## Dynamic landscape of the local translation at activated synapses

TM Khlebodarova<sup>1</sup>, VV Kogai<sup>2,3</sup>, EA Trifonova<sup>1</sup> and VA Likhoshvai<sup>1,3</sup>

The mammalian target of rapamycin (mTOR) signaling pathway is the central regulator of cap-dependent translation at the synapse. Disturbances in mTOR pathway have been associated with several neurological diseases, such as autism and epilepsy. RNA-binding protein FMRP, a negative regulator of translation initiation, is one of the key components of the local translation system. Activation and inactivation of FMRP occurs via phosphorylation by S6 kinase and dephosphorylation by PP2A phosphatase, respectively. S6 kinase and PP2A phosphatase are activated in response to mGluR receptor stimulation through different signaling pathways and at different rates. The dynamic aspects of this system are poorly understood. We developed a mathematical model of FMRP-dependent regulation of postsynaptic density (PSD) protein synthesis in response to mGluR receptor stimulation and conducted *in silico* experiments to study the regulatory circuit functioning. The modeling results revealed the possibility of generating oscillatory (cyclic and quasi-cyclic), chaotic and even hyperchaotic dynamics of postsynaptic protein synthesis as well as the presence of multiple attractors in a wide range of parameters of the local translation system. The results suggest that autistic disorders associated with mTOR pathway hyperactivation may be due to impaired proteome stability associated with the formation of complex dynamic regimes of PSD protein synthesis in response to stimulation of mGluR receptors on the postsynaptic membrane of excitatory synapses on pyramidal hippocampal cells.

## INTRODUCTION

Nowadays, there is convincing evidence that rapid and well-coordinated changes in the quantitative and qualitative content of proteins at the synapse ensure its dynamic plasticity in response to external stimuli and underlie learning and memory.<sup>1–7</sup> Disruption of local translation control at synapses has been associated with various neuropsychiatric diseases, including autism spectrum disorders, epilepsy, Parkinson's and Alzheimer's diseases (see reviews<sup>8–13</sup>), which are characterized by a shift in the balance of synaptic plasticity and lead to changes in behavior, cognitive abilities and memory.

The mammalian target of rapamycin (mTOR) pathway is the central regulator of cap-dependent translation at the synapse. Several recent studies have highlighted a pathogenic role of somatic mutations in genes of mTOR signaling pathway in the progression of certain forms of epilepsy and monogenously inherited autism spectrum disorders, such as type 1 neurofibromatosis, Noonan syndrome, Costello syndrome, Kauden syndrome, Tuberous sclerosis, X-chromosome fragility syndrome and Rett syndrome.<sup>13–19</sup>

It is believed that syndromic forms of autism account for up to 25% of the total autism spectrum<sup>20</sup>; however, microarray analysis of peripheral blood from patients with general/idiopathic autism has shown an abnormal activity of the signaling pathways associated with translation initiation<sup>21</sup>; and a direct measurement of Akt/mTOR pathway in cells isolated from the blood of children with non-syndromic autism demonstrated increased Akt/mTOR pathway activity as compared to the control group, suggesting a

pathological role of mTOR pathway in the entire autism spectrum.<sup>22</sup>

Fragile X syndrome is the most common known syndromic form of autism,<sup>23,24</sup> caused by expansion of the CGG repeat in the 5'-untranslated region of *FMR1* gene, leading to its transcriptional silencing. *FMR1* gene encodes the RNA-binding protein FMRP (Fragile X Mental Retardation Protein), which is a regulator of mRNA stability and a negative regulator of local translation at synapses.<sup>25</sup>

The peak *FMR1* gene expression takes place during embryonic development, followed by mild reduction. The highest level of *FMR1* gene expression has been recorded in the cells of hippocampus, cerebellum and cerebral cortex.<sup>26</sup> In particular, FMRP controls the efficiency of dendritic mRNA translation in response to the stimulation of mGluR receptors (metabotropic glutamate receptors) on the postsynaptic membrane of excitatory synapses on pyramidal hippocampal cells.<sup>1,27</sup> FMRP is the target of S6 kinase and PP2A phosphatase that are activated in response to stimulation of mGluR receptors.<sup>28,29</sup> In a phosphorylated state, FMRP blocks translation by binding to mRNA, ribosomes and translation initiation factor eIF4E.<sup>30–32</sup> Dephosphorylation disrupts FMRP binding to its targets, which leads to the activation of mRNA translation.

FMRP target mRNAs encode proteins involved in mTOR signaling pathway (PI3K kinase, PTEN phosphatase, TSC2—tuberous sclerosis complex-2, mTOR, PP2A phosphatase), receptor proteins (mGluR, NMDAR, AMPAR), proteins forming the postsynaptic membrane (NLGN, SHANK, PSD95), proteins of the

**Figure 1.** Signaling pathways regulating the activity of local cap-dependent translation at glutamatergic synapses in response to mGluR receptor stimulation. Names of proteins encoded by genes whose mutations are associated with neurodegenerative diseases, including autism, are marked with red color:  $\tau_e$ —total time of translation and inclusion of protein into the postsynaptic membrane,  $\tau_a$  and  $\tau_b$ —delay parameters of the activation and suppression of translation, respectively.

ubiquitin-dependent protein degradation system (E3 ubiquitin ligase) and the FMR1 protein.<sup>24,30,33–36</sup> These data demonstrate that FMRP plays a key role in the dynamic regulation of the synaptic proteome (see also reviews<sup>37,38</sup>).

