2D and 3D medical image data.

Our approach differs from the one of Leventon et al. (2000) in several aspects: We incorporate statistical shape knowledge in the evolution process of a Mumford-Shah based segmentation (Mumford and Shah, 1989), which is not implemented as a level set evolution. We are aware that the level set approach has several favorable properties, the main one being the possibility to easily handle topological changes of the contour. On the other hand, level set approaches lead, by virtue of the embedding, to quite high-dimensional shape representations which is not preferable from the statistical learning point of view. Furthermore, there are numerous real-world applications such as silhouettes of many known objects where topological shape changes can be excluded a priori. For these reasons, and since we will focus on the statistical learning part in our future work, we prefer to work with low-dimensional explicit shape representations for the time being.

We propose a modification of the Mumford-Shah functional which allows an explicit parameterization of the contour as a closed spline curve. In particular, we modify the usual length constraint on the contour in a way which simplifies the evolution equation and which strongly improves the spline-based formulation since it enforces an equidistant spacing of the spline control points. This modification turns out to be vital, since the contour normal vector becomes ill-defined as soon as control points overlap. As a result, we obtain the diffusion snake, a hybrid model which combines the external energy of the Mumford-Shah functional with the internal energy of the snakes (Kass et al., 1988).

We then build a statistical shape model on a set of training shapes by approximating the corresponding spline control point vectors by a Gaussian probability distribution. At this point, we do not perform a projection into the subspace of learnt contour deformations as is commonly done (Cootes et al., 1995; Kervrann, 1995; Wang and Staib, 1998; Leventon et al., 2000). Instead, we derive a shape energy with support on the full space of possible contour deformations. This allows to treat the shape energy term and the Mumford-Shah energy in one single energy functional. Rather than
iterating a two-step process of contour evolution and optimization of the shape dissimilarity, a knowledgedriven segmentation process is obtained by gradient descent on a single functional. The shape term in the resulting evolution equation is similar to that introduced in Leventon et al. (2000) for the level set evolution of geodesic active contours. However, in our case the relaxation towards the most probable shape is weighted by the inverse of a modified covariance matrix: Deformation modes which are less familiar from the learning process will decay faster.
Moreover, we incorporate invariance of the shape prior with respect to similarity transformations of the contour in the variational approach. We derive a closedform, parameter-free solution by aligning the evolving contour with the training shapes before applying the statistical shape energy. Consequently, the evolving contour is restricted to a submanifold of familiar shapes, while being free to translate, rotate and scale.
We present numerical studies of our methods in realworld images: Segmentation results with and without prior knowledge demonstrate the capacity of the shape prior to compensate for missing or misleading information due to noise, clutter and occlusion. We also present a similar implementation of the cartoon limit of the Mumford-Shah functional (Morel and Solimini, 1988; Mumford and Shah, 1989). Numerical results exhibit interesting differences in the convergence properties of the two models. We compare segmentation results of our spline-based Mumford-Shah implementation to those obtained by a level set implementation of geodesic active contours (Caselles et al., 1995; Kichenassamy et al., 1995). Finally, we present two different numerical approximations of the diffusion process underlying the curve evolution. This paper comprises and extends work which has been presented on scientific meetings (Cremers et al., 2000, 2001).

## 2. Variational Integration of Shape Statistics and Segmentation

We propose to combine image information and previously acquired shape information in one variational framework. For a given contour $C$ we define an energy

$$
\begin{equation*}
E(u, C)=E_{i}(u, C)+\alpha \cdot E_{c}(C) \tag{1}
\end{equation*}
$$

The functional $E_{i}$ measures how well the contour and the associated segmentation $u$ approximate the
input grey value information. $E_{c}$ favors contours which are familiar from a learning process. The parameter $\alpha$ allows to define the relative weight of the prior.

In the following, we propose for $E_{i}$ a modification of the Mumford-Shah functional and its cartoon limit, which facilitates a parameterization of the contour as a closed spline curve. Shape learning and shape statistics are then conveniently defined on the distribution of spline control points.

### 2.1. Spline-Based Mumford-Shah Segmentation

The variational approach to image segmentation proposed by Mumford and Shah (1989) consists in minimizing the following energy functional:

$$
\begin{align*}
E_{i}(u, C)= & \frac{1}{2} \int_{\Omega}(f-u)^{2} d x \\
& +\lambda^{2} \frac{1}{2} \int_{\Omega-C}|\nabla u|^{2} d x+v\|C\| . \tag{2}
\end{align*}
$$

The input image $f$ is approximated on the image plane $\Omega$ by a piecewise smooth function $u$, which may be discontinuous across a boundary $C$, its length being denoted by $\|C\|$.

We implement this functional by representing the boundary as a closed spline curve:

$$
\begin{equation*}
C:[0,1] \rightarrow \Omega, \quad C(s)=\sum_{n=1}^{N} p_{n} B_{n}(s), \tag{3}
\end{equation*}
$$

where $B_{n}$ are periodic, quadratic B -spline basis functions (Farin, 1997; Blake and Isard, 1998) and $p_{n}=$ $\left(x_{n}, y_{n}\right)^{t}$ are the spline control points. Certainly this parametric representation restricts the class of permissible contours, not allowing open boundaries, and contour splitting or merging. However, it facilitates the generation and incorporation of a statistical prior on the shape of the boundary, which will be done in Section 2.2.

As is commonly done, we originally implemented the contour length in Cremers et al. (2000) by the $\mathrm{L}_{1}{ }^{-}$ norm of $C_{s}$ :

$$
\begin{equation*}
\|C\|=\int_{0}^{1}\left|C_{s}(s)\right| d s \tag{4}
\end{equation*}
$$

This produces a term proportional to the curvature in the evolution equation of the contour. However, in our
framework of spline contours this term does not restrict the spline control points from clustering in one place. Once control points overlap, the normal becomes illdefined. Since the contour is evolved along its normal, the process becomes instable.

We therefore replace the original length norm (4) by the squared $L_{2}$-norm, to obtain the functional for the diffusion snake
(DS)

$$
\begin{align*}
E_{i}(u, C)= & \frac{1}{2} \int_{\Omega}(f-u)^{2} d x \\
& +\frac{1}{2} \lambda^{2} \int_{\Omega-C}|\nabla u|^{2} d x+v \mathrm{~L}(C) \tag{5}
\end{align*}
$$

where

$$
\begin{equation*}
\mathrm{L}(C)=\int_{0}^{1} C_{s}^{2} d s \tag{6}
\end{equation*}
$$

The diffusion snake (5) can be considered a hybrid model which combines the external energy of the Mumford-Shah functional with the internal energy of the snakes (Kass et al., 1988). Further modifications of the Mumford-Shah functional with respect to length and curvature measures have been considered in Mantegazza (1993).

Minimizing the squared $L_{2}$-norm (6) with respect to $C$ leads to an Euler-Lagrange equation of the simple form

$$
\begin{equation*}
C_{s s}(s)=0, \quad \text { for all } s \in[0,1] . \tag{7}
\end{equation*}
$$

For the quadratic B-spline curve this is equivalent to

$$
\begin{equation*}
p_{i}=\frac{p_{i-1}+p_{i+1}}{2}, \quad i=1, \ldots, N . \tag{8}
\end{equation*}
$$

Therefore, by minimizing (5), each control point $p_{i}$ tends to be centered between its two neighbors. This is what makes (5) well suited for our spline-based implementation. Moreover, we experimentally verified that a sufficiently fine parameterization enables the formation of arbitrarily sharp corners.

