- 292 To further dissect the genetic architecture of colorectal cancer (CRC), we performed
- 293 whole-genome sequencing of 1,439 cases and 720 controls, imputed discovered sequence
- 294 variants and Haplotype Reference Consortium panel variants into genome-wide association
- study data, and tested for association in 34,869 cases and 29,051 controls. Findings were
- followed up in an additional 23,262 cases and 38,296 controls. We discovered a strongly
- protective 0.3% frequency variant signal at *CHD1*. In a combined meta-analysis of 125,478
- individuals, we identified 40 new independent signals at  $P < 5 \times 10^{-8}$ , bringing the number of
- 299 known independent signals for CRC to approximately 100. New signals implicate lower-
- 300 frequency variants, Krüppel-like factors, Hedgehog signaling, Hippo-YAP signaling, long
- 301 noncoding RNAs, somatic drivers, and support a role of immune function. Heritability
- analyses suggest that CRC risk is highly polygenic, and larger, more comprehensive studies
- enabling rare variant analysis will improve understanding of underlying biology, and
- impact personalized screening strategies and drug development.
- 306 Colorectal cancer (CRC) is the fourth leading cancer-related cause of death worldwide<sup>1</sup> and
- presents a major public health burden. Up to 35% of inter-individual variability in CRC risk has
- been attributed to genetic factors<sup>2,3</sup>. Family-based studies have identified rare high-penetrance
- mutations in at least a dozen genes but, collectively, these account for only a small fraction of

310 familial risk<sup>4</sup>. Over the past decade, genome-wide association studies (GWAS) for sporadic 311 CRC, which constitutes the majority of cases, have identified approximately 60 association signals at over 50 loci<sup>5–22</sup>. Yet, most of the genetic factors contributing to CRC risk remain 312 313 undefined. This severely hampers our understanding of biological processes underlying CRC. It 314 also limits CRC precision prevention, including individualized preventive screening 315 recommendations and development of cancer prevention drugs. The contribution of rare 316 variation to sporadic CRC is particularly poorly understood. 317 318 To expand the catalog of CRC risk loci and improve our understanding of rare variants, genes, 319 and pathways influencing sporadic CRC risk, and risk prediction, we performed the largest and 320 most comprehensive whole-genome sequencing (WGS) study and GWAS meta-analysis for 321 CRC to date, combining data from three consortia: the Genetics and Epidemiology of Colorectal 322 Cancer Consortium (GECCO), the Colorectal Cancer Transdisciplinary Study (CORECT), and 323 the Colon Cancer Family Registry (CCFR). Our study almost doubles the number of individuals 324 analyzed, incorporating GWAS results from >125,000 individuals, and substantially expands and 325 strengthens our understanding of biological processes underlying CRC risk. 326 327 **RESULTS** 328 **Study Overview** 329 We performed WGS of 1,439 CRC cases and 720 controls of European ancestry at low coverage 330 (3.8-8.6×). We detected, called, and estimated haplotype phase for 31.8 million genetic variants, 331 including 1.7 million short insertion-deletion variants (indels) (Online Methods). These data 332 include many rare variants not studied by GWAS. Based on other large-scale WGS studies 333 employing a similar design, we expected to have near-complete ascertainment of single 334 nucleotide variants (SNVs) with minor allele count (MAC) greater than five (minor allele frequency (MAF) >0.1%), and high accuracy at heterozygous genotypes<sup>23,24</sup>. We tested 14.4 335 336 million variants with MAC  $\geq$ 5 for CRC association using logistic regression (Online Methods) 337 but did not find any significant associations. To increase power to detect associations with rare 338 and low-frequency variants of modest effect, we imputed variants from the sequencing 339 experiment into 34,869 cases and 29,051 controls of predominantly European (91.7%) and East 340 Asian ancestry (8.3%) from 30 existing GWAS studies (Online Methods and Supplementary

| 341 | Table 1). By design, two thirds of sequenced individuals were CRC cases, thereby enriching the               |
|-----|--|
| 342 | panel for rare or low-frequency alleles that increase CRC risk. We contributed our sequencing                |
| 343 | data to the Haplotype Reference Consortium (HRC) <sup>25</sup> and imputed the 30 existing GWAS              |
| 344 | studies to the HRC panel, which comprises haplotypes for 32,488 individuals. Results of these                |
| 345 | GWAS meta-analyses (referred to as Stage 1 meta-analysis; Online Methods) informed the                       |
| 346 | design of a custom Illumina array comprising the OncoArray, a custom array to identify cancer                |
| 347 | risk loci <sup>26</sup> , and 15,802 additional variants selected based on Stage 1 meta-analysis results. We |
| 348 | genotyped 12,007 cases and 12,000 controls of European ancestry with this custom array, and                  |
| 349 | combined them with an additional 11,255 cases and 26,296 controls with GWAS data, resulting                  |
| 350 | in a Stage 2 meta-analysis of 23,262 CRC cases and 38,296 controls (Online Methods,                          |
| 351 | Supplementary Fig. 1, and Supplementary Table 1). Next, we performed a combined (Stage 1                     |
| 352 | + Stage 2) meta-analysis of up to 58,131 cases and 67,347 controls. This meta-analysis was                   |
| 353 | based on the HRC-panel-imputed data because, given its large size, this panel results in superior            |
| 354 | imputation quality and enables accurate imputation of variants with MAFs as low as $0.1\%^{25}$ .            |
| 355 | Here, we report new association signals discovered through our custom genotyping experiment                  |
| 356 | and replicating in Stage 2 at the Bonferroni significance threshold of $P < 7.8 \times 10^{-6}$ (Online      |
| 357 | Methods), as well as distinct association signals passing the genome-wide significance (GWS)                 |
| 358 | threshold of $P < 5 \times 10^{-8}$ in the combined meta-analysis of up to 125,478 individuals.              |
| 359 |  |
| 360 | CRC risk loci  |
| 361 | In the combined meta-analysis, we identified 30 new CRC risk loci reaching GWS and >500kb                    |
| 362 | away from previously reported CRC risk variants (Table 1; Supplementary Fig. 2 and 3).                       |
| 363 | Twenty-two of these were represented on our custom genotyping panel, either by the lead variant              |
| 364 | (15 loci) or by a variant in linkage disequilibrium (LD) (7 loci; $r^2 > 0.7$ ). Of these 22 variants,       |
| 365 | eight attained the Bonferroni significance threshold in the Stage 2 meta-analysis (Table 1).                 |
| 366 |  |
| 367 | Among these eight loci is the first rare variant signal identified for sporadic CRC, involving five          |
| 368 | 0.3% frequency variants at 5q21.1, near genes CHD1 and RGMB. SNP rs145364999, intronic to                    |
| 369 | CHD1, had high quality genotyping (Supplementary Fig. 4). The variant was well imputed in                    |
| 370 | the remaining sample sets (imputation quality $r^2$ ranged from 0.66 to 0.87; <b>Supplementary</b>           |
| 371 | <b>Table 2</b> ) and there was no evidence of heterogeneity of effects (heterogeneity $P=0.63$ ;             |

