Abstract

The signature of cold-core eddies and their role in altering the biological productivity of the Bay of Bengal was examined using two recent sets of hydrographic data collected along the central and western Bay of Bengal during fall (14 September – 12 October, 2002) and spring (12 April – 7 May, 2003) intermonsoons under the Bay of Bengal Process Studies (BOBPS) programme. Based on the thermohaline structure and the satellite-derived sea-level anomaly maps 9 cyclonic eddies were identified. Out of this, 4 cyclonic eddies – 2 each along the central Bay and along the western boundary – occurred during fall intermonsoon 2002, while 5 occurred – 3 along the central Bay and 2 along the western boundary – during spring intermonsoon. The eddy depressed the temperature, which varied from 3°C to 7°C at 120 m depth. Maximum depression of temperature was associated with spring-time eddies in the northern Bay, where subsurface stability was low. The reduced water column stability in spring leads to greater eddy-pumping, thereby cooling the water to a greater extent. However, the cyclonic eddies were unable to break the stratification of the top 20m layer, thereby curtailing their effects below this depth during both seasons. Eddy-pumping not only cooled the water column but also enhanced the nutrient concentrations. This in turn increased the biological productivity of the Bay to 1½-2 times. In addition, the subsurface chlorophyll maximum (SCM), which is generally located between 40 and 70 m in fall and 60 and 90 m in spring intermonsoons, shallowed under the influence of the eddies and also enhanced the chlorophyll concentration in the SCM to more than double. Thus, eddy-pumping of nutrients controls the biological productivity of the Bay of Bengal during both the seasons. In the fall intermonsoon, however, the riverine input of nutrients and sediments in the northern Bay also plays a role in altering the biological productivity. This has an overall implication to the basin-wide new production and export flux and, at least partly, resolves the reason for the comparable annual fluxes of organic carbon

between the high-productivity Arabian Sea and low-productivity Bay of Bengal.

1. Introduction

The Bay of Bengal, bounded in the north at around twenty-two degrees, is a tropical basin situated in the eastern part of the northern Indian Ocean. The dominant atmospheric forcing is the semi-annually reversing monsoon winds, southwesterly during June-September (summer/southwest monsoon) and northeasterly during November-February (winter/northeast monsoon), which causes a semi-annual reversal of the surface circulation as well. On an annual scale this basin receives excess precipitation over evaporation to the tune of $\sim 2 \text{ m yr}^{-1}$ (Prasad, 1997), while the runoff from the peninsular rivers amounts to about $1.625 \times 10^{12} \text{ m}^3 \text{ yr}^{-1}$ (Subramanian, 1993). The suspended sediment discharge associated with the river runoff into the Bay is estimated to be about $1.382 \times 10^9 \text{ tonnes yr}^{-1}$ (Subramanian, 1993). The excess precipitation over evaporation and runoff freshen the upper layer waters of the basin. As a result, the annual mean surface salinity ranges from 30 (practical salinity scale) in the north to 34 towards the southern part (Fig.1). Apart from freshening of the surface layers, the river discharge is expected to add nutrients to the upper layers and increase the biological productivity of the Bay. However, recent measurements using clean techniques (Madhupratap et al., 2003) corroborate the traditional concept that the Bay of Bengal is a region of lesser biological productivity. The reason for this is variously attributed to cloud cover, large sediment load, narrow shelf, stratification, etc (see Qasim, 1977; Sengupta et al., 1977; Radhakrishna, 1978; Gomes et al., 2000). In a recent study Prasanna Kumar et al. (2002)

showed that the surface and the integrated chlorophyll *a* in the Bay of Bengal during summer monsoon was 4-5 times lesser than that in the Arabian Sea while the integrated primary productivity was about 8 times less. Based on the physical forcing, Prasanna Kumar et al. (2002) argued that this low biological production stems primarily from the lack of availability of nutrients in the upper layers arising from strong stratification and weaker winds, which curtail vertical mixing.