The same modification can be performed for the cartoon model (Morel and Solimini, 1988; Mumford and Shah, 1989), which is obtained as $\lambda \rightarrow \infty$. Replacing the $\mathrm{L}_{1}$-norm by the $\mathrm{L}_{2}$-norm, we obtain the simplified diffusion snake:
(SDS) $\quad E_{i}\left(\left\{u_{k}\right\}, C\right)=\frac{1}{2} \sum_{k} \int_{\Omega_{k}}\left(f-u_{k}\right)^{2} d x+\nu \mathrm{L}(C)$.

During minimization of (9), the segmented image $u$ is restricted to the constants $\left\{u_{k}\right\}$ which will take on the mean grey value of the input image $f$ on the set of regions $\left\{\Omega_{k}\right\}$ separated by the contour $C$.

### 2.2. From Learnt Shape Statistics to a Shape Energy

The explicit parameterization of the contour allows to represent a set of sample shapes in a vector space and to approximate their distribution statistically. To this end, the images of training objects are binarized, a spline contour is fit to the boundary and the set of training contours is aligned with respect to similarity transformations (Goodall, 1991; Cootes et al., 1995) and cyclic permutation of the control points.

The distribution of control point vectors

$$
\begin{equation*}
z=\left(x_{1}, y_{1}, \ldots, x_{N}, y_{N}\right)^{t} \tag{10}
\end{equation*}
$$

is assumed to be Gaussian. The mean control point vector $\mu$ and sample covariance matrix $\Sigma$ are determined for the training set.

The advantage of assuming a Gaussian shape probability is that the associated shape energy has the following favorable property: The Mumford-Shah functional has by itself a non-convex dependency upon the contour. Adding the quadratic shape energy (13) will "convexify" the total energy. That is, given an arbitrary input image, the total energy (1) will be convex for sufficiently large $\alpha$.

In general, $\Sigma$ will not have full rank-especially if the number of sample shapes is smaller than the dimension $2 N$ of the underlying vector space. The associated Gaussian probability will vanish for any shape outside the subspace spanned by the training shapes. In order to define a probability density with support in the full 2 N -dimensional space, we artificially extend the Gaussian probability to the space orthogonal to the subspace of learnt deformations in the following way:

Let $D$ be the diagonal matrix of the ordered non-zero eigenvalues $\sigma_{1} \geq \cdots \geq \sigma_{r}>0$ of the covariance matrix $\Sigma$, and $V$ the matrix of corresponding eigenvectors. The covariance matrix is then regularized by replacing all zero eigenvalues by an appropriate constant $\sigma_{\perp}>0$ :

$$
\begin{equation*}
\Sigma_{\perp}=V D V^{t}+\sigma_{\perp}\left(I-V V^{t}\right) \tag{11}
\end{equation*}
$$

The inverse of this matrix is well-defined, and the
corresponding probability distribution

$$
\begin{equation*}
\mathcal{P}(z) \propto \exp \left(-\frac{1}{2}(z-\mu)^{t} \Sigma_{\perp}^{-1}(z-\mu)\right) \tag{12}
\end{equation*}
$$

is differentiable on the full space. It associates a finite non-zero value with any shape $z$.
The Gaussian probability (12) corresponds to the quadratic energy
$E_{c}(z)=-\log (\mathcal{P}(z))+$ const. $=\frac{1}{2}(z-\mu)^{t} \Sigma_{\perp}^{-1}(z-\mu)$,
which is similar to the Mahalanobis distance. Note that this shape energy is automatically derived from a set of binary training images.

### 2.3. On Regularizing the Covariance Matrix

What is the optimal value for the regularizing constant $\sigma_{\perp}$ in (11)? A similar regularization of the covariance matrix was proposed by Moghaddam and Pentland (1995), Roweis (1998), and Tipping and Bishop (1997). However, there the underlying purpose is quite different. Namely Moghaddam and Pentland (1995) and Tipping and Bishop (1997) intend to obtain a sparse representation by replacing the smallest eigenvalues $\sigma_{r+1}, \ldots, \sigma_{2 N}$ by a constant $\sigma_{\perp}$. By minimizing the Kullback-Leibler distance between the two probability distributions-corresponding to the covariance matrices with and without this replacement-they obtain an optimal value for $\sigma_{\perp}$, given by the mean of the replaced eigenvalues:

$$
\begin{equation*}
\sigma_{\perp}=\frac{1}{2 N-r} \sum_{i=r+1}^{2 N} \sigma_{i} \tag{14}
\end{equation*}
$$

We believe this estimate not to be appropriate in our context. The implicit assumption underlying this derivation is that the covariance matrix estimated from the data is the one corresponding to the true probability distribution. This, however, is not the case since we only have a finite-and in our case even fairly smallnumber of training samples.

Based on a more intuitive explanation of the regularization, we therefore propose a different estimate of $\sigma_{\perp}$ : Given an unfamiliar shape variation (corresponding to a zero eigenvalue of $\Sigma$ ), we associate a probability with it which is not zero, but which is smaller or equal to the probability of any shape variation
encountered in the learning process. This is equivalent to the bound: $0<\sigma_{\perp} \leq \sigma_{r}$, where $\sigma_{r}$ is the smallest non-zero eigenvalue of $\Sigma$. Lacking a more precise estimate, we fixed

$$
\begin{equation*}
\sigma_{\perp}=\sigma_{r} / 2 \tag{15}
\end{equation*}
$$

which worked well for all our experiments. Moreover, we found in numerical experiments that the curve evolution is not very sensitive to the exact value of $\sigma_{\perp}$.

## 3. Energy Minimization by Gradient Descent

The total energy (1) is iteratively minimized with respect to both the segmenting contour $C$ and the segmented image $u$.

### 3.1. Curve Evolution

Minimizing the diffusion snake (DS) functional (5) with respect to the contour $C$ (for fixed $u$ ) leads to the Euler-Lagrange equation

$$
\begin{align*}
\frac{\partial E_{i}}{\partial C}= & {\left[e^{-}(s)-e^{+}(s)\right] \cdot n(s)-v C_{s s}(s)=0 } \\
& \forall s \in[0,1] . \tag{16}
\end{align*}
$$

The terms $e^{+}$and $e^{-}$denote the energy density

$$
\begin{equation*}
e^{+/-}=(f-u)^{2}+\lambda^{2}(\nabla u)^{2} \tag{17}
\end{equation*}
$$

in the regions adjoining the contour $C(s)$, and $n$ denotes the outer normal vector on the contour. For the simplified diffusion snake (SDS) (9), $u$ is piecewise constant and the second term in (17) disappears.

Solving the minimization problem by gradient descent results in the evolution equation

$$
\begin{align*}
\frac{\partial C}{\partial t}=-\frac{\partial E_{i}}{\partial C}= & {\left[e^{+}(s, t)-e^{-}(s, t)\right] \cdot n(s, t) } \\
& +\nu C_{s s}(s, t) \forall s, \tag{18}
\end{align*}
$$

where an artificial time parameter $t$ has been introduced.