Supplementary Table 2). The rare allele confers a strong protective effect (allelic odds ratio 372 373 (OR)=0.52 in Stage 2; 95% confidence interval (CI)=0.40-0.68). Chromatin remodeling factor 374 CHD1 provides an especially plausible candidate and has been shown to be a syntheticallyessential gene<sup>27</sup> that is occasionally deleted in some cancers, but always retained in PTEN-375 deficient cancers<sup>28</sup>. The resulting mutually exclusive deletion pattern of *CHD1* and *PTEN* has 376 been observed in prostate, breast, and CRC TCGA data<sup>28</sup>. We hypothesize that the rare allele 377 378 confers a protective effect through lowering CHD1 expression, which is required for nuclear 379 factor-κβ (NF-κβ) pathway activation and growth in cancer cells driven by loss of the tumor suppressor PTEN<sup>28</sup>. However, we cannot rule out involvement of nearby candidate gene RGMB 380 381 that encodes a co-receptor for bone morphogenetic proteins BMP2 and BMP4, both of which are linked to CRC risk through GWAS<sup>9,11</sup>. Additionally, RGMB has been shown to bind to PD-L2<sup>29</sup>, 382 383 a known ligand of PD-1, an immune checkpoint blockade inhibitor targeted by cancer 384 immunotherapy<sup>30</sup>. 385 386 The vast majority of new association signals involve common variants. We found associations 387 near strong candidate genes for CRC risk in pathways or gene families not previously implicated by GWAS. Locus 13q22.1, represented by lead SNP rs78341008 (MAF 7.2%;  $P=3.2\times10^{-10}$ ), is 388 389 near KLF5, a known CRC oncogene that can be activated by somatic hotspot mutations or superenhancer duplications<sup>31,32</sup>. *KLF5* encodes transcription factor Krüppel-like factor 5 (KLF5). 390 391 which promotes cell proliferation and is highly expressed in intestinal crypt stem cells. We also 392 found an association at 19p13.11, near KLF2. KLF2 expression in endothelial cells is critical for normal blood vessel function<sup>33,34</sup>. Down-regulated KLF2 expression in colon tumor tissues 393 394 contributes to structurally and functionally abnormal tumor blood vessels, resulting in impaired blood flow and hypoxia in tumors<sup>35</sup>. Another locus at 9q31.1 is near *LPAR1*, which encodes a 395 396 receptor for lysophosphatidic acid (LPA). LPA-induced expression of hypoxia-inducible factor 1 (HIF-1α), a key regulator of cellular adaptation to hypoxia and tumorigenesis, depends on 397 398 KLF5<sup>36</sup>. Additionally, LPA activates multiple signaling pathways and stimulates proliferation of colon cancer cells by activation of KLF5<sup>37</sup>. Another locus (7p13) is near SNHG15, encoding a 399 400 long non-coding RNA (lncRNA) that epigenetically represses KLF2 to promote pancreatic cancer proliferation<sup>38</sup>. 401

403 We found two loci near members of the Hedgehog (Hh) signaling pathway. Aberrant activation 404 of this pathway, caused by somatic mutations or changes in expression, can drive tumorigenesis in many tumors<sup>39</sup>. Notably, downregulated stromal cell Hh signaling reportedly accelerates 405 colonic tumorigenesis in mice<sup>40</sup>. Locus 3q13.2, represented by low-frequency lead SNP 406 rs72942485 (MAF 2.2%;  $P=2.1\times10^{-8}$ ), overlaps BOC, encoding a Hh coreceptor molecule. In 407 408 medulloblastoma, upregulated BOC promotes Hh-driven tumor progression through Cyclin D1induced DNA damage<sup>41</sup>. In pancreatic cancer, a complex role for stromal *BOC* expression in 409 tumorigenesis and angiogenesis has been reported<sup>42</sup>. Locus 4q31.21 is near *HHIP*, encoding an 410 411 inhibitor of Hh signaling. Of note, the Hh signaling pathway was also significantly enriched in 412 our pathway analysis (described below). 413 414 Locus 11q22.1 is near YAPI, which encodes a critical downstream regulatory target in the Hippo 415 signaling pathway that is gaining recognition as a pivotal player in organ size control and tumorigenesis<sup>43</sup>. YAP1 is highly expressed in intestinal crypt stem cells, and in transgenic mice, 416 417 overexpression resulted in severe intestinal dysplasia and loss of differentiated cell types<sup>44</sup>, 418 reminiscent of phenotypes observed in mice and humans with deleterious germline APC 419 mutations. Further, Hypoxia-inducible factor  $2\alpha$  (HIF- $2\alpha$ ) promotes colon cancer growth by upregulating YAP1 activity<sup>45</sup>. 420 421 422 We provide further evidence for a link between immune function and CRC pathogenesis, and 423 implicate the major histocompatibility complex (MHC) in CRC risk. We identified a locus near genes *HLA-DRB1/HLA-DQA1*, which is associated with immune-mediated diseases<sup>46</sup>. 424 425 426 We identified two new loci near known tumor suppressor genes. Locus 4q24 is near TET2, a 427 chromatin-remodeling gene frequently somatically mutated in multiple cancers, including colon cancer<sup>47</sup>, and overlapping GWAS signals for multiple other cancers<sup>48–50</sup>. The CDKN2B-428 429 CDKN2A-ANRIL locus at 9p21.3 is a well-established hot spot of pleiotropic GWAS associations for many complex diseases including coronary artery disease<sup>51</sup>, type 2 diabetes<sup>52</sup>, 430 and cancers  $^{50,53,54-56}$ . Interestingly, lead variant rs1537372 is in high LD ( $r^2$ =0.82) with variants 431 associated with coronary artery disease<sup>51</sup> and endometriosis<sup>57</sup>, but not with the other cancer-432 433 associated variants. CDKN2A/B encode cyclin-dependent kinase inhibitors that regulate the cell

| 434 | cycle. CDKN2A is one of the most commonly inactivated genes in cancer, and is a high                                 |
|-----|--|
| 435 | penetrance gene for melanoma <sup>58,59</sup> . CDKN2B activation is tightly controlled by the cytokine              |
| 436 | TGF- $β$ , further linking this signaling pathway with CRC tumorigenesis <sup>60</sup> .                             |
| 437 |  |
| 438 | Our findings implicate genes in pathways with established roles in CRC pathogenesis. We                              |
| 439 | identified loci at SMAD3 and SMAD9, members of the TGF-β signaling pathway that includes                             |
| 440 | genes linked to familial CRC syndromes (e.g., SMAD4 and BMPR1A) and several GWAS-                                    |
| 441 | implicated genes (e.g., SMAD7, BMP2, BMP4) <sup>61</sup> . We identified another locus near TGF-β                    |
| 442 | Receptor 1 (TGFBR1). Nearby gene GALNT12 reportedly harbors inactivating germline and                                |
| 443 | somatic mutations in human colon cancers <sup>62</sup> and, therefore, could also be the regulated effector          |
| 444 | gene. We identified a locus at 14q23.1 near DACT1, a member of the Wnt-β-catenin pathway                             |
| 445 | with genes previously linked to familial CRC syndromes (APC <sup>63</sup> ), and several GWAS-implicated             |
| 446 | genes (e.g., $CTNNB1^{18}$ and $TCF7L2^{17}$ ). Genes related to telomere biology were linked by other               |
| 447 | GWAS: TERC <sup>10</sup> and TERT <sup>22</sup> , encoding the RNA and protein subunit of telomerase respectively,   |
| 448 | and FENI <sup>17</sup> , involved in telomere stability <sup>64</sup> . A new locus at 20q13.33 harbors another gene |
| 449 | related to telomere biology, RTEL1. This gene is involved in DNA double-strand break repair,                         |
| 450 | and overlaps GWAS signals for cancers <sup>55,65</sup> and inflammation-related phenotypes, including                |
| 451 | inflammatory bowel disease <sup>66</sup> and atopic dermatitis <sup>67</sup> .                                       |
| 452 |  |
| 453 | Of 61 signals at 56 loci previously associated with CRC at GWS, 42 showed association                                |
| 454 | evidence at $P < 5 \times 10^{-8}$ in the combined meta-analysis, and 55 at $P < 0.05$ in the independent            |
| 455 | Stage 2 meta-analysis (Supplementary Table 3). Of note, the association of rs755229494 at                            |
| 456 | locus 5q22.2 (P=2.1×10 <sup>-12</sup> ) was driven by studies with predominantly Ashkenazi Jewish ancestry           |
| 457 | and this SNP is in perfect LD with known missense SNP rs1801155 in the APC gene (I1307K),                            |
| 458 | the minor allele of which is enriched in this population (MAF 6%), but rare in other                                 |
| 459 | populations <sup>68,69</sup> .   |
| 460 |  |
| 461 | Delineating distinct association signals at CRC risk loci  |
| 462 | To identify additional independent association signals at known or new CRC risk loci, we                             |
| 463 | conducted conditional analysis using individual-level data of 125,478 participants (Online                           |
| 464 | Methods). At nine loci we observed 10 new independent association signals that attained $P_1$                        |

- 465 <5×10<sup>-8</sup> in a joint multiple-variant analysis (**Table 2**; **Supplementary Table 4**; **Supplementary**
- 466 Fig. 5). Because this analysis focused on <5% of the genome, we also report signals at  $P_{\rm J} < 1 \times 10^{-1}$
- 467 <sup>5</sup> in **Supplementary Table 5**. At 22 loci, we observed 25 new suggestive associations with  $P_{\rm J}$
- $468 < 1 \times 10^{-5}$ .