Contrary to the above pattern of chlorophyll and primary productivity in the Arabian Sea and the Bay of Bengal, sediment trap data shows that the average annual fluxes of organic carbon are comparable in both basins (Ramaswamy and Nair, 1994). This is intriguing considering the fact that there is no evidence of strong upwelling in the Bay of Bengal except for very localized upwelling close to the southwestern boundary during summer (Murty and Varadachari, 1968; Shetye et al., 1991) and that the comparatively weaker winds are unable to break the strong upper ocean stratification through wind-driven mixing. Thus, in the Bay of Bengal the traditional mechanisms of nutrient supply to the oligotrophic upper ocean waters such as wind-driven mixing, upwelling, aeolian dust input, etc. cannot account for the annual particle flux collected in sediment traps. Based on 2001 summer monsoon data, Prasanna Kumar et al. (2004) identified cold core eddies in the Bay of Bengal and proposed eddy pumping as a possible mechanism of vertical transfer of nutrients across the halocline to the oligotrophic euphotic zone during summer monsoon, when the upper ocean is highly stratified. This cold-core eddy was found to enhance the biological productivity by more than double. Though the existence of eddies in the Bay of Bengal has been documented by several authors (Ramasastry and Balaramamurty, 1957; Rao and Sastry, 1981; Legeckis, 1987; Babu et al.,

1991; Murty et al., 1993; Shetye et al., 1993; Sanilkumar et al., 1997; Babu et al., 2003; Madhusoodhanan and James, 2003; Prasanna Kumar et al., 2004) their role in the context of biological production is yet to be explored fully. An attempt towards this was made by Prasanna Kumar et al. (2004) using data collected during summer monsoon. In the present paper we examine the hydrographic data collected during fall and spring intermonsoons in the Bay of Bengal to identify the signature of eddies and explore their role in altering the biological productivity. The spring (March-April) and the fall (September-October) intermonsoon seasons represent the primary and secondary heating season in the Bay of Bengal during which the winds are weak and variable (Narvekar and Prasanna Kumar, 2006). The fresh water discharge from peninsular rivers is the least during spring intermonsoon, while it is at its peak during end of summer and beginning of fall intermonsoon (August-September). Unlike this, the summer (June-August) monsoon is characterized by strong (~ 10 m/s) and organized winds from southwesterly direction and high precipitation.

2. Data and method

As a part of the Bay of Bengal Process Studies (BOBPS) to understand the seasonal cycle of the upper ocean variability and associated changes in the biogeochemistry, *in situ* measurements were carried out onboard ORV Sagar Kanya along two transects – in the central Bay and along the western boundary (Fig.1) – during fall (14 September – 12 October, 2002) and spring (12 April – 7 May, 2003) intermonsoons. The measurements in fall intermonsoon were aimed at capturing the effect of freshwater in put, while those in spring intermonsoon were to understand the effect of solar heating. In all 24 CTD (Conductivity-Temperature-Depth) stations were occupied at

1-degree intervals, 14 in the central Bay of Bengal along 88°E and 10 along the western boundary. A Sea-Bird CTD having a rosette sampler fitted with 10/30-L Go-Flo bottles was used to obtain profiles of temperature and salinity in the upper 1000 m. CTD salinity was calibrated against water samples collected simultaneously and analyzed with a Guildline 8400 Autosal. Water samples collected from various depths were analyzed for nitrate and silicate using a spectrophotometer. The detection limits for nitrate and silicate were 0.1 and 0.5 μM , while standard deviations were 0.02 and 0.05 μM respectively.

In addition to the high-resolution physical and chemical measurements, nine biological stations (5 in the central Bay of Bengal and 4 along the western boundary) (Fig.1) were also occupied for over 24h for measuring primary production according to an *in situ* incubation protocol (UNESCO, 1994). Details of these measurements are reported in Madhupratap et al. (2003). Briefly, water samples collected at pre-dawn from eight discrete depths (near surface, 10, 20, 40, 60, 80, 100 and 120 m) by the CTD rosette sampler were used for measuring primary production (PP). Water samples from each depth were collected into four 300 ml polycarbonate (Nalgene, Germany) bottles (three light, one dark). One ampoule of $\text{NaH}^{14}\text{CO}_3$ (specific activity of 185 kBq; Board of Radiation and Isotope Technology, Mumbai) was added to each bottle. Following this, all bottles were tied on to a mooring system before dawn and, incubated *in situ* at respective depths for 12h. The mooring was *in situ* from just-before-sunrise to half hour past sunset. Uptake of ^{14}C was measured by filtering 100 ml of sample from each bottle through GF/F filters (25 mm dia, 0.7 μm pore size, Whatman, USA); filters transferred into scintillation vials and exposed to HCl (0.5 N) fumes