Equation (18) can be converted to an evolution equation for the control points by inserting the definition (3) of the contour as a spline curve. Including the
contribution of the shape energy (13), we obtain for the coordinates of control point $m$ :

$$
\begin{align*}
\frac{d x_{m}(t)}{d t}= & \sum_{i}\left(\mathbf{B}^{-1}\right)_{m i}\left[\left(e^{+}\left(s_{i}, t\right)-e^{-}\left(s_{i}, t\right)\right) n_{x}\left(s_{i}, t\right)\right. \\
& \left.+v\left(x_{i-1}-2 x_{i}+x_{i+1}\right)\right] \\
& -\alpha\left[\Sigma_{\perp}^{-1}(z-\mu)\right]_{2 m-1} \\
\frac{d y_{m}(t)}{d t}= & \sum_{i}\left(\mathbf{B}^{-1}\right)_{m i}\left[\left(e^{+}\left(s_{i}, t\right)-e^{-}\left(s_{i}, t\right)\right) n_{y}\left(s_{i}, t\right)\right. \\
& \left.+v\left(y_{i-1}-2 y_{i}+y_{i+1}\right)\right]-\alpha\left[\Sigma_{\perp}^{-1}(z-\mu)\right]_{2 m} \tag{19}
\end{align*}
$$

The equation has been discretized with a set of nodes $s_{i}$ along the contour to obtain a set of linear differential equations. The cyclic tridiagonal matrix $\mathbf{B}$ contains the spline basis functions evaluated at these nodes: $B_{i j}=B_{i}\left(s_{j}\right)$, where $s_{i}$ corresponds to the maximum of $B_{i}$.

The three terms in the respective equations in (19) can be interpreted as follows: The first term forces the contour towards the object boundaries, the second term enforces an equidistant spacing of control points and the third term causes a relaxation towards the most probable shape. The indices $2 m-1$ and $2 m$ are simply associated with the $x$ - and $y$-coordinates of control point $m$ in the notation of (10).

Note that the relaxation towards the most probable shape is weighted by the inverse of the modified covariance matrix, such that less familiar shape deformations will decay faster. This interesting property arises automatically due to the proposed variational integration of the Gaussian prior.

### 3.2. Inhomogeneous Linear Diffusion

In order to minimize the $\mathbf{D S}$ (5) with respect to the segmented image $u$, we rewrite the functional in the following way:

$$
\begin{align*}
E_{i}(u, C)= & \frac{1}{2} \int_{\Omega}(f-u)^{2} d x+\lambda^{2} \frac{1}{2} \int_{\Omega} w_{c}(x)|\nabla u|^{2} d x \\
& +\nu \mathrm{L}(C) . \tag{20}
\end{align*}
$$

The contour dependence is now implicitly represented
by an indicator function

$$
w_{c}: \Omega \rightarrow\{0,1\}, \quad w_{c}(x)=\left\{\begin{array}{ll}
0 & \text { if } x \in C  \tag{21}\\
1 & \text { otherwise }
\end{array} .\right.
$$

The Euler-Lagrange equation corresponding to this minimization problem is given by:

$$
\begin{equation*}
\frac{1}{\lambda^{2}} \frac{d E}{d u}=\frac{1}{\lambda^{2}}(u-f)-\nabla \cdot\left(w_{c}(x) \nabla u\right)=0 \tag{22}
\end{equation*}
$$

This equation corresponds to the steady state of the following diffusion process:

$$
\begin{equation*}
\frac{\partial u}{\partial t}=\nabla \cdot\left(w_{c} \nabla u\right)+\frac{1}{\lambda^{2}}(f-u) \tag{23}
\end{equation*}
$$

in which the contour enters as an inhomogeneous diffusivity defining a boundary to the diffusion process. This underlying diffusion process is what gave rise to the term diffusion snake.

Two different schemes have been used to approximate the diffusion process: A simple explicit approximation to the diffusion equation (23), and a more sophisticated multigrid scheme solving the corresponding steady state equation (22). Both schemes are not straightforward because the strongly inhomogeneous coefficient function $w_{c}$ has to be taken into account. Standard implementations may easily lead to diffusion across the discontinuity curve $C$ and to a slowdown of convergence, in particular in the case of multigrid iteration. The technical details concerning these two schemes are given in Appendix A.

In the case of the cartoon limit (SDS), the diffusion process is replaced by an averaging process, such that the image $u$ takes on the mean grey values over a set of regions:

$$
\begin{equation*}
u_{k}=\frac{1}{\left|\Omega_{k}\right|} \int_{\Omega_{k}} f d x \tag{24}
\end{equation*}
$$

These are dynamically updated during the evolution of the contour.

## 4. Invariance in the Variational Framework

By construction, the shape energy $E_{c}(z)$ in (13) is not invariant with respect to similarity transformations of the shape $z$. Such an invariance could be introduced by
replacing $E_{c}$ with the energy

$$
\begin{equation*}
E_{\text {shape }}(z)=\min _{s, R_{\theta}, t} E_{c}\left(s R_{\theta}(z-t)\right) \tag{25}
\end{equation*}
$$

where minimization is done with respect to scale, rotation and translation. It appears infeasible to obtain an analytic solution (as a function of $z$ ) for the above minimization problem. Moreover, even a numerical optimization (cf. Chen et al., 2001) is problematic as discussed in 5.7.

Therefore, we propose to eliminate the rotation angle and the scale in the following way: Since the training shapes were aligned to their mean shape $\mu$ with respect to translation, rotation and scaling and then normalized to unit size, we shall do the same to the argument $z$ of the shape energy before calculating the energy $E_{c}$. We eliminate the translation by centering the control point vector:

$$
\begin{equation*}
z_{c}=\left(I_{2 N}-\frac{1}{N} T\right) z \tag{26}
\end{equation*}
$$

where $I_{2 N}$ denotes the unit matrix, $N$ is the number of control points, and the $2 N \times 2 N$-matrix $T$ is given by:

$$
T=\left(\begin{array}{ccccc}
1 & 0 & 1 & 0 & \cdots  \tag{27}\\
0 & 1 & 0 & 1 & \cdots \\
1 & 0 & 1 & 0 & \cdots \\
\vdots & \vdots & \vdots & \vdots & \ddots
\end{array}\right)
$$

Next, we eliminate rotation and scaling by aligning with respect to the mean of the training data. The final shape energy is then given by:

$$
\begin{equation*}
E_{\text {shape }}(z)=E_{c}(\hat{z}), \quad \text { with } \hat{z}=\frac{R_{\theta} z_{c}}{\left|R_{\theta} z_{c}\right|} \tag{28}
\end{equation*}
$$

where $\theta$ denotes the angle corresponding to the optimal rotation of the control point polygon $z_{c}$ with respect to the mean shape $\mu$. We shall not go into detail about the derivation of $R_{\theta}$. Derivations can be found in Werman and Weinshall (1995) and Dryden and Mardia (1998). The final result is given by the formula:

$$
\hat{z}=\frac{M z_{c}}{\left|M z_{c}\right|}, \quad \text { with } M=I_{N} \otimes\left(\begin{array}{cc}
\mu^{t} z_{c} & -\mu \times z_{c}  \tag{29}\\
\mu \times z_{c} & \mu^{t} z_{c}
\end{array}\right)
$$

where $\otimes$ denotes the Kronecker product and $\mu \times z_{c}:=$ $\mu^{t} R_{\pi / 2} z_{c}$.