- 470 At 11q13.4, near *POLD3* and *CHRDL2*, we identified a new low-frequency variant (lead SNP
- 471 rs61389091, MAF 3.94%) separated by a recombination hotspot from the known common
- variant signal  $^{12}$  (LD  $r^2$  between lead SNPs <0.01). At 5p15.33, we identified another lower-
- 473 frequency variant association (lead SNP rs78368589, MAF 5.97%), which was independent from
- 474 the previously reported common variant signal 56kb away near *TERT* and *CLPTM1L* (LD  $r^2$  with
- lead SNP rs2735940 <0.01)<sup>22</sup>. Variants in this region were linked to many cancer types,
- including lung, prostate, breast, and ovarian cancer<sup>70</sup>.

- The remaining eight new signals involved common variants. At new locus 2q33.1, near genes
- 479 *PLCL1* and *SATB2*, two statistically independent associations (LD  $r^2$  between two lead SNPs
- 480 <0.01) are separated by a recombination hotspot (**Supplementary Fig. 5**). In the MHC region,
- we identified a conditionally independent signal near genes involved in NF-κβ signaling,
- including the gene encoding tumor necrosis factor- $\alpha$ , genes for the stress-signaling proteins
- 483 MICA/MICB, and *HLA-B*. Locus 20p12.3, near *BMP2*, harbored four distinct association signals
- 484 (**Figure 1**), two of which were reported previously <sup>10,11</sup> (**Supplementary Table 5**). All four SNPs
- selected in the model were in pairwise linkage equilibrium (maximum LD  $r^2 = 0.039$ , between
- 486 rs189583 and rs994308). Our conditional analysis further confirmed that the signal  $\sim$ 1-Mb
- 487 centromeric of *BMP2*, near gene *HAO1*, is independent. At 8q24.21 near *MYC*, the locus
- showing the second strongest statistical evidence of association in the combined meta-analysis
- (lead SNP rs6983267;  $P = 3.4 \times 10^{-64}$ ), we identified a second independent signal (lead SNP
- 490 rs4313119,  $P_J = 2.1 \times 10^{-9}$ ; LD  $r^2$  with rs6983267 < 0.001). At the recently reported locus
- 491 5p13.1<sup>22</sup>, near the non-coding RNA gene *LINC00603*, we identified an additional signal (lead
- SNP rs7708610) that was partly masked by the reported signal in the single-variant analysis due
- 493 to the negative correlation between rs7708610 and rs12514517 (r = -0.18;  $r^2 = 0.03$ ). This
- caused significance for both SNPs to increase markedly when fitted jointly (rs7708610,
- unconditional  $P = 1.5 \times 10^{-5}$  and  $P_J = 3.8 \times 10^{-9}$ ). At 12p13.32 near *CCND2*, we identified a new

- signal (lead SNP rs3217874,  $P_J = 2.4 \times 10^{-9}$ ) and confirmed two previously associated signals <sup>13–15</sup>
- 497 (Supplementary Text). At the *GREM1* locus on 15q13.3, two independent signals were
- 498 previously described<sup>11</sup>. Our analyses suggest that this locus harbors three signals. A new signal
- represented by SNP rs17816465 is conditionally independent from the other two signals ( $P_J$  =
- 500 1.4×10<sup>-10</sup>, conditioned on rs2293581 and rs12708491; LD with conditioning SNPs  $r^2$ <0.01;
- 501 **Supplementary Text**).

- Additionally, signals with  $P_{\rm J}$  values approaching GWS were observed at new locus 3q13.2 near
- BOC (rs13086367, unconditional  $P = 6.7 \times 10^{-8}$ ,  $P_J = 6.9 \times 10^{-8}$ , MAF=47.4%), 96kb from the low-
- frequency signal represented by rs72942485 (unconditional  $P = 2.1 \times 10^{-8}$ ,  $P_J = 1.3 \times 10^{-8}$ ,
- 506 MAF=2.2%); at known locus 10q22.3 near ZMIZ1 (rs1250567, unconditional  $P = 3.1 \times 10^{-8}$ ,  $P_{\rm J} =$
- $7.2 \times 10^{-8}$ , MAF=45.1%); and at new locus 13q22.1 near *KLF5* (rs45597035, unconditional P =
- 508  $2.7 \times 10^{-9}$ ,  $P_{\rm J} = 8.1 \times 10^{-8}$ , MAF=34.4%) (**Supplementary Table 5**). Furthermore, we clarify
- previously reported independent association signals (Supplementary Text).

510

511

- Associations of CRC risk variants with other traits
- Nineteen of the GWS association signals for CRC were in high LD ( $r^2 > 0.7$ ) with at least one
- 513 SNP in the NHGRI-EBI GWAS Catalog<sup>46</sup> that has significant association in GWAS of other
- traits. Notable overlap included SNPs associated with other cancers, immune-related traits (e.g.,
- tonsillectomy, inflammatory bowel disease, and circulating white blood cell traits), obesity traits,
- blood pressure, and other cardiometabolic traits (**Supplementary Table 6**).

517

- Mechanisms underlying CRC association signals
- To further localize variants driving the 40 newly identified signals, we used association evidence
- 520 to define credible sets of variants that are 99% likely to contain the causal variant (Online
- Methods). The 99% credible set size for new loci ranged from one (17p12) to 93 (2q33.1). For
- 522 11 distinct association signals, the set included ten or fewer variants (**Supplementary Table 7**).
- At locus 17p12, we narrowed the candidate variant to rs1078643, located in exon 1 of the
- lncRNA LINC00675 that is primarily expressed in gastrointestinal tissues. Small credible sets
- were observed for locus 4g31.21 (two variants, indexed by synonymous SNP rs11727676 in
- 526 *HHIP*), and signals at known loci near *GREM1* (one variant) and *CCND2* (two variants).

527 528 We performed functional annotation of credible set variants to nominate putative causal variants. 529 Eight sets contained coding variants but only the synonymous SNP in *HHIP* had a high posterior 530 probability of driving the association (Supplementary Table 8). Next, we examined overlap of 531 credible sets with regulatory genomic annotations from 51 existing CRC-relevant datasets to 532 examine non-coding functions (Online Methods). Also, to better refine regulatory elements in 533 active enhancers, we performed ATAC-seq to measure chromatin accessibility in four colonic 534 crypts and used resulting data to annotate GWAS signals. 535 536 Of the 40 sets, 36 overlapped with active enhancers identified by histone mark H3K27ac 537 measured in normal colonic crypt epithelium, CRC cell lines, or CRC tissue (Supplementary 538 **Table 8**; Supplementary Fig. 6). Twenty of these 36 overlapped with super-enhancers. Notably, 539 when compared with epigenomics data from normal colonic crypt epithelium, all 36 sets 540 overlapped enhancers with gained or lost activity in one or more CRC specimens. Eleven of 541 these sets overlapped enhancers recurrently gained or lost in >20 CRC cell lines. 542 543 The locus at GWAS hot spot 9p21 overlaps a super-enhancer, and the credible set is entirely 544 intronic to ANRIL, alias CDKN2B-ASI. The Genotype-Tissue Expression (GTEx) data show that 545 the antisense lncRNA ANRIL is exclusively expressed in transverse colon and small intestine. 546 Interestingly, ANRIL recruits SUZ12 and EHZ2 to epigenetically silence tumor suppressor genes 547  $CDKN2A/B^{71}$ . 548 549 Noncoding somatic driver mutations or focal amplifications have been reported in regions regulating expression of MYC<sup>72</sup>, TERT<sup>73</sup>, and KLF5<sup>31</sup>, now implicated by GWAS for CRC. We 550 551 checked whether GWAS-identified association signals co-localize with these regions and found that the KLF5 signal overlaps the somatically amplified super-enhancer flanked by KLF5 and 552 *KLF12* (**Figure 2**). Also, the previously reported signal in the *TERT* promotor region<sup>22</sup> overlaps 553 with the recurrent somatically mutated region in multiple cancers<sup>73</sup>. 554 555 556 To test whether CRC associations are non-randomly distributed across genomic features, we used GARFIELD<sup>74</sup>. Focusing on DNase I hypersensitive site (DHS) peaks that identify open 557