overnight in a closed container. Five ml liquid scintillation cocktail (Sisco Research Laboratory, Mumbai) was added to each vial and, assayed for radioactivity in a scintillation counter (Wallac 1409 DSA, Perkin Elmer, USA). PP rate was calculated and expressed as $\text{mg C m}^{-3} \text{ d}^{-1}$, 12h being considered as day (UNESCO, 1994). Chlorophyll *a* (chl *a*) concentrations from samples collected at all the depths mentioned above were measured using a fluorometer (Turner Designs, USA). Sub-samples from these depths were filtered through 47mm GF/F filters and, the chl *a* was extracted in 10 ml 90% acetone in the dark for 24h in a refrigerator and its concentration determined. Surface meteorological observations were also made along both tracks, and all the above measurements followed the JGOFS protocols (UNESCO, 1994). From the temperature and salinity data, geostrophic currents were computed with respect to 1000 m depth following the Helland-Hansen method (Pond and Pickard, 1978).

In addition to the *in situ* hydrographic data, we also used remote sensing data on sea-level height and chlorophyll pigment concentrations. The 7-day snapshots of the merged sea-level anomalies of Topex-Posidon/ERS 1/2 satellites obtained from the AVISO (<http://las.aviso.oceanobs.com>) live access server having a spatial resolution of 1/3 of a degree, were examined during September-October 2002 and April-May 2003 to obtain the spatial structure of eddies inferred from the hydrographic data. From the sea-level anomalies velocities were computed assuming the geostrophic relation $2\Omega\sin(\phi).V = g \tan(i)$, where Ω is the earth's angular velocity, ϕ is the latitude, V is the velocity and $\tan(i)$ is the slope of the sea surface (Pond and Pickard, 1978).

The monthly mean chlorophyll pigment concentration data was derived from (<http://reason.gsfc.nasa.gov/OPS/Giovanni/ocean.seawifs.shtml>) SeaWiFS global 9-km monthly imagery.

3. Results

3.1 Fall intermonsoon 2002

3.1.1. Thermohaline structure

Thermal structure along the central Bay transect showed a shallow upper isothermal layer of about 20 m thickness in the south, which deepened to about 70 m at 11°N and then shoaled towards the north (Fig.2a). The temperature of this layer was about 28°C except in the northernmost regions (18-20°N), where it was 1°C higher. The thermocline was characterized by oscillations and exhibited a gradual shoaling towards north. Three regions could be identified with well defined upward sloping followed by downward sloping centered at 8°N, 14°N and 18°N. For example, the 22°C isotherm showed a 30-m shoaling in all the three regions from about 100 m to 70 m at 8°N, 110 m to 80 m at 14°N, and 90 m to 60 m at 18°N. In general, the up/down sloping depressed the ambient temperature by about 3°C in all three regions. It may be noted that the influence of the up/down sloping was discernible even in the upper 50 m in the case of oscillations centered at 8°N and 18°N, while that at 14°N was confined mostly below 80 m. Below 300 m, however, the oscillations in the isotherms were very small.

The vertical salinity structure showed the presence of very low salinity waters in the surface, as low as 29, in the northern region (Fig.2b). The surface salinity increased rapidly towards the south attaining the maximum

value of 34. The salinity front arising from the freshening of waters from the north was confined mainly to the upper 50 m and north of 12°N. As a result, salinity distribution also showed a strong vertical gradient with an increase in salinity of about 5.5 in the upper 50 m. The vertical gradient weakened towards the south with an increase in salinity of 1 in the upper 80 m. Below 50 m and down to 1000 m the salinity remained almost same. The up/down sloping of isohalines, though weakly perceptible in the region of 17-18°N, was absent near 8°N and 14°N. This was due to the weak salinity gradient towards the south and below 80 m.

The density (σ_t) distribution essentially reflected 3 prominent regions of isopycnal doming (Fig.2c) coinciding with those seen in the thermal structure, apart from the strong density stratification in the north associated with the salinity gradient.

Along the western boundary, the thermal structure exhibited a warmer (in excess of 30°C) and shallower (~10 m) isothermal layer except in the south and north where it was colder (~29°C) and thicker (in excess of 20 m) (Fig.3a). The most distinct features were two prominent regions of upward isotherm sloping followed by a downward sloping located at 12°N and 18°N, respectively (Fig.3a). The doming of isotherms was more pronounced at 18°N with the 22°C isotherm showing a vertical displacement of 50 m from 110 m to 60 m, while that at 12°N shoaled by about 30 m. This upward/downward sloping of isotherms lowered the temperature by about 3°C at 12°N and 5°C at 18°N. Unlike the central Bay of Bengal thermal structure, the oscillation of isotherms at 12°N penetrated deeper than the thermocline and was noticed even down to 900 m.