The fact that stimulation of mGluR receptors is accompanied not only by rapid (~ 1 min) activation of PP2A phosphatase and, consequently, translation of FMRP-dependent mRNAs, but also by rapid activation of S6 kinase (2–5 min), which rephosphorylates FMRP and blocks the translation process,<sup>28,29</sup> suggests dynamic interplay between the components of these signaling pathways at the activated synapse, ensuring its normal functioning.

Nowadays, the dynamic aspects of local translation at the activated synapse are poorly understood. It is possible that, in some cases, neuropsychiatric manifestations due to defects in synaptic function can be related to the peculiarities of the dynamic behavior of the local translation machinery. In the present work, we considered a simple regulatory contour of a local FMRP-dependent translation of postsynaptic density (PSD) proteins in response to stimulation of mGluR receptors on the postsynaptic membrane of an individual synapse and studied its dynamic properties by mathematical modeling. Structure of the investigated regulatory contour is illustrated in Figure 1.

In accordance with the analysis of dynamic properties of the model, there is a probability of observing complex dynamics of vibrational, chaotic and even hyperchaotic postsynaptic protein synthesis, depending on the ratio between the rate parameters for activation and suppression of local translation at the activated synapse. Moreover, the model has revealed parametric regions where coexistence of multiple attractors occur, which suggests the possibility of simultaneous existence of synapses with different dynamic properties. All these findings can hardly correlate with a stable proteome necessary for synaptic plasticity and memory formation.<sup>7,10</sup> We do not exclude the possibility that these causes can underlie autistic and other types of disorders associated with

activation of mTOR signaling pathway, which are manifested at higher hierarchical levels of the nervous system.

### Model

The model describes the simplest genetic contour of FMRP-dependent local translation of PSD proteins at glutamatergic synapses in response to mGluR receptor stimulation, depending on the ratio between the delay parameters of activation and suppression of translation (Figure 1). In order to study the internal properties of the regulatory contour, it is assumed in the model that a certain PSD protein density on the postsynaptic membrane of the activated synapse is maintained by *de novo* protein synthesis. Recycling of membrane proteins was not considered in the model. This simplification is justified for PSD proteins whose post-synaptic density in response to mGluR receptor stimulation is determined, among other things, by the balance between PSD protein synthesis and degradation. Such possibility has been demonstrated for PSD95, NMDAR and SHANK proteins with FMRP-dependent local synthesis<sup>33,35,37</sup> and ubiquitin-dependent degradation<sup>39–41</sup> at the activated synapse. It can also be true for mGluR protein itself, whose synthesis also depends on FMRP<sup>36</sup> and internalization—on the process of its ubiquitination.<sup>42</sup> In the model, the genetic contour (Figure 1) is described by the differential equation with delayed arguments

$$\frac{da(t)}{dt} = V_i \cdot F_n(a(t-\tau_{ae}), a(t-\tau_{be})) - k_a a(t) \quad (1)$$