| 338 | chromatin, we observed significant enrichment across many cell types, particularly fetal tissues,                |
|-----|--|
| 559 | with strongest enrichment observed in fetal gastrointestinal tissues, CD20 <sup>+</sup> primary cells (B         |
| 560 | cells), and embryonic stem cells (Supplementary Fig. 7; Supplementary Table 9).                                  |
| 561 |  |
| 562 | We used MAGENTA <sup>75</sup> to identify pathways or gene sets enriched for associations with CRC,              |
| 563 | assessing two gene P-value cutoffs: 95th and 75th percentiles. At the 75th percentile, we                        |
| 564 | observed enrichment of multiple KEGG cancer pathways at a false discovery rate (FDR) of 0.05.                    |
| 565 | This was not observed for the 95th percentile cutoff and suggests that many more loci that are                   |
| 566 | shared with other cancer types remain to be identified in larger studies. Using the 75th (95th)                  |
| 567 | percentile cutoff, at FDR 0.05 and 0.20, we found enrichment of 7 (5) and 53 (24) gene sets,                     |
| 568 | respectively. Established pathways related to TGF- $\beta$ /SMAD and BMP signaling were among the                |
| 569 | top enriched pathways. Other notable enriched pathways included Hedgehog signaling, basal cell                   |
| 570 | carcinoma, melanogenesis, cell cycle, S phase, and telomere maintenance (Supplementary                           |
| 571 | Table 10).   |
| 572 |  |
| 573 | Polygenicity of colorectal cancer and contribution of rare variants  |
| 574 | To estimate the contribution of rare variants (MAF $\leq$ 1%) to CRC heritability, we used the LD-               |
| 575 | and MAF-stratified component GREML (GREML-LDMS) method implemented in GCTA <sup>76</sup>                         |
| 576 | (Online Methods). Assuming a lifetime risk of 4.3%, we estimated that all imputed autosomal                      |
| 577 | variants explain 21.6% (95% CI=17.5-25.7%) of the variation in liability for CRC, with almost                    |
| 578 | half of this contributed by rare variants ( $h_g^2 = 9.7\%$ , 95% CI=6.2-13.3%; likelihood ratio test            |
| 579 | P=0.003); the estimated liability-scale heritability for variants with MAF > 1% is 11.8% (95%)                   |
| 580 | CI=8.9-14.7%). Our overall estimate falls within the range of heritability reported by large twin                |
| 581 | studies <sup>2</sup> . Because heritability estimates for rare variants are sensitive to potential biases due to |
| 582 | technical effects or population stratification <sup>77</sup> and the contribution of rare variants is probably   |
| 583 | underestimated due to limitations of genotype imputation, results should be interpreted with                     |
| 584 | caution. Overall, findings suggest that missing heritability is not large, but that many rare and                |
| 585 | common variants have yet to be identified.   |
| 586 |  |

# Familial relative risk explained by GWAS-identified variants

Adjusting for winner's curse<sup>78</sup>, the familial relative risk (RR) to first-degree relatives ( $\lambda_0$ ) 588 589 attributable to GWAS-identified variants rose from 1.072 for the 55 previously described 590 autosomal risk variants that showed evidence for replication at P < 0.05, to 1.092 after inclusion 591 of 40 new signals, and increased further to 1.098 when we included 25 suggestive association 592 signals reported in **Supplementary Table 5** (Online Methods). Assuming a  $\lambda_0$  of 2.2, the 55 593 established signals account for 8.8% of familial RR explained (95% CI: 8.1-9.4). Established 594 signals combined with 40 newly discovered signals account for 11.2% (95% CI: 10.5-12.0), and 595 adding 25 suggestive signals increases this to 11.9% (95% CI: 11.1-12.7). 596 597 **Implications for stratified screening prevention** 598 We demonstrate how using a polygenic risk score (PRS) derived from 95 independent 599 association signals could impact clinical guidelines for preventive screening. The difference in 600 recommended starting age for screening for those in the highest 1% (and 10%) percentiles of risk 601 compared with lowest percentiles is 18 years (and 10 years) for men, and 24 years (and 12 years) 602 for women (Figure 3; Online Methods). Supplementary Table 11 gives risk allele frequency 603 (RAF) estimates in different populations for variants included in the PRS. As expected, RAFs 604 vary across populations. Furthermore, differences in LD between tagging and true causal variants 605 across populations can result in less prediction accuracy and subsequent lower predictive power 606 of the PRS in non-European populations. Accordingly, it will be important to develop ancestry-607 specific PRSs that incorporate detailed fine-mapping results for each GWAS signal. 608 609 **DISCUSSION** 610 To further define the genetic architecture of sporadic CRC, we performed low-coverage WGS 611 and imputation into a large set of GWAS data. We discovered 40 new CRC signals and 612 replicated 55 previously reported signals. We found the first rare variant signal for sporadic 613 CRC, which represents the strongest protective rare allelic effect identified to date. Our analyses 614 highlight new genes and pathways contributing to underlying CRC risk and suggest roles for 615 Krüppel-like factors, Hedgehog signaling, Hippo-YAP signaling, and immune function. Multiple loci provide new evidence for an important role of lncRNAs in CRC tumorigenesis<sup>79</sup>. Functional 616 617 genomic annotations support that most sporadic CRC genetic risk lies in non-coding genomic

regions. We further show how newly discovered variants can lead to improved risk prediction.

This study underscores the critical importance of large-scale GWAS collaboration. While discovery of the rare variant signal was only possible through increased coverage and improved imputation accuracy enabled by imputation panels, sample size was pivotal for discovery of new CRC loci. Results suggest that CRC exhibits a highly polygenic architecture, much of which remains undefined. This also suggests that continued GWAS efforts, together with increasingly comprehensive imputation panels that allow for improved low-frequency and rare genetic variant imputation, will uncover more CRC risk variants. In addition, to investigate sites that are not imputable, large-scale deep sequencing will be needed. Importantly, the prevailing European bias in CRC GWAS limits the generalizability of findings and the application of PRSs in non-European (especially African) populations<sup>80</sup>. Therefore, a broader representation of ancestries in CRC GWAS is necessary. Studies of somatic genomic alterations in cancer have mostly focused on the coding genome and identification of noncoding drivers has proven to be challenging<sup>73</sup>. Yet, noncoding somatic driver mutations or focal amplications in regulatory regions impacting expression have been reported for  $MYC^{72}$ ,  $TERT^{73}$ , and  $KLF5^{31}$ . The observed overlap between GWAS-identified CRC risk loci and somatic driver regions strongly suggests that expanding the search of somatic driver mutations to noncoding regulatory elements will yield additional discoveries and that searches for somatic drivers can be guided by GWAS findings. Additionally, we found loci near proposed drug targets, including CHDI, implicated by the rare variant signal, and *KLF5*. To date, cancer drug target discovery research has almost exclusively focused on properties of cancer cells, yielding drugs that target proteins either highly expressed or expressed in a mutant form due to frequent recurrent somatic missense mutations (e.g., BRAF<sup>V600E</sup>) or gene fusion events. In stark contrast with other common complex diseases, cancer GWAS results are not being used extensively to inform drug target selection. It has been estimated that selecting targets supported by GWAS could double the success rate in clinical development<sup>81</sup>. Our discoveries corroborate that not using GWAS results to inform drug discovery is a missed opportunity, not only for treating cancers, but also for chemoprevention in high-risk individuals.