The surface salinity showed fresher waters in the north compared to the central Bay with salinity as low as 25 (Fig.3b). The salinity structure

remained more or less similar to that of the central Bay, but with much stronger vertical gradients. However, the upward/downward sloping of isohalines was much sharper and more pronounced at 18°N in comparison with the central Bay. At 12°N the isohaline below 500 m also showed upward/downward sloping.

Once again the density (σ_t) structure showed features similar to that of the thermal structure along with very strong stratification of the upper layers in the north (Fig.3c).

3.1.2. Geostrophic currents

The geostrophic velocities computed from temperature and salinity profiles showed alternate bands of positive (eastward) and negative (westward) flows along both transects (Fig.4). Along the central Bay transect the flow was eastward between 7 and 8°N with a speed of 20 cm/s at 8°N, which decreased towards 9°N and turned into a westward flow with maximum speed of 25 cm/s at 11°N (Fig.4a). Once again, the flow was eastward between 12° and 14°N with maximum speed of 25 cm/s. Currents, in general, were weak (~5 cm/s) and westward north of 15°N, except for a region between 16° and 18°N where a weak (10 cm/s) and shallow (~70 m) eastward flow was encountered. It may be noted that the flows with speed greater than 10 cm/s were confined to the upper 150 m.

Along the western boundary (Fig.4b), the flow was eastward at 11°N with a speed of 20 cm/s, which gradually decreased to a minimum at 12°N and turned to a westward flow of magnitude 20 cm/s centered 13°N. The current changed its direction towards the east at 16°N with speed increasing to ~20 cm/s between 16 and 17°N followed by another change in direction towards the west. The maximum speed of this westward current was about 25 cm/s

between 18 and 19°N. Here again, the flows with speed greater than 10 cm/s were confined to 150 m, except between 11° and 13°N.

In general, the computed geostrophic flow reversals were associated with the upward/downward sloping of isotherms/isopycnals observed in the thermohaline structure. The eastward flow corresponds to the region of upward sloping while the westward flow coincides with downward sloping of isotherms/isopycnals. Thus, the alternating zonal flows associated with the doming of isopleths in the thermohaline structure appear to be a part of the cyclonic circulation feature and we infer them to be the signature of a cold-core eddy. In order to establish this, we analyzed the 7-day sea-level anomaly maps during 18 September to 15 October 2002 (Fig.5). Note that the CTD measurements along the central Bay transect were during 17 to 27 September 2002, while those along the western boundary were during 30 September to 11 October 2002. Hence the left panel in Fig.5 represents sea-level anomaly during the central Bay transect sampling period, while that in the right panel represents the sea-level anomaly during the sampling period along western boundary.

In the sea-level anomaly maps, we noticed two cyclonic eddies in the north centered at 17°N, 88°E and 17.5°N, 85°E, embedded in a large cyclonic circulation between 84° and 89°E longitude and 14° and 19°N latitude (Fig.5). This was consistent with the geostrophic flow computed from the hydrographic data, which showed a large cyclonic circulation with eastward flow between 12° and 14°N and a westward flow north of it extending up to 19°N. Note that *in situ* measurements sampled both eddies, one along the central Bay transect and the other along the western boundary track, away from its center. Similarly, two more cyclonic eddies – one centered at 12°N, 82°E near the western boundary and the other at 8.5°N, 87°E in the central

Bay transect – were visible in the sea-level anomaly maps. These eddies depressed the sea level by about 20-25 cm. The sea-level anomaly map showed that the CTD station at 14°N along the central Bay transect falls at the edge of the large cyclonic circulation within which the two northern cyclonic eddies – central Bay and along the western boundary – were embedded (Fig.5). Thus, it is evident from the sea-level anomaly maps that there were only 4 distinct cyclonic eddies, two each along the open ocean and along western boundary, which were sampled during fall intermonsoon 2002.