In order to determine the gradient of the similarity invariant shape energy in (28), we will denote the differentiation of vector-valued functions $f: \mathbb{R}^{n} \rightarrow \mathbb{R}^{m}$ by:

$$
\frac{d f}{d x}=\left(\begin{array}{ccc}
\frac{\partial f_{1}}{\partial x_{1}} & \cdots & \frac{\partial f_{1}}{\partial x_{n}}  \tag{30}\\
\vdots & \ddots & \vdots \\
\frac{\partial f_{m}}{\partial x_{1}} & \cdots & \frac{\partial f_{m}}{\partial x_{n}}
\end{array}\right)
$$

To incorporate the similarity invariant shape prior into the segmentation process, we simply replace the last term in the evolution equation (19) by the gradient on the similarity invariant shape energy (28). With results (29) and (26), this is obtained by applying the chain rule:
$\frac{d E_{\text {shape }}(z)}{d z}=\frac{d E_{c}(\hat{z})}{d \hat{z}} \cdot \frac{d \hat{z}}{d z}=\frac{d E_{c}(\hat{z})}{d \hat{z}} \cdot \frac{d \hat{z}}{d z_{c}} \cdot \frac{d \hat{z}_{c}}{d z}$.
The three terms in this product can be interpreted as follows:

- The first term is the gradient of the original energy evaluated for the aligned shape $\hat{z}$. It contains the shape information extracted from the training set. For the quadratic energy (13), it is given by:

$$
\begin{equation*}
\frac{d E(\hat{z})}{d \hat{z}}=\left(\Sigma_{\perp}^{-1}(\hat{z}-\mu)\right)^{t} \tag{32}
\end{equation*}
$$

It causes a relaxation of the aligned shape $\hat{z}$ towards the mean shape $\mu$, weighted by the inverse of the regularized covariance matrix. This weighting causes unfamiliar deformations from the mean to decay faster.

- The second term in the product of (31) takes into account the influence of changes in the centered shape $z_{c}$ onto the aligned shape $\hat{z}$. In matrix notation it is given by:

$$
\begin{equation*}
\frac{d \hat{z}}{d z_{c}}=\frac{M^{\prime} z_{c}+M}{\left\|M z_{c}\right\|}-\frac{\left(M z_{c}\right)\left(M z_{c}\right)^{t}\left(M^{\prime} z_{c}+M\right)}{\left\|M z_{c}\right\|^{3}} \tag{33}
\end{equation*}
$$

where $M$ is the matrix defined in (29) and $M^{\prime}$ denotes the tensor of rank 3 given by:

$$
\begin{equation*}
M^{\prime}=\frac{d M}{d z_{c}} \tag{34}
\end{equation*}
$$

The entries of this constant sparse tensor are given by:

$$
\begin{align*}
& M_{i j k}^{\prime}=\frac{d M_{i k}}{d\left(z_{c}\right)_{j}} \\
& \quad=\left\{\begin{aligned}
\mu_{j}, & i=k \\
\mu_{j+1}, & i=k+1, i \text { even, } j \text { odd } \\
-\mu_{j-1}, & i=k+1, i \text { even, } j \text { even } \\
-\mu_{j+1}, & i=k-1, i \text { odd, } j \text { odd } \\
\mu_{j-1}, & i=k-1, i \text { odd, } j \text { even } \\
0, & \text { otherwise }
\end{aligned}\right. \tag{35}
\end{align*}
$$

- The third term in the product of (31) accounts for the change of the centered shape $z_{c}$ with the input shape $z$. According to definition (26), it is given by:

$$
\begin{equation*}
\frac{d z_{c}}{d z}=\left(I_{2 N}-\frac{1}{N} T\right) \tag{36}
\end{equation*}
$$

This term centers the energy gradient, as a direct consequence of the translation invariance of the shape energy. Accordingly, the force which minimizes the shape energy has no influence on the translation of the contour. Similarly, rotation and scaling of the shape are not affected by the shape optimization, due to the term (33) in the evolution equation (31).

Note that, due to the analytical minimization with respect to similarity transformations based on the control point representation of the spline curve, no additional parameters enter the above evolution equation to account for scale, rotation and translation. The advantages of this approach over modeling explicit parameters for translation, scale and rotation-cf. Chen et al. (2001)—will be discussed in Section 5.7.

In a given segmentation task, invariance with respect to the group of similarity transformations may be too general. Obviously, one can-depending on the specific application-incorporate only a subgroup of the suggested invariances, such as translation invariance. Moreover, since there exists a similar closed form solution for the optimal alignment of two polygons with respect to the more general affine group (Werman and Weinshall, 1995), the above approach could be extended to define a shape prior which is invariant with respect to affine transformations. However, we will not elaborate this possibility.

## 5. Experimental Results and Discussion

In Section 5.1, we give an example of dealing with occlusion in an artificial image. In Section 5.2, we show the segmentation properties of our approach for a realworld image in the absence of a statistical prior, and in Section 5.3, we show how segmentation is improved by including a prior. In Section 5.4, we then present an example of a strongly cluttered background for which the desired segmentation is not obtained unless the statistical prior is included. The different convergence properties of the diffusion snake and its cartoon limit are analyzed in Section 5.5. Section 5.6 offers a comparison to segmentation results obtained for the same images with a level set implementation of geodesic active contours. In Section 5.7, we present results on rotation and scale invariance and discuss the advantages of the parameter-free implementation over other approaches. In Section 5.8, we investigate the potential and limitations of the shape prior in dealing with occlusion in real-world images. In Section 5.9, we demonstrate the capacity of the shape prior to cope for missing information due to noise.

### 5.1. Coping with Occlusion

A common difficulty in segmentation problems is the fact that the object of interest may be partially occluded. In this case, the prior shape knowledge can help to recover missing information. Figure 1 shows the basic principle: Depicted are the input image (black) of an ellipse occluded by a bar, the initial contour, and the final segmentation obtained with the cartoon model (SDS), both without and with a statistical prior. The statistical shape energy was constructed from a set of six ellipses, as explained in Section 2.2. In order to demonstrate more clearly the effect of the prior on the curve deformation, only translation invariance was included into the shape energy-see Section 4 for details.

Figure 1. Segmentation results for the SDS with a prior favoring ellipse-like shapes. A number of intermediate contours (right) indicates how the contour evolution is restricted to the submanifold of familiar shapes. In the final segmentation with prior, the occluding bar is removed.

Without a statistical shape prior, the contour segments the entire black region corresponding to the object and the occlusion. Upon introduction of the shape prior, however, the evolving contour is restricted to ellipse-like shapes during the minimization process. Figure 1, right side, shows some intermediate steps in the contour evolution: The effective search space for the segmenting contour is drastically reduced, and unfamiliar object features are ignored.