648

- 650
- In summary, in the largest genome-wide scan for sporadic CRC risk thus far, we identified the
- 652 first rare variant signal for sporadic CRC, and almost doubled the number of known association
- signals. Our findings provide a substantial number of new leads that may spur downstream
- 654 investigation into the biology of CRC risk, and that will impact drug development and clinical
- guidelines, such as personalized screening decisions.

Figure 1 Conditionally independent association signals at the *BMP2* locus. Regional association plot showing the unconditional  $-\log_{10}(P\text{-value})$  for the association with CRC risk in the combined meta-analysis of up to 125,478 individuals, as a function of genomic position (Build 37) for each variant in the region. The lead variants are indicated by a diamond symbol and its positions are indicated by dashed vertical lines. The color-labeling and shape of all other variants indicate the lead variant with which they are in strongest LD. The two new genomewide significant signals are indicated by an asterisk.

Figure 2 Functional genomic annotation of new CRC risk locus overlapping KLF5 super**enhancer.** Top: Regional association plot showing the unconditional  $-\log_{10}(P\text{-value})$  for the association with CRC risk in the combined meta-analysis of up to 125,478 individuals, as a function of genomic position (Build 37) for each variant in the region. The lead variants are indicated by a diamond symbol and its positions are indicated by dashed vertical lines. The color-labeling and shape of all other variants indicate the lead variant with which they are in strongest LD. **Bottom:** UCSC genome browser annotations for region overlapping the superenhancer flanked by KLF5 and KLF12, and spanning variants in LD with rs78341008, and with two conditionally independent association signals indexed by rs45597035 and rs1924816. The region is annotated with the following tracks (from top to bottom): UCSC gene annotations; epigenomic profiles showing MACS2 peak calls as transparent overlays for different samples taken from non-diseased colonic crypt cells or colon tissue (purple) and from different primary CRC cell lines or tumor samples (teal); position of the lead variants and variants in LD with the lead; variants in the 99% credible set; the union of super-enhancers called using the ROSE package; gray bars highlight the targeted enhancers (e1,e3, and e4) previously shown by Zhang et al.<sup>31</sup> to have combinatorial effects on KLF5 expression. ATAC-seq data newly generated for this study show high resolution annotation of putative binding regions within the active superenhancer further fine-mapping putative causal variants at each of the three signals.

## Figure 3 Recommended age to start CRC screening based on a polygenic risk score (PRS).

The PRS was constructed using the 95 known and newly discovered variants. The horizontal lines represent the recommended age for the first endoscopy for an average-risk person in the

current screening guideline for CRC. The risk threshold to determine the age for the first screening was set as the average of 10-year CRC risks for a 50-year-old man (1.25%) and woman (0.68%), i.e. (1.25%+0.68%)/2=0.97%, who have not previously received an endoscopy. Details are given in the Online Methods.

Lead variant is the most associated variant at the locus. rsIDs based on NCBI dbSNP Build 150. Alleles are on the + strand. Chr.: Chromosome. RAF: Risk allele frequency, based on stage 2 data. OR, odds ratio estimate for the risk allele. All *P*-values reported in this table are based on fixed-effects inverse variance-weighted meta-analysis.

\*Indicates that variant or LD proxy ( $r^2 > 0.7$ ) was selected for our custom genotyping panel and formally replicates in the Stage 2 meta-analysis at a Bonferroni significance threshold of  $P < 7.8 \times 10^{-6}$ .

<sup>§</sup>Indicates that variant or LD proxy ( $r^2 > 0.7$ ) was selected for our custom genotyping panel but did not attain Bonferroni significance in the Stage 2 meta-analysis.

This SNP reached genome-wide significance in the combined (Stage 1 + Stage 2) sample-size weighted meta-analysis based on likelihood ratio test results ( $P = 4.9 \times 10^{-8}$ ).

Table 2 Additional new conditionally independent association signals at known and newly identified CRC risk loci that reach genome-wide significance ( $P < 5 \times 10^{-8}$ ) in the combined meta-analysis of up to 125,478 individuals.

Lead variant is the most associated variant at the locus in the conditional analysis. rsIDs based on NCBI dbSNP Build 150. Alleles are on the + strand. Chr.: Chromosome. RAF: Risk allele frequency, based on stage 2 data. OR, odds ratio estimates are for the risk allele. Conditioning variants are the lead variant of other conditionally independent association signals with  $P < 1 \times 10^{-5}$  within 1-Mb of the new association signal. Because of extensive LD we used a 2-Mb distance for the MHC region (6p21.32). All lead variants for the new association signals are in linkage equilibrium with any previously reported CRC risk variants at the locus ( $r^2 < 0.10$ ).

<sup>\*</sup>Indicates that the conditioning variant is either the index variant, or a variant in LD with the index variant reported in previous GWAS. Details and full results are provided in Supplementary Table 5.

#### 955 **ONLINE METHODS** 956 Study samples. 957 After quality control (QC), this study included whole-genome sequencing (WGS) data for 1,439 958 colorectal cancer (CRC) cases and 720 controls from 5 studies, and GWAS array data for 58,131 959 CRC or advanced adenoma cases (3,674; 6.3% of cases) and 67,347 controls from 45 studies 960 from GECCO, CORECT, and CCFR. The Stage 1 meta-analysis comprised existing genotyping data from 30 studies that were included in previously published CRC GWAS<sup>13,18,22</sup>. After QC, 961 962 the Stage 1 meta-analysis included 34,869 cases and 29,051 controls. Study participants were 963 predominantly of European ancestry (31,843 cases and 26,783 controls; 91.7% of participants). 964 Because it was shown previously that the vast majority of known CRC risk variants are shared between Europeans and East Asians<sup>17</sup>, we included 3,026 cases and 2,268 controls of East Asian 965 966 ancestry to increase power for discovery. The Stage 2 meta-analysis comprised newly generated 967 genotype data involving 4 genotyping projects and 22 studies. After QC, the Stage 2 meta-968 analysis included 23,262 cases and 38,296 controls, all of European ancestry. Studies, sample 969 selection, and matching are described in the Supplementary Text. Supplementary Table 1 970 provides details on sample numbers, and demographic characteristics of study participants. All 971 participants provided written informed consent, and each study was approved by the relevant 972 research ethics committee or institutional review board. Four normal colon mucosa biopsies for 973 ATAC-seq were obtained from patients with a normal colon at colonoscopy at the Institut 974 d'Investigació Biomèdica de Bellvitge (IDIBELL), Spain. Patients signed informed consent, and 975 the protocol was approved by the Bellvitge Hospital Ethics Committee (Colscreen protocol 976 PR084/16). 977 978 Whole-genome sequencing. 979 We performed low-pass WGS of 2,192 samples from 5 studies at the University of Washington 980 Northwest Genomics Center (Seattle, WA, USA). Cases and controls were processed and 981 sequenced together. Libraries were prepared with ThruPLEX DNA-seq kits (Rubicon Genomics) 982 and paired-end sequencing performed using Illumina HiSeq 2500 sequencers. Reads were 983 mapped to human reference genome (GRCh37 assembly) using Burrows-Wheeler aligner BWA v0.6.2<sup>82</sup>. Fold genomic coverage averaged 5.3× (range: 3.8-8.6×). We used the GotCloud 984 population-based multi-sample variant calling pipeline<sup>83</sup> for post-processing of BAM files with 985

initial alignments, and to detect and call single nucleotide variants (SNVs) and short insertions and deletions (indels). After removing duplicated reads and recalibrating base quality scores, QC checks included sample contamination detection. Variants were jointly called across all samples. To identify high-quality sites, the GotCloud pipeline performs a two-step filtering process. First, lower quality variants are identified by applying individual variant quality statistic filters. Next, variants failing multiple filters are used as negative examples to train a support vector machine (SVM) classifier. Finally, we performed a haplotype-aware genotype refinement step via Beagle<sup>84</sup> and ThunderVCF<sup>85</sup> on the SVM-filtered VCF files. After further sample QC, we excluded samples with estimated DNA contamination >3% (16), duplicated samples (5) or related individuals (1), sex discrepancies (0), and samples with low concordance with GWAS array data (11). We checked for ancestry outliers by performing principal components analysis (PCA) after merging in data for shared, linkage disequilibrium (LD)-pruned SNVs for 1,092 individuals from the 1000 Genomes Project<sup>86</sup>. After QC, sequences were available for 1,439 CRC cases and 720 controls of European ancestry.