3.1.3. Nutrients

Consistent with thermal structure, the vertical distributions of nitrate along the central Bay transect also showed oscillations and a general northward shoaling of isopleths in the upper ocean (Fig.6a). The doming of isopleths centered at 8°N, 14°N, and 18°N, in general, coincided with the locations of eddies identified from the thermohaline structure as well as from the sea-level anomaly maps, except that at 14°N, which was located at the edge of a large cyclonic circulation. The upper 20 m, however, showed concentrations below detection level; the 1 μM nitrate isopleth, which was generally located close to 50 m, shoaled to about 25 m in the south (south of 15°N) under the influence of the doming while in the north it shoaled to shallower than 10 m. Silicate showed a distribution similar to that of nitrate below 30 m (Fig.6b). However, unlike the nitrate the silicate levels were high in the upper 30 m. The surface silicate concentrations increased from 0.5 μM in the south to 2 μM in the north.

Along the western margin, the prominent features in the nitrate distribution were two regions of doming isopleths, centered at 12°N and 17.5°N (Fig.6c), which coincided with the locations of eddies inferred from the thermohaline structure and the sea-level anomaly maps. The top 20 m was devoid of nitrate except in the north and south where the doming introduced nitrate to shallower than 10 m. In fact, the 1- μ M nitrate isopleth was deepest at 16°N and shoaled under the influence of eddies. Silicate also showed a distribution similar to that of nitrate below 20 m (Fig.6d). In the upper 20 m, unlike the nitrate pattern, high silicate levels were encountered towards the north with surface concentrations increasing from 5 μ M at 17°N to 15 μ M at 19°N. This high surface concentration, which decreased rapidly in the upper 30 m, suggests a source in the north.

3.1.4. Chlorophyll a and primary productivity

Chlorophyll *a* in the top 120 m along the central Bay transect varied from 0.12 mg/m³ to 0.37 mg/m³, with higher values towards south (Fig.7a). The most prominent feature was the occurrence of enhanced chlorophyll *a* concentrations, which coincided with the location of eddies inferred from the thermohaline structure and sea-level anomaly maps. In fact, the top 40 m of the water column in the eddy region contained the highest chlorophyll concentrations. The subsurface chlorophyll maximum (SCM), which was generally located at 60 m, shoaled under the influence of the eddy. As a result, very low chlorophyll *a* concentrations (<0.05 mg/m³), which occurred below 80 m in the south (south of 15°N), also shoaled (~ 60 m) towards the north. Surface primary production (PP) varied from 5.34 to 17.66 mg C m⁻³ d⁻¹, while column integrated PP (up to 120) ranged from 513 to 182 mg C m⁻²

d^{-1} (Table 1). Here again, the higher values of PP, both surface and column integrated, occurred in the eddy region, except at 18°N .

Along the western boundary surface chlorophyll *a* concentrations varied marginally from 0.13 to 0.18 mg/m^3 except at 19°N and at 16°N where the highest (0.77 mg/m^3) and lowest (0.08 mg/m^3) values occurred respectively (Fig.7b). Though enhanced chlorophyll concentrations were seen in the eddy region, unlike the open ocean, the concentrations were more prominent and uniformly distributed in the north (in the vicinity of 18°N) than the south. This is also reflected in the surface and column-integrated PP. Surface PP varied from 3.16 to 45.15 $\text{mg C m}^{-3} \text{d}^{-1}$, while the column-integrated values ranged from 196 to 350 $\text{mg C m}^{-2} \text{d}^{-1}$. Though the eddy caused the nitracline to shoal both in the north and in the south along the central Bay, the column-integrated PP was highest in the south, more than $2\frac{1}{2}$ times that in the north. In fact, it was also $1\frac{1}{2}$ times higher than the highest PP in the north along the western boundary.

3.2 Spring intermonsoon 2003

3.2.1 Thermohaline structure

Thermal structure along the central Bay transect during spring intermonsoon showed a thin isothermal layer of about 10 m in the south, south of 15°N , within which the temperature was in excess of 30°C (Fig.8a). Towards the north, the isothermal layer was thicker (~ 30 m) and 1°C colder. In general, the isotherms in the upper 50 m showed a shoaling trend from 7°N to 15°N , while further north it deepened towards 17°N and once again shoaled at 19°N . However, below 50 m there was a reversal in the slope of the isotherms, which showed a deepening trend from 7°N towards 18°N . As

during the fall intermonsoon, we noticed oscillations in the thermocline and three distinct regions of isotherm upward sloping followed by downward sloping centered at 11°N, 16°N and 19°N. At 11°N, the upward/downward sloping of isotherms was the least, while at 19°N it was at a maximum. For example, the 22°C isotherm shoaled by about 20 m at 11°N and 16°N, which depressed the temperature at 120 m by 2-3°C. At 19°N the shoaling exhibited by the 22°C isotherm was as large as 70 m, which resulted in a drop in the temperature by about 7°C at 120 m. The upward/downward sloping of isotherms centered at 16°N was seen even at greater depths.