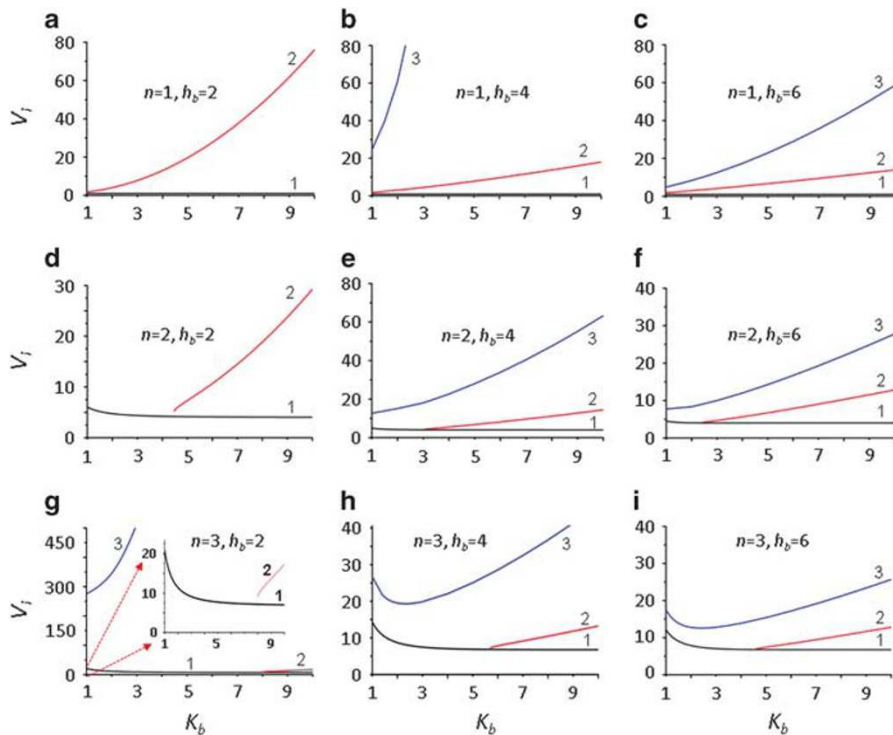

where  $a(t)$ , concentration of glutamate-specific receptors;  $V_i \cdot F_n(a(t-\tau_{ae}), a(t-\tau_{be}))$ , recovery rate for synaptic receptors;  $k_a a(t)$ , rate of membrane receptor utilization,  $k_a$ , rate constant for utilization;  $F_n$ , function describing regulation of local translation activation and suppression;  $V_i$ , parameter that sets the maximum initiation rate for local translation of receptors;  $\tau_{ae} = \tau_a + \tau_e$  and  $\tau_{be} = \tau_b + \tau_e$ , durations of the signal passage along the activation and translation contours, respectively;  $\tau_a$ , duration between signal generation on the receptor under the influence of glutamate molecule and signal realization in the form of FMRP dephosphorylation;  $\tau_b$ , duration between signal generation on the receptor under the influence of glutamate molecule and signal realization in the form of FMRP phosphorylation;  $\tau_e$ , total time of protein translation and its incorporation into the receptor complex.

The control function has the following form

$$F_n(x, y) = \left[ \frac{\left(\frac{x}{K_a}\right)^{h_a}}{1 + \left(\frac{x}{K_a}\right)^{h_a} + \left(\frac{y}{K_b}\right)^{h_b}} \right]^n \quad (2)$$

It belongs to the class of generalized Hill functions<sup>43</sup> and, in the simplest phenomenological form, describes activation and suppression of local translation: as  $x$  increases, the value of  $F_n$  increases, and as  $y$  increases, the value of  $F_n$  decreases. Parameters  $K_a$  and  $K_b$  have the dimensionality of concentration and determine the impact of glutamate-specific signal on activation and suppression of local translation, respectively; parameters  $h_a$  and  $h_b$  are dimensionless Hill coefficients and determine the nonlinearity of the signal influence on the phosphorylation and dephosphorylation of FMRP,  $n$  is the dimensionless Hill coefficient that determines the number of FMRP molecules dissociating with mRNA during activation process.

The evaluation of the model parameters ( $\tau_a, \tau_b, \tau_e, h_a, h_b, n, V_i, K_a, K_b$ ) was carried out on the basis of a wide range of existing data on the structure and functions of glutamatergic synapses and mechanisms of local translation regulation in the activated synapse.<sup>28,29,31,32,36,44–54</sup> Detailed description is given in Supplementary note 1.

**Figure 2.** Areas of unconditional stability and predicted chaotic state of the maximal positive steady state solution of the model (1),(2) depending on the values of the efficiency constant for the suppression of local translation at the synapse ( $K_b$ ) and the maximal rate of receptor protein synthesis ( $V_i$ ).

## MATERIALS AND METHODS

### Calculation method

Integration of the equation was carried out by the steps method<sup>55</sup> using an original program written in Fortran. Calculations were carried out on the computer complex of the Information and Computing Center of Novosibirsk State University (<http://www.nusc.ru>).

### Stability analysis method for nonnegative steady-state solutions of equations (1) and (2)

Stability analysis method for a particular type of equations (1) and (2) has had no analogs in the literature and developed by us. Its detailed description and stability conditions for nonnegative steady-state solutions with nonzero values of the delayed arguments  $\tau$  are given in Supplementary note 2.

### An empirical criterion for the existence of chaotic dynamics in the delay differential equation of a special type

To estimate the values of the parameters  $V_i, k_a, K_a, K_b, h_p$  and  $h_b$ , for which chaotic dynamics is predicted for equation (1), an empirical criterion was applied.<sup>56</sup>

Let us give its formulation. Let there be given an equation with delayed argument of the following form

$$\frac{dp(t)}{dt} = f(p(t-\tau)) - p(t)g(p(t-\tau)) \quad (3)$$

Let us consider a chaotic one-dimensional mapping  $x_{m+1} = G(x_m)$ ,  $G(x) = f(x)/g(x)$  of a segment into itself. Then, equation (5) would have a strange attractor for certain value of  $\tau$ . For equations (1) and (2), we have  $G(x) = (V_i/k_a)F_n(x, x)$ .

To estimate the degree of chaos for the one-dimensional mapping  $x_{m+1} = G(x_m)$ , we applied the Li-Yorke theorem, according to which the existence of a cycle of length 3 means that this mapping is chaotic.<sup>57</sup> There is no corresponding criterion for unequal values of the delayed arguments  $\tau_{ae} \leq \tau_{be}$ . Therefore, the chaotic dynamics was studied by numerical analysis, which was determined using three criteria: the sensitivity of solutions with respect to initial data, the positivity of the value of the

largest Lyapunov exponent and the special form of the Poincaré map generated by the solution. Let us give a brief description.

### Chaos criterion for the oscillatory dynamics

The sensitivity of the oscillatory dynamics was calculated as the difference between two trajectories of one variable, calculated by two identical models that start at zero time point with the initial functions that vary by a 'small' value. If, as we iterate over values, the difference became comparable with the fluctuation amplitude, the dynamics was concluded to be sensitive to initial data.