### GWAS genotype data and quality control.

Details of genotyping and QC for studies included in the Stage 1 meta-analysis are described elsewhere <sup>13,18,22</sup>. **Supplementary Table 1** provides details of genotyping platforms used. Before association analysis, we pooled individual-level genotype data of all Stage 1 studies for a subset of SNPs to enable identification of unexpected duplicates and close relatives. We calculated identity by descent (IBD) for each pair of samples using KING-robust<sup>87</sup> and excluded duplicates and individuals that are second-degree or more closely related. As part of Stage 2, 28,805 individuals from 19 studies were newly genotyped on a custom Illumina array based on the Infinium OncoArray-500K<sup>26</sup> and a panel of 15,802 successfully manufactured custom variants (described in **Supplementary Text**). An additional 8,725 individuals from 5 studies were genotyped on the Illumina HumanOmniExpressExome-8v1-2 array. Genotyping and calling for both projects were performed at the Center for Inherited Disease Research (CIDR) at Johns Hopkins University. Genotypic data that passed initial QC at CIDR subsequently underwent QC at the University of Washington Genetic Analysis Center (UW GAC) using standardized methods detailed in Laurie *et al.* <sup>88</sup>. The median call rate for the custom Infinium OncoArray-500K data was 99.97%, and error rate estimated from 301 sample duplicate pairs was 9.99e-7. A

| 1017 | relatively low number of samples (246) had a missing call rate >2%, with the highest being                       |
|------|--|
| 1018 | 3.48%, and were included in analysis. For the HumanOmniExpressExome-8v1-2 data, median                           |
| 1019 | call rate was 99.96%, and the error rate estimated from 179 sample duplicate pairs was 2.65e-6.                  |
| 1020 | Thirty samples had a missing call rate >2%, with the highest being 3.79%, and were included in                   |
| 1021 | analysis. We excluded samples with discrepancies between reported and genotypic sex based on                     |
| 1022 | X chromosome heterozygosity and the means of sex chromosome probe intensities, unintentional                     |
| 1023 | duplicates, and close relatives defined as individuals that are second-degree or more closely                    |
| 1024 | related. After further excluding individuals of non-European ancestry as determined by PCA (see                  |
| 1025 | below), the custom OncoArray data included in analysis comprised 11,852 CRC cases and                            |
| 1026 | 11,895 controls, and the HumanOmniExpressExome-8v1-2 array data included in analysis                             |
| 1027 | comprised 4,439 CRC cases and 4,115 controls. Only variants passing QC were used for                             |
| 1028 | imputation. We excluded variants failing CIDR technical filters or UW GAC quality filters,                       |
| 1029 | which included missing call rate >2%, discordant calls in sample duplicates, and departures from                 |
| 1030 | Hardy-Weinberg equilibrium (HWE) ( $P < 1e-4$ ) based on European-ancestry controls. The Stage                   |
| 1031 | 2 analysis also included genotype data from the CORSA study (Supplementary Text). In total,                      |
| 1032 | 2,354 individuals were genotyped using the Affymetrix Axiom Genome-Wide Human CEU 1                              |
| 1033 | Array. We called genotypes using the AxiomGT1 algorithm. All samples had missing call rate                       |
| 1034 | <3%. We excluded samples with discrepancies between reported and genotypic sex (20), close                       |
| 1035 | relatives defined as individuals that are second-degree or more closely related (94), as inferred                |
| 1036 | using KING-robust <sup>87</sup> , and individuals of non-European ancestry (6) as inferred from PCA. After       |
| 1037 | QC, data included in analysis comprised 1,460 cases and 774 controls. Prior to phasing and                       |
| 1038 | imputation, we filtered out SNPs with missing call rate $>2\%$ , or HWE $P < 1e-4$ . Imputed                     |
| 1039 | genotype data were obtained from UK Biobank and QC and imputation are described                                  |
| 1040 | elsewhere <sup>89</sup> . A nested case-control dataset was constructed as described in the <b>Supplementary</b> |
| 1041 | Text. We excluded individuals of non-European ancestry as inferred from PCA, and randomly                        |
| 1042 | dropped one individual from each pair that were more closely related than third-degree relatives                 |
| 1043 | as inferred using KING-robust. This resulted in excluding 137 samples. In total, 5,356 CRC                       |
| 1044 | (5,004) or advanced adenoma (352) cases and 21,407 matched controls were included in the                         |
| 1045 | replication analysis.  |

Principal components analysis.

| 1048 | After excluding close relatives, we performed PCA using PLINK1.990 on LD-pruned sets of                     |
|------|---|
| 1049 | autosomal SNPs obtained by removing regions with extensive long-range LD <sup>91,92</sup> , SNPs with       |
| 1050 | minor allele frequency (MAF) $<5\%$ , or HWE $P < 1e-4$ , or any missingness, and carrying out LD           |
| 1051 | pruning using the PLINK option '-indep-pairwise 50 5 0.2'. To identify population outliers we               |
| 1052 | merged in 1,092 individuals from 1000 Genomes Project Phase III and performed PCA using the                 |
| 1053 | intersection of variants <sup>93</sup> .  |
| 1054 |   |
| 1055 | Genotype imputation.  |
| 1056 | The 2,159 whole-genome sequences described above were used to create a phased imputation                    |
| 1057 | reference panel. After estimating haplotypes for all GWAS array data sets using SHAPEIT294,                 |
| 1058 | we used minimac3 <sup>95</sup> to impute from this reference panel (19.6 million variants with minor allele |
| 1059 | count (MAC) >1) into the GWAS datasets described above. We also imputed to the Haplotype                    |
| 1060 | Reference Consortium (HRC) panel <sup>25</sup> (39.2 million variants) using the University of Michigan     |
| 1061 | Imputation Server <sup>95</sup> . To improve imputation accuracy for Stage 1 data sets, phasing and         |
| 1062 | imputation were performed after pooling studies/genotype projects that used the same, or very               |
| 1063 | similar, genotyping platforms (Supplementary Table 1). For Stage 2, we performed phasing                    |
| 1064 | and imputation separately for each genotyping project data set and imputed to the HCR panel.                |
| 1065 |   |
| 1066 | Statistical analyses.   |
| 1067 | Association testing of sequence data.   |
| 1068 | We tested variants with MAC $\geq$ 5 for CRC association using Firth's bias-reduced logistic                |
| 1069 | $regression\ as\ implemented\ in\ EPACTS\ (genome.sph.umich.edu/wiki/EPACTS)\ and\ adjusted\ for$           |
| 1070 | sex, age, study, and 3 principal components (PCs) calculated from an LD-pruned set of                       |
| 1071 | genotypes. We performed rare variant aggregate tests at the gene and enhancer level using the               |
| 1072 | Mixed effects Score Test (MiST) <sup>96</sup> . This unified test is a linear combination between           |
| 1073 | unidirectional burden and bidirectional variance component tests that performs best in terms of             |
| 1074 | statistical power across a range of architectures <sup>97</sup> .   |
| 1075 |   |
| 1076 | Association and meta-analysis.  |
| 1077 | Stage 1 comprised two large mega-analyses of pooled individual-level genotype data sets                     |
| 1078 | (Supplementary Table 12). The four Stage 2 genotyping project data sets were analyzed                       |