### 5.2. Segmentation Results with No Prior

In this subsection we will demonstrate the segmentation properties of the two Mumford-Shah adaptations for closed spline curves, in the case when the prior information is completely switched off, i.e. $\alpha=0$ in Eq. (1). The goal is to segment a hand in a given image.
Both the diffusion snake (DS) and its cartoon limit (SDS) differ from many segmentation functionals such as the classical snake approach (Kass et al., 1988) in that they do not fit a contour to the local image gradient. It is the diffusion process or the averaging in case of the cartoon limit, which collects grey value information from the entire image plane. The effect is that the contour converges to the final segmentation over larger distances. Yet, since the functional is not defined in terms of a pre-smoothed input image, details of the image information such as the precise location of corners and edges are preserved.
Figure 2, left side, shows a grey level image containing a hand and the initial contour (dashed line). The second image shows the final segmentation obtained with the DS. Due to a large weight of the term minimizing the length of the contour, the thumb is cut off and the fingers are not fully segmented. If the parameter $v$ in (5) and (9) is decreased, the final contour is allowed to increase in length. The resulting segmentation is shown in the third image of Fig. 2 for the SDS. The hand is approximated better. However, some of the clutter in the background is included in the segmentation, while the fingers are still not fully segmented. The right image shows a segmentation obtained by a level set implementation of geodesic active contours (see Section 5.6).

### 5.3. Knowledge-Driven Segmentation

In the above example-though it does not contain a lot of clutter-the final segmentation is not quite the

Figure 2. Segmentation with no prior. Initial contour (top left), final segmentation for the DS, the SDS, and a level set implementation of geodesic active contours. Depending on the size of the length constraint, part of the background clutter will be incorporated into the segmentation, although details such as part of the fingers are not yet fully segmented.
desired one. The segmentations in Fig. 2 were obtained without any statistical prior. In order to include prior information, we constructed a shape energy upon a set of six binarized hand images as explained in Section 2.2, the hand in Fig. 2 not being part of the training set. Again, in order to gradually increase the model complexity, we only included translation invariance. The training shapes all had the same rotation and scale as the object in the image. Results including scale and rotation invariance will be shown separately later on.

We then performed a gradient descent upon the full energy (1) for the DS in Eq. (5) with the same initial contour as in Fig. 2, left side. Figure 3 indicates the contour evolution from the initialization (top left) to the final segmentation (bottom right).

The statistical prior effectively restricts the contour deformations to the subspace of learnt deformations. However, due to the embedding of the shape probability into the full space of possible deformations, as explained in Section 2.2, some deformation outside this subspace is still feasible-as can be seen in the intermediate steps in Fig. 3. This flexibility turns out to strongly

Figure 3. Contour evolution for the diffusion snake with a statistical shape prior. Due to the prior, the evolving contour is effectively restricted to a submanifold of familiar shapes. In contrast to the result without prior in Fig. 2, the background clutter is not included in the segmentation, and the fingers are fully segmented.
improve the ability of the system to evade incorrect local segmentations. The final segmentation is cut at the wrist, since the training shapes were all cropped there for simplicity.

The question of which value to assign to the lengthgoverning parameter $v$ in Eqs. (5) and (9), discussed in Section 5.2, becomes obsolete: The effective restriction of shape deformations imposed by the prior allows to drop the additional length minimization term. However, for the purpose of analyzing the effect of the prior we kept the value of $v$ constant throughout these experiments.

Segmentation results of equal quality as in Fig. 3 were obtained by including statistical shape prior in the cartoon model.

### 5.4. Coping with Clutter

The scene in Fig. 2 contained little clutter. Therefore, segmentation results were fairly close to the desired one, even in the case when no prior knowledge was included. Once the amount of clutter is increased, this changes. Figure 4 shows an example of a hand in front of a strongly cluttered background. Note that the grey

Figure 4. Segmentation with no prior in strongly cluttered background. Initial contour (top left), segmentation results obtained by the DS, the SDS and a level set scheme of geodesic active contours. Due to the similar grey value properties of object and background, none of these purely data-driven segmentation approaches produces the desired segmentation.
value of the background is approximately the same as that of the object of interest. Without the statistical prior, none of the segmentation approaches is able to extract the object of interest. Note that due to the underlying diffusion process the DS converges more locally than its cartoon limit, the SDS. This will be discussed in more detail in Section 5.5.

As in the previous example, we now include the shape prior and perform a gradient descent on the total energy (1) to obtain the segmentation shown in Fig. 5, left side, for the case of the DS. Again, the shape in the image was not part of the training set.

The final segmentation produced with the statistical prior is the desired one. Small discrepancies between the object boundary and the final contour in the area between the fingers are probably due to the fact that the shape prior does not fully suppress some shape variability in that area. This could be improved with a more elaborate alignment of the training shapes during shape learning. However, we prefer to explicitly avoid any shape learning that involves the calculation of landmarks or any manual interaction such as the labeling of correspondences.

The segmentation obtained with statistical prior in the case of the cartoon model was not successful, as can be seen in Fig. 5, middle. The reason for this failure to capture the object of interest will be discussed next.

### 5.5. Comparing the Modified Mumford-Shah Model and its Cartoon Limit

The full Mumford-Shah functional and its cartoon limit differ in their contour evolution equation in that the former collects grey value information from the area surrounding the contour by means of a diffusion process, whereas the latter does this by separately averaging over the areas which are separated by the present contour. The images in Fig. 6 show that the solution for the diffused image converges to that of the cartoon limit for $\lambda \rightarrow \infty$. In the full Mumford-Shah model the contour

Figure 5. Left and middle: Segmentation with prior in strongly cluttered environment for the modified Mumford-Shah (DS) and its cartoon limit (SDS). Right: Corresponding energy plots (see text). Comparison with the respective images in Fig. 4 shows, that the introduction of the shape prior drives the segmenting contour towards the desired segmentation for the DS. However, since the SDS is more strongly affected by global grey value changes, it does not converge to the desired segmentation for the given initialization (Fig. 4, top left).

Figure 6. From the diffusion model to the cartoon limit. Original image and diffused versions for a fixed contour. With growing values of the smoothing parameter $\lambda$, the amount of information about the local context is reduced. The contour is modeled by edgels "between pixels," such that all pixels belong to one of the two regions and are therefore affected by the diffusion process.
motion is affected mostly by the image information in the neighborhood-at least for not too large values of $\lambda$ in (5). The cartoon model, however, is equally affected by information in any part of the image. This explains the very different segmentation results obtained for the image in Figs. 4 and 5-both with and without prior.

The segmentation obtained with the cartoon model will be affected by grey value differences on a global scale. To analyze which effect this property has upon the energy landscape, we calculated the value of the DS and its cartoon limit, the SDS, for a fixed contour which we simply translated in $x$ - and $y$-direction. This corresponds to a suppression of shape deformation. We used the same input image as in Fig. 4. The contour was optimally placed upon the hand boundaries and then shifted in equidistant steps up to 30 pixels in each direction. The resulting energies are plotted in Fig. 5, right side, as a function of the displacement from the optimal position. Note that the bottom of the image corresponds to the top right side of the energy plots. Both energies show a minimum at the optimal position of the contour. However, the energy for the SDS (below) is strongly slanted towards the bottom of the image. This is caused by the global change in brightness from the top of the image towards the bottom. This is what drives the contour to segment the entire bottom part of the image if no prior is given-cf. Fig. 4, bottom left. Even in the case of added shape prior, the hand contour is pushed to the bottom of the image in the SDS-cf. Fig. 5, middle.