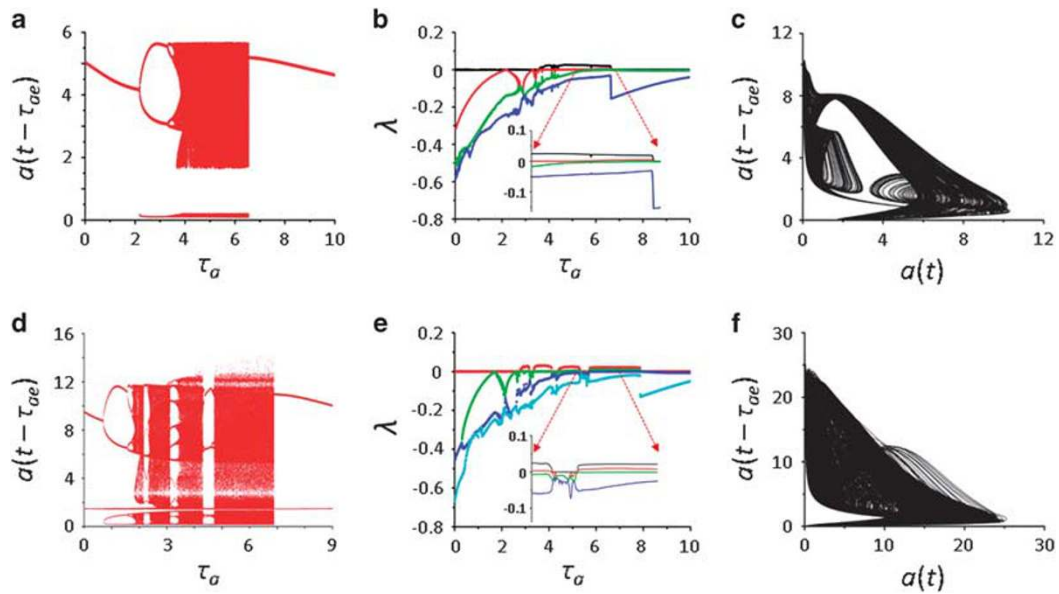

### Lyapunov exponents

To quantify the instability of the solution with respect to initial data, Lyapunov exponents were used that characterize the degree of exponential growth (or decay) of disturbances near the attractor trajectory. A spectrum of Lyapunov exponents has a dimensionality of the phase space. For systems of equations with delayed arguments, for which the phase space is infinite, the number of Lyapunov exponents is also infinite. However, only a few senior Lyapunov exponents have a significant impact. Knowing the spectrum of Lyapunov exponents enables to solely identify the motion nature in the system. Presence of at least one positive Lyapunov exponent is a measure of chaos. If a chaotic dynamics had two or more positive Lyapunov exponents, such dynamics was identified to be hyperchaotic.<sup>58</sup>

Method for calculating the largest Lyapunov exponent for the delay equation is a modification of the Benettin method<sup>59,60</sup> and was previously described.<sup>61,62</sup>

### Poincaré map

A characteristic form of the Poincaré map (the so-called succession map) allows to explicitly identify the motion pattern in the system. Thus, a cyclic trajectory generates a Poincaré map consisting of a finite number of points through which the trajectory passes with certain regularity. A quasicyclic trajectory is mapped onto a plane as a set of closed curves. The Poincaré map corresponding to a strange attractor represents an unordered infinite set of points. The method for constructing the Poincaré map has been described earlier.<sup>61,62</sup>

**Figure 3.** Solutions of equations (1, 2) for a similar proportion of delay parameters of activation and suppression of translation  $\tau_a = \tau_b = \tau$ . **(a,d)** bifurcation diagrams constructed from the intersection of the trajectory  $(a(t), a(t - \tau_{ae}))$  and the Poincaré plane  $a(t) = 5$ ; **(b,e)** values of the largest Lyapunov exponents depending on the delay parameter  $\tau_a$ ; **(c)** chaos at  $\tau_a = \tau_b = 4$ ; **(f)** hyperchaos at  $\tau_a = \tau_b = 7$ , the largest Lyapunov exponents:  $\lambda_1 = 0.02127$ ,  $\lambda_2 = 0.0078$ . Parameter values:  $n = 1$ ,  $h_b = 4$ ,  $V_i = 30$  **(a-c)**,  $n = 3$ ,  $h_b = 2$ ,  $V_i = 700$  **(d-f)**, values of the remaining parameters:  $k_a = 1$ ,  $K_a = 1$ ,  $K_b = 1$ ,  $h_a = 1$ ,  $\tau_e = 3$ .

## RESULTS

In this section, we analyzed a model, in which the time was measured in minutes and the concentration—in units equal to  $K_a$ . The transition to this concentration unit was carried out by the standard procedure for changing the variables  $a(t) := a(t)/K_a$ ,  $V_i := V_i/K_a$ ,  $K_b := K_b/K_a$ . For the sake of convenience, we left the same notation of the variable and the parameters. Also, according to the experimental data (see the section ‘Estimation of the model parameters’), we fixed  $k_a = 1 \text{ min}^{-1}$  and  $h_a = 1$ .