separately. Within each data set, variants with an imputation accuracy  $r^2 > 0.3$  and MAC > 501079 1080 were tested for CRC association using the imputed genotype dosage in a logistic regression 1081 model adjusted for age, sex, and study/genotyping project-specific covariates, including PCs to 1082 adjust for population structure (Supplementary Table 12). To account for residual confounding 1083 within CORSA, we tested association with each variant using a linear mixed model and kinship matrix calculated from the data, as implemented in EMMAX<sup>98</sup>. To enable meta-analysis, we then 1084 1085 calculated approximate allelic log odds ratios (OR) and corresponding standard errors as described in Cook et al. 99. 1086 1087 Next, we combined association summary statistics across analyses via fixed-effects inverse 1088 variance-weighted meta-analysis. Because Wald tests can be notably anti-conservative for rare 1089 variant associations, we also performed likelihood ratio-based tests, followed by sample-size weighted meta-analysis, as implemented in METAL<sup>100</sup>. In total, 16,900,397 variants were 1090 1091 analyzed. To examine residual population stratification, we inspected quantile-quantile plots of 1092 test statistics (Supplementary Figure 8), and calculated genomic control inflation statistics 1093  $(\lambda_{GC})$ .  $\lambda_{GC}$  for the combined meta-analysis was 1.105, and for Stage 1 and 2 meta-analyses was 1.071 and 1.075, respectively. Because  $\lambda_{GC}$  increases with sample size for polygenic phenotypes, 1094 even in the absence of confounding biases<sup>101</sup>, we investigated the effect of confounding due to 1095 residual population stratification using LD score regression<sup>102</sup>. Because of limitations of LD 1096 1097 score regression, this analysis is restricted to common variants (MAF $\geq$ 1%) for which  $\lambda_{GC}$  was 1098 1.188 in the combined meta-analysis. The LD score regression intercept was 1.067, which is substantially less than  $\lambda_{GC}$ , indicating at most a small contribution of bias and that inflation in  $\chi^2$ 1099 1100 statistics results mostly from polygenicity. We also calculated  $\lambda_{1,000}$  which is the equivalent inflation statistic for a study with 1,000 cases and 1,000 controls 103. For the combined meta-1101 1102 analysis,  $\lambda_{1000}$  was 1.004 and for both Stage 1 and 2 meta-analyses this was 1.003. 1103 1104 Significance threshold for the replication genotyping experiment. 1105 To protect against probe design failure, we built redundancy into the custom genotyping panel by 1106 including LD proxies of independently associated variants selected for follow-up. To determine 1107 the number of independent tests, we performed LD clumping of the 9,198 analyzed variants that

were selected for replication genotyping based on the Stage 1 meta-analysis, and that survived

filters described above. Using an  $r^2$  threshold of 0.1 this translated to 6.438 independent tests and 1109 a Bonferroni significance threshold of  $0.05/6,438=7.8\times10^{-6}$ . 1110 1111 1112 Conditional and joint multiple-variant analysis. 1113 To identify additional distinct association signals at CRC loci, we performed a series of conditional meta-analyses. At each locus attaining  $P < 5 \times 10^{-8}$ , we included the genotype dosage 1114 1115 for the variant showing the strongest statistical evidence for association in the region in the 1116 combined meta-analysis, as an additional covariate in the respective logistic regression models. 1117 Association summary statistics for each variant in the region were then combined across studies by a fixed-effects meta-analysis. If at least one association signal attained a significance level of 1118  $P < 1 \times 10^{-5}$  in this meta-analysis, we performed a second round of conditional meta-analysis, 1119 adding the variant showing the strongest statistical evidence for association in the region in the 1120 1121 first round of conditional meta-analysis as a covariate to the logistic regression models used in 1122 the first round. We repeated this procedure and kept adding variants to the model until no additional variants at the locus attained  $P < 1 \times 10^{-5}$ . Finally, we performed a joint multiple-variant 1123 analysis in which we jointly estimated the effects of variants selected in each step and tested for 1124 each variant whether the P-value from the joint multiple-variant analysis  $(P_J)$  was  $<1\times10^{-5}$ . 1125 1126 Analyses were performed on 2-Mb windows centered on the most associated variant in the 1127 unconditional analysis. If windows overlapped, we performed the analysis on the collapsed 1128 genomic region. Because of extensive LD, we used a 4-Mb window for the MHC region. 1129 1130 Definition of known loci. 1131 We compiled a list of 62 previously reported genome-wide significant CRC association signals 1132 from the literature (Supplementary Table 3). Because of improved power and coverage of our 1133 study, we identified the most associated variant at each signal, and used these lead variants for further analyses, rather than the previously reported index variant. 1134 1135 1136 Refinement of association signals. To refine new association signals, we constructed credible sets that were 99% likely, based on 1137 posterior probability, to contain the causal disease-associated SNP<sup>104</sup>. In brief, for each distinct 1138 signal, we retained a candidate set of variants by identifying all analyzed variants with  $r^2 > 0.1$ 1139

with the most associated variant within a 2-Mb window centered on the most associated variant.

We calculated approximate Bayes' factors (ABF)<sup>105</sup> for each variant as:

1142

1140

1141

1143 
$$ABF = \sqrt{1 - r} e^{rz^2/2}$$

1144

1145

1146

1147

1148

1149

1150

where  $r = 0.04/(\text{s.e.}^2 + 0.04)$ ,  $z = \beta/\text{s.e.}$ , and  $\beta$  and s.e. are the log OR estimate and its standard error from the combined meta-analysis. For loci with multiple distinct signals, results are based on conditional meta-analysis, adjusting for all other index variants in the region. We then calculated the posterior probability of being causal as ABF/T where T is the sum of ABF values over all candidate variants. Next, variants were ranked in decreasing order by posterior probabilities and the 99% credible set was obtained by including variants with the highest posterior probabilities until the cumulative posterior probability >99%.

1151 1152

1153

### Functional genomic annotation.

1154 To nominate variants for future laboratory follow-up, we performed bioinformatic analysis at 1155 each new signal using our functional annotation database, and a custom UCSC analysis data hub. Using ANNOVAR<sup>106</sup>, we annotated lead variants and variants in LD ( $r^2 \ge 0.4$ ) with the lead 1156 variant, relative to features pertaining to i) gene-centric function (PolyPhen2<sup>107</sup>), ii) genome-1157 wide functional prediction scores (CADD<sup>108</sup>, DANN<sup>109</sup>, EigenPC<sup>110</sup>), iii) disease relatedness 1158 (GWAS catalog<sup>46</sup>), and iv) CRC-relevant regulatory functions (enhancer, repressor, DNA 1159 accessible, and transcription factor binding site (TFBS)<sup>111,112</sup>; **Supplementary Table 13**). 1160 **Supplementary Table 8** summarizes variant annotations relative to the CCDS Project<sup>113</sup>, and 1161 1162 reference genome GRCh37. Variants were maintained in **Supplementary Table 8** if they met 1163 any of the following conditions: DANN score ≥0.9, CADD phred score ≥20, Eigen-PC phred score ≥17, PolyPhen2 "probably damaging", "stop loss", "stop gain", "splicing", or were 1164 1165 positioned in a predicted regulatory element. We visually inspected loci overlapping with CRC-1166 relevant functional genomic annotations. Variants positioned in enhancers with aberrant CRC activity were identified by comparing epigenomes of non-diseased colorectal tissues/colonic 1167 1168 crypt cells to epigenomes of primary CRC cell lines (data accessible at NCBI GEO database, 1169 accession GSE77737). We prioritized target genes for loci with predicted regulatory function. 1170 Evidence suggests that Topological Association Domains (TADs) can be used to map physical