The vertical salinity structure showed an isohaline layer of about 30 m thickness having a salinity of about 33, except between 16° and 17°N, and south of 9°N (Fig.8b). In the former, salinity was 0.5 fresher, while in the latter salinity showed a steady increase. The halocline was located between 30 and 100 m depth, within which salinity increased north of 9°N by 1.5. In the south, however, the gradient in the vertical salinity showed a steady decrease. Below 100 m salinity showed only small variation. The isohalines in the upper 100 m showed upward/downward sloping centered at 11°N, 16°N and 19°N.

The density (σ_t) structure, in general, showed a weaker stratification in the upper 50 m with a thicker isopycnal layer north of 14°N compared to south (Fig.8c). The pycnocline was confined between 50 and 200 m, within which there was marked upward/downward sloping of isopycnals centered at 11°, 16°, and 19°N. Consistent with temperature and salinity structures, the vertical displacements of isopycnals were largest centered at 19°N.

Along the western margin the thermal structure showed a comparatively deep isothermal layer south of 16°N with a thickness of about 40 m and temperature in excess of 30°C (Fig. 9a). Towards the north the isothermal

layer was thin, about 10 m, and the temperature of this layer was about 1°C colder. In general, the isotherms in the upper thermocline showed a northward shoaling with the 29°C isotherm located at about 70 m deep in the south, which shoaled to about 10 m in the north. The most prominent feature was the upward/downward sloping of isotherms centered at 14°N and 17.5°N, the latter being the most pronounced. The amplitude of isotherm displacement, though seen towards the deeper layers in both the cases, was greater at 14°N. For example, at 14°N, the 22°C isotherm shoaled by about 30 m, while at 17.5°N it shoaled by about 70 m. In contrast, in the deeper layers the 10°C isotherm showed a shoaling of about 140 m, whereas it shoaled only by 40 m at 17.5°N. The vertical displacement of isotherms at 100 m resulted in a depressing of the temperature by about 3°C at 14°N and by about 5°C at 17.5°N.

The vertical salinity structure also showed a gradual shoaling of isohalines from south towards north in the upper 100 m, with surface waters north of 15°N fresher by 0.5 (Fig.9b). Accordingly, the vertical gradient of salinity in the upper 100 m was only 0.5 in the south, but it was 1 in the north. Consistent with the thermal structure, salinity distribution showed prominent isohaline displacements centered at 14°N and 17.5°N.

The density (σ_t) distribution essentially reflected the features in thermohaline structure (Fig.9c).

3.2.2. *Geostrophic currents*

The geostrophic velocities computed from the hydrographic data during spring intermonsoon also showed alternate bands of positive (eastward) and negative (westward) flows along both the central Bay and the western boundary transects (Fig.10). Along the central Bay transect flow was

westward from 7°N to 13°N, except for a weak (~10 cm/s) and shallow eastward flow centered at 10.5°N (Fig.10a). The maximum westward flow of 25 cm/s was encountered at 12°N. The westward flow reverses to eastward flow from 13°N to 16°N and had an average speed of about 10 cm/s. Once again the flow reverses to westward between 16° and 18°N and then to an eastward flow north of 18°N. In general, the strongest flow was encountered north of 16°N with the core of the westward flow (speed 35 cm/s) centered at 17°N, while that of the eastward flow (speed 50 cm/s) was centered at 19°N.

Along the western boundary, the flow was eastward south of 14°N with a maximum speed of 30 cm/s followed by a stronger but narrower westward flow between 14 and 15.5°N with peak speed of 40 cm/s (Fig.10b). Once again eastward and westward flows were encountered at the southern and northern side of 18°N respectively. The westward currents, however, were much weaker (~10 cm/s) in the latter case and confined to the upper 60 m.