Analysis of the steady-state stability and chaotic potential stability in model (1),(2)

The results of the positive steady-state stability analysis depending on the values of the parameters  $V_i$  and  $K_b$  are presented in Figure 2. Calculations were made for nine variants of  $h_b$  and  $n$  values, which were changed in discrete ranges:  $h_b = 2, 4, 6$  and  $n = 1, 2, 3$ .

For each variant, the area of existence of positive steady states of model (1),(2) lies above curve 1. There are no positive steady states of the model in the area below curve 1. When  $n = 1$ , curve 1 represents the line  $V_i = 1$  (Figures 2a–c), that is, it is exactly equal to the physiological minimum of this parameter, defined in the section ‘Estimation of the model parameters’, Supplementary note 1. When  $n = 2, 3$ , the boundary of existence of a positive steady state (curve 1) is a function monotonically decreasing from  $K_b$ . When  $n = 2$ , the function tends to the limit  $V_i = 4$  from above, and when  $n = 3$  it tends to the limit  $V_i = 6.75$ . That is, with an increase of  $n$ , the minimum value of  $V_i$  that determines the applicability of the model to the target object increases.

Areas between curves 1 and 2 represent regions of unconditional stability, since maximum steady states in this areas remain stable for any values of delayed arguments,  $\tau_{be} \geq \tau_{ae} \geq 0$ . When  $n = 1$  (Figures 2a–c), the region of unconditional stability exists over the entire range of the parameter  $K_b$  from 1 to 10. When  $n = 2$  (Figures 2d–f) and  $n = 3$  (Figures 2g–i), the boundary of the unconditional stability region shifts to the right from the origin and this region is absent for the values of the parameter  $K_b$  lying

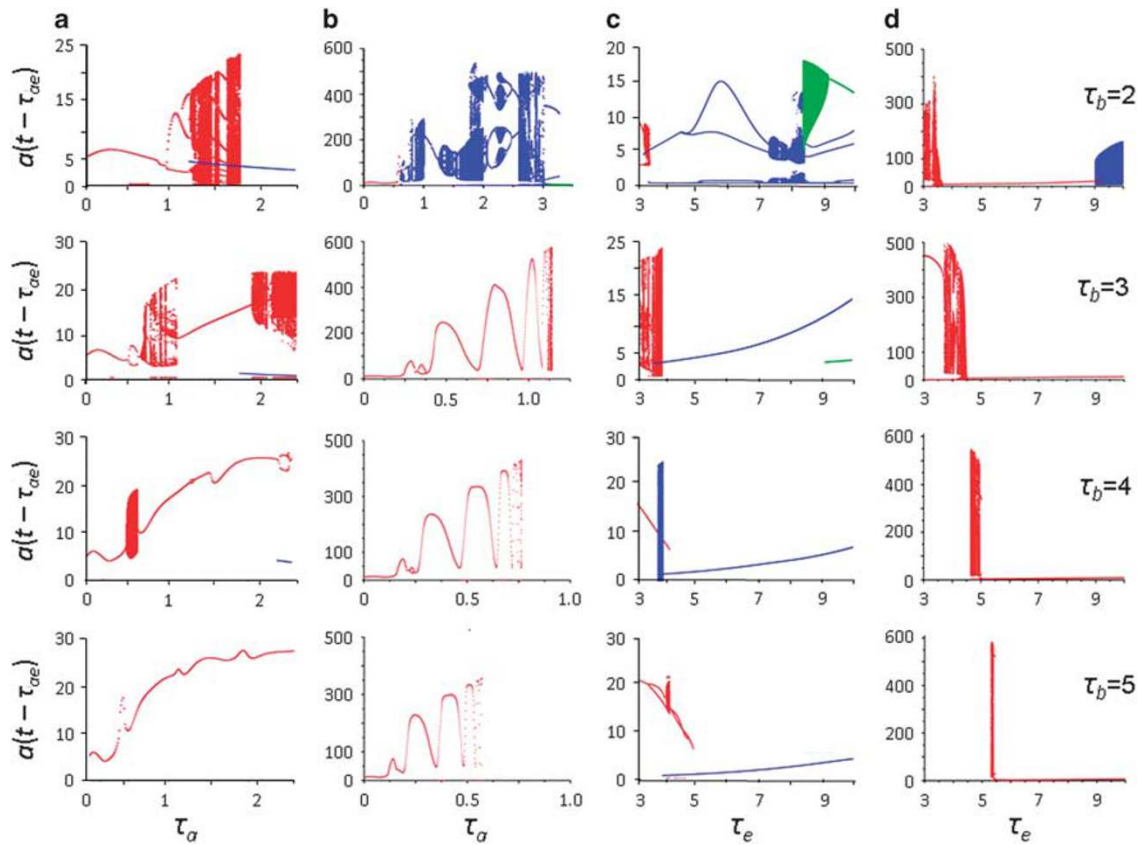

to the left of this boundary. Qualitative behavior of the unconditional stability region is invariable for all values of  $n$ . It monotonically increases with increasing value of  $K_b$  and for  $n = 2, 3$  its boundary shifts to the origin when the value of parameter  $h_b$  increases. That is, unconditional stability region increases with the decrease in the efficiency of functioning of the FMRP-dependent activation/suppression of translation.