### 5.6. Comparison with Geodesic Active Contours When Using No Shape Prior

In order to compare our results to another segmentation approach, we performed a level set implementation of geodesic active contours. We opted for this comparison since the level set formulation of geodesic active
contours is one of the most competitive among present data-driven segmentation methods. For the same input images $f$ and the same initial contours $C$, we minimized the energy functional (Caselles et al., 1995; Kichenassamy et al., 1995)

$$
\begin{equation*}
E_{f}(C)=\int_{0}^{1} g\left(\left|\nabla f_{\sigma}(C(s))\right|^{2}\right)\left|C_{s}(s)\right| d s \tag{37}
\end{equation*}
$$

with Gaussian-smoothed input image $f_{\sigma}$, and metric (Weickert, 2001)

$$
g\left(s^{2}\right)= \begin{cases}1, & \text { if } s^{2}=0  \tag{38}\\ 1-\exp \left(-\frac{3.315}{(s / \lambda)^{8}}\right), & \text { if } s^{2}>0\end{cases}
$$

Here $\lambda$ serves as contrast parameter.
We did not include any additional terms such as balloon forces since they assume a prior knowledge about whether the object of interest is inside or outside the initial contour. Moreover, the two segmentation approaches based on the Mumford-Shah functional do not contain any such term either.
Our geodesic active contour implementation used an efficient pyramid additive operator splitting (AOS) scheme that does not require to recalculate a distance transformation in each iteration (Weickert, 2001).

The comparison in Fig. 2 shows that the segmentation obtained by the Mumford-Shah based models and the one obtained by the geodesic active contour model are similar for homogeneous background. However, the comparison with Fig. 4 indicates that in a strongly cluttered background the geodesic contours give a more satisfactory approximation of the object of interestindicating at least its approximate location.

One should however keep in mind, that the model formulations are conceptually very different: Whereas the geodesic active contour model is directly governed by the gradient of the smoothed input image, this is different for the Mumford-Shah modelespecially for the case of the cartoon limit, which is a region-based rather than an edge-based segmentation
approach. Thus, the segmentation results in Fig. 4 indicate that the hypothesis of piecewise homogeneous grey value is more strongly violated than the hypothesis that the object is defined by pronounced edges.

Moreover, in the case of the geodesic active contour model, the final contour is obtained as the zero level set of a higher dimensional surface. In our model formulation the final segmentation curve is obtained in form of a parameterized spline curve. The latter permits a straight-forward implementation of shape statistics and similarity invariance and may be of advantage for further post-processing of the contour information.

### 5.7. Invariance to Similarity Transformations

By construction the shape energy (28) is invariant with respect to translation, rotation and scaling. Figure 7 shows a minimization by gradient descent from the initial contour (top left) to the final segmentation, with a shape prior constructed from a set of 10 binarized hand images (bottom right). During its evolution, the contour is effectively restricted to the subspace of familiar contours, but translation, rotation and scaling are permitted.

Due to the closed-form solution for eliminating translation, scale and rotation from the shape energy, no additional parameters enter the minimization. A commonly employed alternative approach is to explicitly model a translation, an angle and a scale and minimize with respect to these quantities (by gradient descent or other). In our opinion this has several drawbacks:

- The introduction of four explicit pose parameters makes numerical minimization more complicatedcorresponding parameters to balance the gradient descent must be chosen. In practice, this is not only tedious, but it may cause numerical instabilities if the corresponding step sizes are chosen too large.
- The joint minimization of pose and shape parameters mixes the degrees of freedom corresponding to scale and rotation with those corresponding to shape deformation.
- Potential local minima may be introduced by the additional pose parameters. In a given application, this may prevent the convergence of the contour towards the desired segmentation.

On several segmentation tasks we could confirm these effects by comparing the two approaches. For example,

Figure 7. Invariance with respect to similarity transformation. Minimization by gradient descent from the initial contour to the final segmentation. Due to the closed-form solution (28), no additional parameters enter the minimization to account for scale, rotation and translation. Due to the intrinsic alignment of the evolving contour, the relative position, scale and rotation of the training set (bottom right) are of no importance to the knowledge-driven segmentation process.

Figure 8. Segmentation process for the SDS with a similarity invariant shape prior in a strongly cluttered background. Note that the contour initially shrinks in size, before expanding again towards the desired segmentation. Since the shape energy is invariant with respect to scaling, rotation and translation, the contour will in particular undergo scale changes in order to maximize the grey value homogeneity criterion. This property induces an increased flexibility of the evolving contour.
for the problem presented in Fig. 7, we did not manage to balance the minimization in a way that it would converge to the desired segmentation when using the latter approach of minimizing explicit pose parameters.

In many applications, we found the similarity invariance to facilitate the convergence of the evolving contour towards the desired segmentation. Figure 8 shows the result of a segmentation process with a similarity invariant shape prior on the same image as in Fig. 4, however with a slightly different initialization. Interestingly, it appears to be energetically favorable for the evolving contour to initially shrink in size (in order to fulfill the grey value homogeneity requirement) before expanding again towards the correct segmentation.

### 5.8. Occlusion Revisited

The main idea of introducing the shape prior is that it is to cope for missing or misleading information. In the case of occlusion, for example, we expect the statistical shape prior to induce a reconstruction of the shape silhouette in parts where the object is not visible. This is demonstrated in Fig. 9. A partially occluded image of a hand was segmented by the SDS with a similarity invariant shape prior. The silhouette of the

Figure 9. Dealing with occlusion. Contour evolution for the SDS with a similarity invariant shape prior. While the segmentation without shape prior (bottom right) fails to capture the object of interest (for the same initialization), the statistical shape prior permits a reconstruction of the occluded parts of the silhouette (bottom center).

Figure 10. With increasing occlusion, the information contained in the image may not be sufficient to correctly guide the segmentation process. Therefore the final segmentation eventually degrades: In this example, the last two fingers are not correctly segmented.
object is reconstructed according to the shape prior in areas where it is occluded.

Naturally, the quality of the final segmentation slowly degrades as the size of the occlusion is increased. This is demonstrated in Fig. 10, which shows segmentation results obtained for the SDS with a similarity invariant statistical shape prior. A comparison with Fig. 9 shows that due to the increased occlusion, there is not sufficient information left to correctly guide
the evolving contour. Such experiments demonstrate that with increasing occlusion, the final segmentation slowly degrades.

### 5.9. Dealing with Noise

A different case of missing information is given when the image containing the object of interest is corrupted by noise. Depending on the amount of noise, there may be very little information to drive the evolving contour towards the desired segmentation. Again, the statistical shape prior can improve segmentation, because it effectively reduces the dimension of the search space in such a way that segmentations which do not correspond to familiar shapes are ruled out a priori.

Figure 11, top left, shows the same input image as in Fig. 3. However, this time, 75\% of the pixels were replaced by an arbitrary grey value sampled from a uniform distribution over the interval [ 0,255 ]. This means that only one out of four pixels contains information about the input image. Figure 11 shows four steps in the contour evolution for the SDS with a similarity invariant shape prior. For the given initialization, the segmentation process with prior is able to converge to

Figure 11. Segmentation of an image corrupted by noise. The input image is the one shown in Fig. 3, with $75 \%$ of the pixels replaced by grey values sampled from a uniform distribution on the interval [0,255]. Four frames from the gradient descent minimization indicate the contour evolution for the cartoon model with a similarity invariant shape prior. The frame on the bottom right shows the final segmentation obtained for the same initialization without a shape prior. By effectively suppressing unfamiliar shape deformations, the statistical prior facilitates convergence to the desired segmentation.
the desired segmentation. In contrast, for the same initialization, the segmentation process without the shape prior fails to segment the object of interest, as shown in Fig. 11, bottom right.