| 1171 | boundaries on gene promoter interactions with distal regulatory elements 114-116. As such, we used          |
|------|---|
| 1172 | GMI12878 Hi-C Chromosome Conformation Capture data to identify gene promoters that were                     |
| 1173 | in the same TADs as risk loci using the WashU Epigenome Browser   |
| 1174 | (https://epigenomegateway.wustl.edu/). Genes in this list were further prioritized based on                 |
| 1175 | biological relevancy and expression quantitative trait loci (eQTL) data from Genotype-Tissue                |
| 1176 | Expression (GTEx) <sup>117</sup> using HaploReg v4.1 <sup>118</sup> .                                       |
| 1177 |   |
| 1178 | ATAC-seq assay.   |
| 1179 | We generated high resolution maps of DNA accessible regions in normal colon mucosa samples                  |
| 1180 | using the Assay for Transposase-Accessible Chromatin using sequencing (ATAC-seq). Using the                 |
| 1181 | updated omni-ATAC protocol for archival samples, we performed ATAC-seq in four colon                        |
| 1182 | mucosa biopsies from the ICO-biobank taken from participants undergoing screening at                        |
| 1183 | IDIBELL, Spain. Biopsies were cryopreserved by slow freezing using a solution of 10% DMSO,                  |
| 1184 | 90% media, and Mr. Frosty Cryo 1°C Freezing Containers (Thermo Scientific). ATAC-seq was                    |
| 1185 | implemented as prescribed with two exceptions. Instead of dounce homogenizer we used a tissue               |
| 1186 | lyser and stainless bead system, pulverizing at 40Hz for 2 mins and pulsing at 50Hz for 10-20               |
| 1187 | seconds. Secondly, Illumina library quantification was performed using picogreen quantitation               |
| 1188 | and TapeStation instead of KAPA quantitative qPCR. Libraries were sequenced to an average of                |
| 1189 | 25M paired end reads using Illumina HiSeq 2500. The ENCODE data processing pipeline was                     |
| 1190 | implemented (https://github.com/kundajelab/atac_dnase_pipelines) aligning to hg19119. QC                    |
| 1191 | results are summarized in Supplementary Table 14.   |
| 1192 |   |
| 1193 | Regulatory and functional information enrichment analysis.  |
| 1194 | We used GARFIELD <sup>74</sup> to identify cell types, tissues, and functional genomic features relevant to |
| 1195 | CRC risk. This method tests for enrichment of association in features primarily extracted from              |
| 1196 | ENCODE and Roadmap Epigenomics Project data, while accounting for sources of confounding,                   |
| 1197 | including LD. We applied default settings and used the author-supplied data which is suitable for           |
| 1198 | analysis of GWAS results based on European-ancestry individuals.  |
| 1199 |   |
| 1200 | Pathway and gene set enrichment analysis.   |

We used MAGENTA to test predefined gene sets (e.g., KEGG pathways) for enrichment for CRC risk associations<sup>75</sup>. We used combined meta-analysis results as input and applied default settings which included removing genes that fall in the MHC region from analysis. Enrichment was tested at two gene *P*-value cutoffs: 95th and 75th percentiles of all gene *P*-values in the genome.

### Estimation of contribution of rare variants to heritability.

We used the LD- and MAF-stratified component GREML (GREML-LDMS) method as implemented in GCTA<sup>76</sup> to estimate the proportion of variation in liability for CRC explained by all imputed autosomal variants (i.e., estimate of narrow-sense heritability  $h_{m{g}}^2$ ), and the proportion contributed by rare variants (MAF  $\leq$ 1%). Because of computational limitations we analyzed a subset of 11,895 cases and 14,659 controls imputed to our WGS panel. We analyzed individuallevel data for 17,649,167 imputed variants with MAC >3 and HWE test  $P \ge 10^{-6}$ . Following Yang et al. 76, we did not filter on imputation quality. In brief, we stratified variants into groups based on MAF (boundaries at 0.001, 0.01, 0.1, 0.2, 0.3, 0.4) and mean LD score (boundaries at quartiles) calculated as described in Yang et al. 76. We then calculated genetic relationship matrices (GRMs) for each of these 28 variant partitions and jointly estimated variance components for these partitions, adjusting for age, sex, study, genotyping batch, and three genotype PCs. From the variance component estimates and their variance-covariance matrix we estimated the contribution of rare variants (MAF  $\leq$ 1%) and common variants (MAF >1%), and calculated standard errors using the delta method. We tested significance of the contribution of rare variants using a likelihood ratio test. To calculate heritability on the underlying liability scale we interpreted K as lifetime risk<sup>120</sup> and used an estimate of 4.3% (Surveillance, Epidemiology, and End Results Program (SEER) Cancer Statistics, 2011-2013).

### Familial relative risk explained by genetic variants.

We assumed a multiplicative model within and between variants and calculated the proportion of familial relative risk (RR) explained by a given set of genetic variants as  $\frac{\sum_i \log \lambda_i}{\log \lambda_0}$ , where  $\lambda_0$  is the overall familial RR to first-degree relatives of cases.  $\lambda_i$  is the familial RR due to variant i calculated as  $\lambda_i = \frac{p_i r_i^2 + q_i}{(p_i r_i + q_i)^2}$ , where  $p_i$  is the risk allele frequency for variant i,  $q_i = 1 - p_i$ , and  $r_i$ 

is the estimated per allele OR<sup>9,121</sup>. We adjusted the OR estimates of new association signals for 1231 winner's curse following Zhong and Prentice<sup>78</sup>. We represented previously identified association 1232 1233

signals by the variant showing the strongest statistical evidence of association in the combined

meta-analysis, and assumed that winner's curse was negligible. We assumed  $\lambda_0$  to be 2.2<sup>122</sup>. 1234

Using the delta method, we computed the variance for the proportion of familial RR as follows:

1236

1235

1238

- Absolute risk of CRC incidence and starting age of first screening.
- 1240 We constructed a polygenic risk score (PRS) as a weighted sum of expected risk allele frequency
- 1241 for common genetic variants, using the per allele OR for each variant as weights. OR estimates
- for newly discovered variants were adjusted for winner's curse to avoid potential inflation<sup>78</sup>. 1242
- 1243 Assuming all genetic variants are independent, let X denote a PRS constructed based on K
- variants:  $X = \sum_{i=1}^K \widehat{\beta_i} Z_i$ , where  $\widehat{\beta_i}$  and  $Z_i$  are the estimated OR and the number of risk alleles for 1244
- variant i. We assumed X follows a normal distribution  $N(\mu, \sigma^2)$ , where the estimates of mean 1245
- 1246 and variance are computed as following:

1247 
$$\hat{\mu} = \sum_{i=1}^{K} \widehat{\beta_i} \times 2 \times \widehat{p_i} \text{ and } \widehat{\sigma^2} = \sum_{i=1}^{K} \widehat{\beta_i^2} \times 2 \times \widehat{p_i} \times (1 - \widehat{p_i}),$$

- where  $\hat{p}_i$  is the risk allele frequency for variant  $i = 1, \dots, K$ . Then the baseline hazard at each 1248
- age t,  $\widehat{\lambda_0}(t)$ , is computed as following: 1249

1250 
$$\widehat{\lambda_0}(1) = \lambda^*(1) \frac{\int f(x) \, dx}{\int e^x f(x) dx}$$

1251 
$$\widehat{\lambda_0}(t) = \lambda^*(t) \frac{\int exp(-\sum_{i=1}^{t-1} \widehat{\lambda_0}(i) e^x) f(x) dx}{\int exp(-\sum_{i=1}^{t-1} \widehat{\lambda_0}(i) e^x) e^x f(x) dx} \text{ for } t = 2, \dots, 100,$$

- 1252 and  $\lambda^*(t)$  are the incidence rates for non-Hispanic whites who have not taken an endoscopy
- before, derived from population incidence rates during 1992-2005 from the SEER Registry. 1253
- 1254 Using these baseline hazard rates, we estimated the 10-year absolute risk of developing CRC
- given age and a PRS as previously described<sup>123</sup>. By setting a risk threshold as the average of the 1255
- 1256 10-year CRC risk for a 50-year old man (1.25%) and woman (0.68%), i.e.,
- (1.25%+0.68%)/2=0.97%, who have not previously received an endoscopy<sup>124</sup>, we estimated the 1257

- recommended starting age of first screening given the PRS. Variants and OR estimates used in
- these analyses are given in **Supplementary Table 15**.

- 1261 Data availability.
- All whole-genome sequence data have been deposited at the database of Genotypes and
- Phenotypes (dbGaP), which is hosted by the U.S. National Center for Biotechnology Information
- 1264 (NCBI), under accession number phs001554.v1.p1. All custom Infinium OncoArray-500K array
- data for the studies in the Stage 2 meta-analysis have been deposited at dbGaP under accession
- number phs001415.v1.p1. All Illumina HumanOmniExpressExome-8v1-2 array data for the
- studies in the Stage 2 meta-analysis have been deposited at dbGaP under accession number
- phs001315.v1.p1. Genotype data for the studies included in the Stage 1 meta-analysis have been
- deposited at dbGaP under accession number phs001078.v1.p1. The UK Biobank resource was
- accessed through application number 8614.