Areas above curve 2 represent regions of conditional stability, since within this region maximal steady states lose stability for certain values of delayed arguments,  $\tau_{be} \geq \tau_{ae} \geq 0$ .

Curve 3 represents the boundary separating the region of conditional stability into two subregions. There is a parametric zone above curve 3 in which, according to the empirical criterion,<sup>56</sup> a chaotic dynamics is predicted. Below these curves, a chaotic dynamics is not predicted. It should be noted that the share of ‘chaotic’ zone in the conditional stability region essentially depends on the parameters of the model and increases markedly with the increase of  $n \times h_b$ . The results of the analysis of the parametric zone in which chaotic dynamics is predicted for model (1),(2) are presented below.

Analysis of the dynamics complexity for particular parameter values

Regulatory delays play an important role in the formation of chaotic dynamics.<sup>61–64</sup> But the empirical criterion does not provide information on the values of delayed arguments. Its implementation only guarantees the presence of certain equal values  $\tau_{ae} = \tau_{be}$ , for which the chaotic dynamics is observed. Moreover, there is yet no criterion for predicting chaotic dynamics for different values  $\tau_{ae} < \tau_{be}$ . In this case, the only analytical method is a numerical experiment. However, a large combinatorial networks of possible combinations of parameter values do not allow for the detailed numerical analysis in the entire physiological range of their variation. In this section, we have considered two polar variants of the values of Hill coefficients  $n$  and  $h_b$ :  $n = 1$ ,  $h_b = 4$  and  $n = 3$ ,  $h_b = 2$ , which reflect the contrast variants of the suppression of local translation at the synapse in the range of physiological

**Figure 4.** Solutions of equations (1) and (2) depending on the delay parameters: bifurcation diagrams constructed from the intersection of the trajectory  $a(t), a(t - \tau_{ae})$  and the Poincaré planes  $a(t) = 5$  (a,c) and  $a(t) = 10$  (b,d). Columns (a),(c) represent a variant  $n = 1, h_b = 4, V_i = 30, \tau_e = 3$  (a),  $\tau_a = 1$  (c); columns (b),(d) variant  $n = 3, h_b = 2, V_i = 700, \tau_e = 3$  (c),  $\tau_a = 1$  (d). Value of the parameter  $\tau_b$  for each row is shown on the right-hand side of the figure. Values of the remaining parameters  $k_a = 1, K_a = 1, K_b = 1, h_a = 1$ . Different branches of solutions (attractors) are shown in different colors.

values defined in the section ‘Estimation of the model parameters’, Supplementary note 1. Calculations for the variant  $n = 1, h_b = 4$  were carried out for  $V_i = 30$ , and for the variant  $n = 3, h_b = 2$  —for  $V_i = 700$ . Both variants, according to the empirical criterion,<sup>56</sup> are located in areas of predicted chaotic dynamics.

Numerical calculations shown in Figure 3 confirmed that model (1),(2) exhibits chaotic dynamics in both variants, at least for  $\sim 5 < \tau_{ae} = \tau_{be} < \sim 9.5$ . This is evidenced by the bifurcation diagrams shown in Figures 3a and d. It is recognized that in both cases the transition to chaos is carried out through a cascade of oscillation period doubling, that is, according to the Feigenbaum scenario.<sup>65,66</sup> This scenario is one of the most frequently observed scenarios of transition to chaos and is described, in particular, in models of dynamic electrical activity of neurons and pancreatic  $\beta$ -cells,<sup>67,68</sup> in models of intracellular oscillations of  $Ca^{2+}$  and NADH concentrations,<sup>69,70</sup> and also in models of alternative splicing.<sup>64,71</sup> It is also seen in Figure 3d that chaotic regions intersect with zones of regular cyclic dynamics. The existence of hyperchaotic solutions for  $n = 3, h_b = 2$  (Figure 3f) is evidenced by the presence of two positive Lyapunov exponents that emerge in the range of values  $\tau_a = 6 \div 8$  (Figure 3e).

Dynamic properties of model (1),(2) depending on the ratio of the delay parameters  $\tau_b/\tau_a > 1$

Since it is known that for the normal activated synapse values of the parameters  $\tau_a$  and  $\tau_b$  are presumably not equal, but differ by a factor of 2–5,<sup>28,29</sup> and application of the empirical criterion does not provide information on the chaotic potential of the model for unequal values of delayed arguments, in this section, we carried

out a direct numerical study of the dynamic properties of the above shown variants of model (1),(2) for  $\tau_{be} > \tau_{ae}$ .

The results of the analysis are shown in Figure 4.