## 6. Summary and Conclusions

We presented an image segmentation approach which allows the integration of statistical shape knowledge in a single energy functional. To this end, we modified the Mumford-Shah functional in a way which facilitates a spline representation of the contour. We proposed to employ the $\mathrm{L}_{2}$-norm as a measure of the contour length. This enforces an equidistant spacing of control points which turns out to be vital for a stable evolution of the explicit contour. The resulting diffusion snake is a hybrid model combining the external energy of the Mumford-Shah functional with the internal energy of the snake.

We extracted the contours of a set of binary example shapes in terms of sets of spline control points in a way which involves no manual labeling of correspondences or landmark calculation. Based on a Gaussian approximation of the shape distribution we calculated a shape energy. By a regularization of the generally noninvertible covariance matrix, we embedded the shape energy from the subspace of learnt contour deformations into the full space of possible deformations. This allows to integrate image information and statistical prior in one variational framework. Minimization of a single functional by gradient descent results in a segmentation process which takes account of both the low-level image information and the higher-level shape dissimilarity.

We introduced invariance with respect to similarity transformations of the contour into the variational approach. To this end, we proposed a closed-form, parameter free integration on the basis of the spline control point representation. Essentially, the statistical energy is applied to the contour upon alignment with respect to the training shapes. The resulting energy can be minimized by gradient descent and no additional parameters need to be introduced to account for translation, scale and rotation.

We presented a thorough experimental study of the segmentation properties of our approach with and without prior knowledge in the case of real-world images. We showed how the statistical prior can help to deal with noise, occlusion and clutter. Moreover we presented results obtained for the so-called cartoon limit,
both with and without clutter. Finally we compared our results to a level set implementation of geodesic active contours.

We included sections on the numerical implementation of the diffusion process underlying the curve evolution, both a simple explicit scheme and a more sophisticated multigrid implementation.

Current work focuses on models of nonlinear shape probability density beyond the Gaussian approximation (Cremers et al., 2002), and on extensions to different low-level segmentation cues such as motion (Cremers and Schnörr, 2002).

## Appendix: A. Implementation of the Diffusion Process

In the following, we will present two different schemes to approximate the diffusion process which is underlying the evolution of the diffusion snake (see Section 3.2): A simple explicit approximation to the diffusion equation

$$
\begin{equation*}
\frac{\partial u}{\partial t}=\nabla \cdot\left(w_{c} \nabla u\right)+\frac{1}{\lambda^{2}}(f-u), \tag{39}
\end{equation*}
$$

and a more sophisticated multigrid scheme solving the corresponding steady state equation

$$
\begin{equation*}
\frac{1}{\lambda^{2}}(u-f)-\nabla \cdot\left(w_{c} \nabla u\right)=0 . \tag{40}
\end{equation*}
$$

Let us start with the explicit scheme.

## A.1. A Simple Numerical Scheme

We approximate equation (39) by finite differences. Let $\tau>0$ denote the step size in $t$ direction and let $u_{i}^{k}$ be an approximation to $u(x, t)$ in some pixel $i$ at $t=k \tau$. In a similar way, $w_{i}^{k}$ and $f_{i}$ serve as approximations to $w_{c}(x, t)$ and $f(x)$, respectively. Moreover, let $\mathcal{N}(i)$ denote the 4 -neighborhood of pixel $i$. If we assume square pixels of size 1 , a consistent discretization of (39) is given by

$$
\begin{align*}
& \frac{u_{i}^{k+1}-u_{i}^{k}}{\tau} \\
& \quad=\sum_{j \in \mathcal{N}(i)} \sqrt{w_{j}^{k} w_{i}^{k}}\left(u_{j}^{k}-u_{i}^{k}\right)+\frac{1}{\lambda^{2}}\left(f_{i}-u_{i}^{k+1}\right) . \tag{41}
\end{align*}
$$

The proposed discretization of the indicator function $w_{c}$ prevents diffusion across the curve $C$.

Assuming that $u_{i}^{k}$ and its neighbors $\left\{u_{j}^{k} \mid j \in \mathcal{N}(i)\right\}$ are already known from the $k$-th iteration step, we can solve this equation explicitly for the unknown $u_{i}^{k+1}$ :

Solving Eq. (47) with standard solvers like GaussSeidel or Jacobi takes a long time, as low frequencies in the error vanish slowly. Therefore, we propose

$$
\begin{equation*}
u_{i}^{k+1}=\frac{\left(1-\tau \sum_{j \in \mathcal{N}(i)} \sqrt{w_{j}^{k} w_{i}^{k}}\right) u_{i}^{k}+\tau \sum_{j \in \mathcal{N}(i)} \sqrt{w_{j}^{k} w_{i}^{k}} u_{j}^{k}+\frac{\tau}{\lambda^{2}} f_{i}}{1+\frac{\tau}{\lambda^{2}}} . \tag{42}
\end{equation*}
$$

This constitutes our simple iteration scheme for all pixels $i$ and all iteration levels $k$.

Let us now investigate its stability. Equation (42) computes $u_{i}^{k+1}$ as a weighted average of $u_{i}^{k}$, its four neighbors $\left\{u_{j}^{k} \mid j \in \mathcal{N}(i)\right\}$, and $f_{i}$. Note that the weights sum up to 1 . Stability of this process can be guaranteed if all weights are nonnegative. Negative weights, however, can only appear in the first term, if $\tau$ is chosen too large. Since

$$
\begin{equation*}
0 \leq \sqrt{w_{j}^{k} w_{i}^{k}} \leq 1 \tag{43}
\end{equation*}
$$

we end up with the stability restriction

$$
\begin{equation*}
\tau \leq \frac{1}{4} \tag{44}
\end{equation*}
$$

In this case we have a convex combination which guarantees that

$$
\begin{equation*}
\min _{j}\left(f_{j}, u_{j}^{k}\right) \leq u_{i}^{k+1} \leq \max _{j}\left(f_{j}, u_{j}^{k}\right) \quad \forall i, k . \tag{45}
\end{equation*}
$$

By initializing $u_{j}^{0}:=f_{j}$ and iterating over $k$, this simplifies to the discrete maximum-minimum principle

$$
\begin{equation*}
\min _{j} f_{j} \leq u_{i}^{k} \leq \max _{j} f_{j} \quad \forall i, k \tag{46}
\end{equation*}
$$

This guarantees that the filtered image remains within the bounds of the original image.

## A.2. A Multigrid Scheme for Diffusion Snakes

In the following, we will detail a multigrid scheme for solving the steady state Eq. (40). We discretize Eq. (40) by finite differences to obtain a linear system with natural (homogeneous Neumann) boundary conditions:

$$
\begin{equation*}
A u=f, \quad \text { and } \quad \partial_{n} u=0 \text { on } \partial \Omega . \tag{47}
\end{equation*}
$$

The contour is represented by edgels "between pixels" (micro-edges), such that all image pixels are affected by the diffusion process.
a multigrid implementation, which consists in recursively transferring the problem from a grid with size $h$ to a coarser grid of size $2 h$, and solving there to obtain a good initialization for the solution on the fine grid.