Thus, the opposing flows and the doming-structure in the thermohaline distribution appear to be the signature of a cold-core eddy. To confirm this, we analyzed the 7-day sea-level anomaly maps during 16 April to 13 May 2003. Since the CTD measurements along the central Bay track were carried out during 16 to 26 April 2003, the left panel in Fig. 12 represents conditions that prevailed in the central Bay sampling period, while the right panel represents the conditions during the sampling along western boundary, which was from 27 April to 5 May 2003. The sea-level anomaly picture showed the presence of three cyclonic eddies along the central Bay transect centered at 11°N, 90°E, 16°N, 89°E, and 19°N, 90°E (Fig.11a). The cyclonic eddy in the north (centered at 19°N, 90°E) was the most intense one, with a negative sea-level anomaly of about 22 cm, followed by the one centered at

16°N, 89°E, with a negative sea-level anomaly of 18 cm. The southern one (centered at 11°N, 90°E) was the least intense, with a negative sea-level anomaly of 6 cm. None of the CTD stations sampled the eddy at its center. The eddy at 11°N was sampled far from its center causing its signature by way of upward/downward sloping of isopleths in the thermohaline structure (Fig.8) to be the least. Note the presence of an anticyclonic eddy at 18°N, 87°E (Fig.11a), the effect of which is seen as the steep dip in the isotherms at 18°N (Fig.8). Along the western boundary also we see two cyclonic eddies, centered at 14°N and 17.5°N, with negative sea-level anomalies of 22 and 18 cm respectively (Fig.11b) which were sampled by CTD stations close to their centers. Thus, we find five cyclonic eddies, three close to the open-ocean track and two along the western boundary, in the sea-level anomaly maps, which were sampled by the CTD stations during spring intermonsoon 2003.

3.2.3. *Nutrients*

Along the central Bay transect noticeable features of the vertical distribution of nitrate were that the concentrations in the upper 30 m below detection level and the oscillations within the nitracline (Fig.12a). Doming of isopleths was found prominently at 4 locations, centered at 9°N, 12°N, 15°N, and 19°N. This resulted in appreciable enhancement of nitrate in the upper 50 m at these locations. For example, the 1- μ M isopleth, which was in general located below 50 m, shoaled to about 25 m in the north under the influence of doming. Though a similar pattern of isopleth doming was observed in the distribution of silicate (Fig.12b), the concentrations in the upper 50 m, unlike those of nitrate, did not vary much. This is primarily due to the greater ambient concentration in the upper 30 m of the water column,

which was in the range 1.5-2 μM . The region of isopleth doming generally coincided with that of isotherms (Fig.8a), except that centered at 9°N. However, from the sea-level anomaly map (Fig.11a) it can be seen that the CTD station at 9°N along the central Bay transect falls at the edge of a large cyclonic circulation feature at 2°-8°N and 84°-96°E, which encompasses two cyclonic eddies (not sampled by CTD stations).

Along the western margin a prominent feature of both nitrate (Fig.12c) and silicate (Fig.12d) distribution was doming of isopleths centered between 17 and 18°N. Under the influence of this doming, the 1- μM nitrate and 2- μM silicate isopleths, which were generally located at about 60 m depth, shoaled to shallower than 10 m and 20 m respectively (Fig.12c & d). A minor doming was centered at 14°N, in both the nitrate and the silicate distribution (Fig.12). As in the case of the central Bay, the nitrate levels in the upper 30 m were below detection except in the region of doming (Fig.12c). The silicate levels in the upper 30 m varied from 1.5 to 2 μM (Fig.12d).

3.2.4. *Chlorophyll a and primary productivity*

Along the central Bay transect, the vertical distribution of chlorophyll *a* in the top 120 m showed that the surface concentration varied from 0.06 to 0.12 mg/m^3 (Fig.7c). The most prominent features were the subsurface chlorophyll maximum (SCM) and enhanced chlorophyll *a* concentrations between 18° and 20°N. The SCM was generally located between 60 m and 80 m, depth where concentrations were in excess of 0.25 mg/m^3 . Under the influence of the eddy between 18° and 20°N not only is the SCM pushed upward but also the chlorophyll concentrations within increase to 0.65 mg/m^3 . Surface primary production (PP) varied from 0.01 to 3.97 mg C m^{-3}

d^{-1} , while column-integrated PP (to 120 m) ranged from 155 to 427 $\text{mg C m}^{-2} \text{d}^{-1}$ (Table 1). The higher value of column-integrated PP occurred in the eddy region in the north, where it was twotimes higher than it was in the non-eddy region.