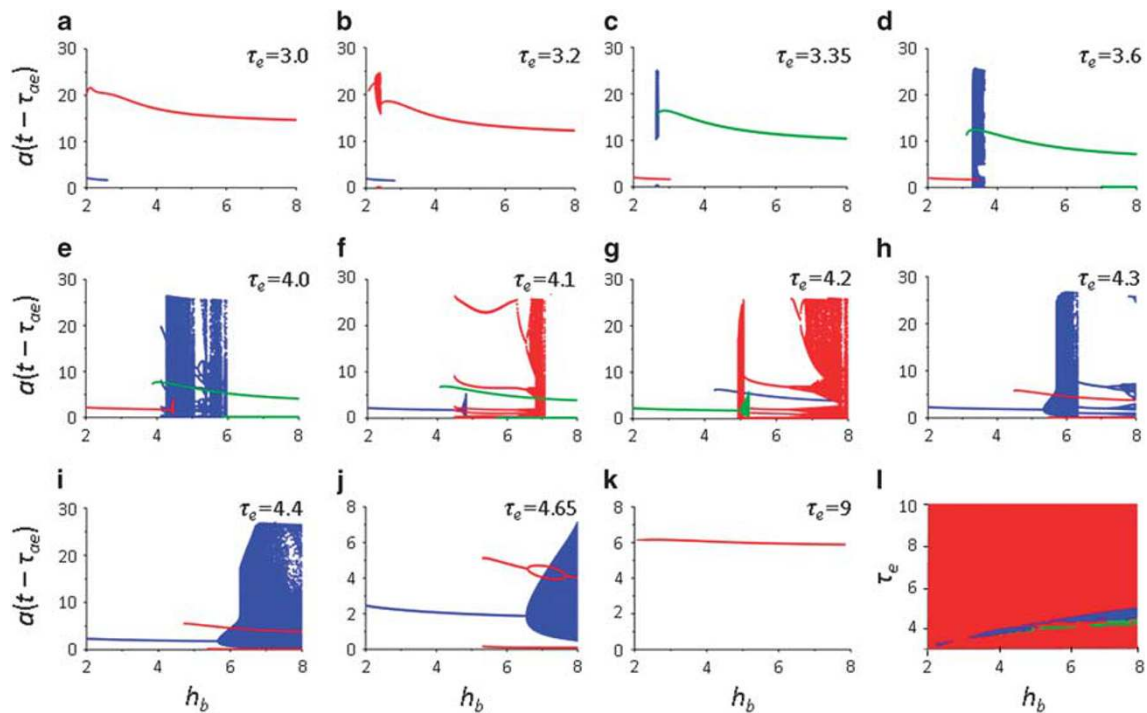

It can be seen that in the entire range of delay values, there are no stable steady states and, on the contrary, a complex pattern of oscillatory dynamics is observed, namely periodic, quasiperiodic or chaotic; and there are existence regions for multiple attractors. It should also be noted that an increase in the  $\tau_{be}/\tau_{ae}$  ratio, although it did not exclude the existence of zones of chaotic attractor, generally led to an increase in the areas with cyclic dynamics (Figure 4, compare rows from top to bottom).

A concrete example demonstrating the existence in the system of local translation of multiple attractors in one parametric area is given in Supplementary Figure S2.

Dynamic properties of model (1),(2) depending on the values of parameters  $h_b$  and  $\tau_e$

Parameter  $h_b$  determines the degree of nonlinearity of the mechanism behind realization of mTOR signaling; and parameter  $\tau_e$  represents the total time of protein synthesis and inclusion of the newly synthesized protein into the PSD.

From the results presented in Figure 4, it can be seen that the particular values of given parameters significantly affect the dynamic behavior of the system. Therefore, we carried out an extended analysis of the joint impact of the parameters  $h_b$  and  $\tau_e$  on the operating modes of model (1),(2). In the analysis, we only considered the case where  $n = 1$ , which corresponds to the currently dominant hypothesis on the mechanisms of translation

**Figure 5.** Modes of functioning of the model (1),(2) implemented for the ratio of delay parameters  $\tau_b/\tau_a = 4$  and depending on the complexity of the mTOR signaling pathway ( $h_b$ ). (a)–(k) bifurcation diagrams constructed from the intersection of the trajectory ( $a(t)$ ,  $a(t-\tau_{oe})$ ) and the Poincaré plane  $a(t)=5$ . Different attractors are shown in different colors. (l) solutions of the model (1),(2) in the value space  $\tau_e=3-10$  and  $h_b=2-8$ . Red color shows periodic solutions, green—quasiperiodic solutions, and blue—chaotic solutions. Values of the remaining parameters:  $k_a=1$ ,  $K_a=1$ ,  $K_b=1$ ,  $h_a=1$ ,  $V_i=30$ ,  $n=1$ ,  $\tau_a=1$ .

regulation through FMRP,<sup>27,67</sup> as well as fixed ratio  $\tau_b/\tau_a = 4$ , which is also physiologically justified.<sup>24,25</sup>

The results of the analysis are summarized in Figure 5.

From Figure 5l it follows that for  $\tau_e > 5$ , only cyclic type of dynamic behavior of model (1),(2) is observed in the whole range of variation  $2 \leq h_b \leq 8$ . At the same time, for  $\tau_e < 5$ , the nature of the dynamics depends considerably on the value of  $h_b$ . Therefore, all types of dynamics are detected in the region  $3.0 \leq \tau_e \leq 5$ : cyclic, quasicyclic and chaotic (Figure 5l), and the transition from one type of behavior of model (1),(2) to another was extremely sensitive to the value of the parameter  $\tau_e$  (Figures 5a–j).