## A.2.1. Hierarchical Representation at Multiple

 Scales. Standard implementation of some numerical multigrid scheme, like the one in Terzopoulos (1983), may in our case easily lead to a poor implementation of the steady state diffusion Eq. (40) due to the strongly inhomogeneous term $w_{c}$. The hierarchical representation of this term at multiple scales is even more difficult. For the diffusion snake to work, smoothing across the curve $C$ must be prevented at all scales.Let $v$ be an approximation to the solution $u$. Denote the error by $e=u-v$, and the residual by $r=f-\boldsymbol{A} v$. With these notations we obtain for every grid $h$ the following equivalence:

$$
\begin{equation*}
\boldsymbol{A}^{h} u^{h}=f^{h} \quad \Leftrightarrow \quad \boldsymbol{A}^{h} e^{h}=r^{h} . \tag{48}
\end{equation*}
$$

In order to solve the latter problem on the fine grid $h$, we transfer the residual $r^{h}$ and the matrix $\boldsymbol{A}^{h}$ to the coarser grid $2 h$, solve

$$
\begin{equation*}
\boldsymbol{A}^{2 h} e^{2 h}=r^{2 h} \tag{49}
\end{equation*}
$$

for $e^{2 h}$, interpolate back to the fine grid and add $e^{h}$ to the fine grid solution $v^{h}$. This idea is recursively extended to more than two grids, which leads to different multigrid cycles, some of which are depicted in Fig. 12. We found that w-cycles showed the best performance in our experiments.
A.2.2. Interpolation, Restriction and Coarse Grid Representation. Starting with the matrix $\boldsymbol{A}^{h}$, we need to construct appropriate prolongation operators $\boldsymbol{P}$ and restriction operators $\boldsymbol{R}$, which define the transition from the coarse to the fine grids and vice versa. For this purpose we introduce the stencil notation, where the stencils shown in Fig. 13 represent the action of the operator $\boldsymbol{A}$ on a pixel and its $3 \times 3$-neighborhood. This notation

Figure 12. Schematic diagrams of multigrid cycles. An elegant recursive definition of different multigrid cycles can be found in Briggs et al. (2000).
allows to intuitively understand the effect of the operator $\boldsymbol{A}$ at a given location. The effect of the boundary conditions imposed by the contour and the image edges is given by the zeros in the stencils in Fig. 13.

The implementation of the contour as a diffusion border prohibits any restriction or prolongation across this border. We therefore use matrix-dependent prolongation and restriction operators, as described in Wesseling (1992). Similar approaches were proposed in Alcouffe et al. (1981), Dendy (1982), and de Zeeuw (1990).

In the following, we will define the prolongation operator, which performs the transition from the coarse grid $2 h$ to the fine grid $h$. According to Wesseling (1992), two constraints have to be fulfilled for the prolongation operator in the one-dimensional case:

$$
\begin{align*}
u_{2 i}^{h} & =[\boldsymbol{P}]_{i, 0}^{2 h} \cdot u_{i}^{2 h}=u_{i}^{2 h},  \tag{50}\\
\left(\boldsymbol{A} \boldsymbol{P} u^{2 h}\right)_{2 i+1} & =0, \tag{51}
\end{align*}
$$

where the first lower index at the stencil denotes the pixel number and the second lower index denotes the position within the stencil, which can be $-1,0$ or 1 for left, middle and right in the 1D case.

The first constraint ensures, that all coarse grid points are transfered directly to the finer grid, the second one

\end{array}\right]\left[\begin{array}{cc}
-\frac{\lambda^{2}}{h^{2}} \\
h^{2} & 1+\frac{2 \lambda^{2}}{h^{2}} \\
0 & 0
\end{array}\right]}
\end{aligned}
$$

Figure 13. Stencils for diffusion snakes. Each stencil defines the action of operator $\boldsymbol{A}$ at a given pixel location, where the zeros denote the effect of a diffusion boundary. Displayed are (from left to right, top to bottom) the stencils $[\boldsymbol{A}]_{(0,0)},[\boldsymbol{A}]_{(i, 0)},[\boldsymbol{A}]_{(M, 0)},[\boldsymbol{A}]_{(0, j)},[\boldsymbol{A}]_{(i, j)}$, $[\boldsymbol{A}]_{(M, j)},[\boldsymbol{A}]_{(0, N)},[\boldsymbol{A}]_{(i, N)},[\boldsymbol{A}]_{(M, N)}$.
ensures, that the prolongation operator is adapted to the matrix $\boldsymbol{A}$. The odd pixels of the finer grid can then be obtained from Eq. (51):

$$
\begin{equation*}
u_{2 i+1}^{h}=-\frac{[\boldsymbol{A}]_{(2 i+1),-1}^{h} \cdot u_{i}^{2 h}+[\boldsymbol{A}]_{(2 i+1), 1}^{h} \cdot u_{i+1}^{2 h}}{[\boldsymbol{A}]_{(2 i+1), 0}^{h}} . \tag{52}
\end{equation*}
$$

A similar solution for the prolongation $\boldsymbol{P}$ is obtained in the two-dimensional case (Wesseling, 1992). The stencils for the restriction correspond to the prolongation stencils, normalized so that they sum up to 1 . Further details can be found in Tischhäuser (2001).

With these definitions of prolongation $\boldsymbol{P}$ and restriction $\boldsymbol{R}$ from the matrix $\boldsymbol{A}^{h}$, we construct the coarse grid matrix $\boldsymbol{A}^{2 h}$ by using Galerkin coarsening:

$$
\begin{equation*}
\boldsymbol{A}^{2 h}=\boldsymbol{R} \boldsymbol{A}^{h} \boldsymbol{P} . \tag{53}
\end{equation*}
$$

To avoid a full matrix multiplication, we exploit the stencil notation as done in the efficient algorithm CALRAP (Wesseling, 1992). Given $\boldsymbol{A}^{2 h}$, we can then construct prolongation and restriction for the next coarser level and so on.

## A.2.3. Results of the Multigrid Implementation.

 Figure 14 shows that using multigrid methods for solving the linear system (47) leads to a performance gain of several orders of magnitude compared to the use of standard algorithms. Using a w-cycle with three descending v-cycles and one step for presmoothing and postsmoothing on each level, one reaches the level of precision of a standard computer in only a few multigrid steps.Analogous to the performance of standard solvers for the common model problems, we found the computation time of the multigrid implementation to be fairly independent of the size of the smoothing parameter $\lambda$. This proves the robustness of our hierarchical scheme with respect to the strongly inhomogeneous diffusivity $w_{c}$. Moreover, the additional storage requirements are

Figure 14. Comparison of different multigrid implementations and the symmetric Gauss-Seidel as a standard solver. The error is defined in logarithmic scale as $\log _{10}\|e\|_{2}$. The numbers of presmoothing, postsmoothing and v-cycles on each level are given in brackets.
not restrictive in our application. Further details can be found in Tischhäuser (2001).

## Acknowledgments

We thank J. Keuchel and C. Kervrann for helpful discussions.