Additionally, we note that multiple attractors were observed for certain values of the parameters  $\tau_e$  and  $h_b$ , which are illustrated in different colors in Figures 5a–j. The phenomenon of the multiplicity of attractors, which we also observed in Figure 4, demonstrates the feasibility of diverse dynamic states of the local translation system at various activated synapses. However, this phenomenon was observed only for relatively low values of the parameter  $3 < \tau_e < 5$  and with increasing  $\tau_e$  the area of the attractor multiplicity shifted to the area with high values of  $h_b$ , so that for  $\tau_e = 9$  only single cyclic attractors were found in the studied range of  $h_b$  (Figure 5k).

Thus, the studies presented above showed that the revealed complex dynamics (stationary, cyclic, quasicyclic, chaotic, hyperchaotic) of model (1),(2) was carried out during the implementation of the positive and negative regulatory loops controlling local translation at real synapses.<sup>28,29</sup>

## DISCUSSION

Existing views on the importance of a stable proteome for the formation of synaptic plasticity and associated processes of learning and memory (see reviews<sup>4,7,10</sup>) reveal the significant role for dysregulation of postsynaptic protein synthesis, recycling

and degradation at the activated synapse in the pathogenesis of neurological diseases (autism, epilepsy, and so on). In this study, given certain experimental data,<sup>28,29</sup> we focused only on the dynamic aspects of functioning of the translation system. It allowed us to single out the simplest regulatory contour and investigate the subtle dynamic relationships between activation and suppression of local translation at glutamatergic synapses in response to their activation. As shown above, these relationships can cause steady-state instabilities of the local translation system and formation of a complex dynamics of postsynaptic protein synthesis in a considerable part of the physiological range. Both cyclic and chaotic dynamics of FMRP-dependent postsynaptic protein synthesis result from a decrease in the activation ratio between S6 kinase and PP2A phosphatase, the two regulators of FMRP phosphorylation, playing a key role in controlling local translation at the synapse. This is possible both as a result of increased activity of mTOR signaling pathway controlling the activity of S6 kinase, and as a result of decreased PP2A phosphatase activity. Therefore, it is not surprising that one of the indications of epilepsy and autistic states is increased mTOR activity,<sup>12,15,16,18,19</sup> which can occur both as a result of mutations and various external influences.

Owing to the simplicity of the presented model, we cannot claim that the model completely reflects all existing interrelations, but one thing is certain: mechanisms that regulate local translation contain destabilizing elements. The very existence of negative and positive regulatory loops in the local translation system is one of the factors sufficient for the formation of complex, chaotic dynamics.<sup>61–64,71</sup>

Another problem is, in what parametric region can this dynamics be implemented and what additional conditions are evolutionarily created by the cell to stabilize the function of the synapse? There are no answers to these questions yet.

First of all, due to the lack of sufficiently detailed data on the mechanisms of synaptic function, it is impossible to easily determine the parametric boundaries of chaos generation. In our model, along with insufficient information on the values of  $K_a$ ,  $K_b$  and  $V_i$  constants, the lack of reliable data on the number of glutamatergic receptors at the PSD activated synapse is the main reason for parametric uncertainty. Existing estimates give a spread of 4 to 1200 molecules per PSD.<sup>52–54</sup> The uncertainty of the data is such that almost no part of the parametric area can be classified as not corresponding to reality.

To illustrate, let us consider the calculation shown in Figure 3c. In this calculation, the dynamics is chaotic and  $a(t)$  ranges from 0.25 to 210 dimensionless units (ratio between the current number of receptors on the membrane and the value of the  $K_a$  parameter). If we set the value of  $K_a$ , which is unknown, considering that the value of  $a(t)$  lies in the experimental boundaries (for example,  $K_a = 5$  molecules per membrane), then the value of  $a(t)$  varies from 1.25 to 1050 molecules per membrane. It is evident that the obtained variation corresponds well with the region between the minimum and maximum estimates: 4–1200 molecules/membrane.<sup>52–54</sup>

As for the second problem, it requires not only parametric certainty, but also additional studies on the structural complexity of the system and its impact on the synaptic stability. In our model, we analyzed only two such parameters, ( $h_b$ ) and ( $n$ ), related to the regulation of FMRP-dependent translation via mTOR signaling pathway. The obtained results clearly indicate that mechanisms of maintaining proteome stability at the activated synapse, that are critical for the formation of synaptic plasticity,<sup>7,10</sup> are directly related to the mechanisms of suppression of FMRP-dependent translation at the activated synapse.

In conclusion, it should be noted that we have obtained theoretical data on the dynamic regimes of functioning of the local translation at the activated synapse, which, however, due to uncertainty in a number of parameters, do not allow us to clearly specify which regimes are implemented in the synapses in norm and pathology. This is a very important issue related to understanding mechanisms of the onset of neuropsychiatric diseases due to disturbed local translation at the synapse.<sup>1,4,15–19,22</sup> Unfortunately, currently existing quantitative data on the structure and function of synapses do not allow to answer this question. This makes the detailed analysis of the biochemical characteristics and parameters of functioning of the synapses extremely important.

## CONFLICT OF INTEREST

The authors declare no conflict of interest.

## ACKNOWLEDGMENTS

This work was partly supported by the Russian State Budget (project No 0324-2016-0008) and by the RFBR (project No 16-01-00237a). We thank Tatyana Kalymbetova for the translation of an article from Russian to English, and Alena Moiseenko for the information support for this study.