Along the western boundary, surface chlorophyll *a* varied from 0.06 to 0.21 mg/m^3 and was, in general, higher than the open ocean values. But as in the case of the central Bay, the higher values were encountered towards the north (Fig. 7d). Here again we see enhanced chlorophyll *a* concentrations of about 0.6 mg/m^3 under the influence of the eddy near 17°N. Surface PP varied from 1.87 to 9.68 $\text{mg C m}^{-3} \text{d}^{-1}$ and column-integrated PP from 250 to 469 $\text{mg C m}^{-2} \text{d}^{-1}$ (Table 1).

4. Discussion and conclusion

The thermohaline structures obtained from the *in situ* hydrographic measurements clearly indicated the presence of cyclonic eddies by way of doming isopleths/thermocline oscillation, both in the open Bay of Bengal and along the western boundary during both fall (2002) and spring (2003) intermonsoons. The spatial dimension of the thermocline oscillations associated with eddy ranged from 200 to 300 km, which means that at the most 3 stations sampled the eddy region. The rotary flows associated with these eddies were seen as alternate bands of reversing zonal currents in the geostrophic computations. In fact, the currents showed cyclonic circulation with eastward flow in the region of upward sloping isopleths and westward flow coinciding with downward sloping isopleths. Satellite-derived sea-level anomaly maps showed 4 distinct cyclonic eddies, 2 each along the central Bay and along western boundary respectively, during fall intermonsoon

2002 and 5 cyclonic eddies during spring intermonsoon, of which 3 were along the central Bay transect and 2 along the western boundary. The sea-level anomaly maps revealed that the eddy generated during the spring intermonsoon had a life span of about 5 months, while that during the fall intermonsoon was short lived.

In the fall intermonsoon, these eddies depressed the ambient temperature by about 3°C in the upper 120 m in all the cases except at 18°N along the western boundary, where the temperature drop was about 5°C. To explore the reason for such differential cooling, we computed the static stability parameter (E) (Pond and Pickard, 1978) during fall intermonsoon. A comparison of the profiles at 18°N, 84.5°E and 14°N, 88°E (Fig.13a) clearly showed that though the water column in the upper 40 m at 18°N was much more strongly stratified than that at 14°N, below this depth and down to 160 m the water column at 18°N was much less stable, which helped the cyclonic eddy at this location to pump more cold water to the top layers. However, the low-salinity surface waters, especially in the north, induced a strong halocline in the upper 50 m of the water column. The observed very low surface salinity of 29 in the open Bay and 25 near the western boundary in the north indicated the strong influence of fresh water flux due to the large E-P, which is in excess of 200 mm/month during June to August (see Fig.9 of Narvekar and Prasanna Kumar, 2006). In addition to the oceanic precipitation there is also a large amount of freshwater input from peninsular rivers. The monthly mean climatology of river discharge of the 6 major rivers Ganges, Brahmaputra, Irrawady, Godavari Krishna, and Cauvery, obtained from Global Runoff Data Center, Germany (<http://grdc.bafg.de/servlet/is/2781/>), showed that the freshwater discharge dominated during July to October (Fig.14a). The cumulative discharge of

these 6 rivers during this period (Fig.14b) amounted to a voluminous $3.46 \times 10^{12} \text{ m}^3$. Note that the precipitation peaks in July (Fig.9 of Narvekar and Prasanna Kumar, 2006), while the river discharge peaks in August (Fig.14a). So there is a time lag between the precipitation and the freshwater discharge peaks.

Thus, though the cyclonic circulation associated with the eddy is capable of pumping cold subsurface waters towards surface as seen from the doming isopleths, the strong stratification associated with the low-salinity waters inhibited the shoaling of isopleths to the surface, thereby capping the eddy signature below 20 m from the surface.

In the spring intermonsoon also these eddies depressed the temperature by 3°C at 120 m in all the cases except at 19°N in the central Bay and 17.5°N along the western boundary, where the cooling was 7°C and 5°C , respectively. Here again, the stability profiles showed that at 19°N , where the cooling was the highest, the water column below 80 m depth was much less stable compared to other eddy locations, for example at 14°N (Fig.13b). But unlike the fall intermonsoon, surface salinity during spring intermonsoon was much higher, with lowest values of 32.5 along the central Bay and 33 along the western boundary towards the north. This high surface salinity arises from positive E-P, which is in excess of 40 mm/month (Fig.9 of Narvekar and Prasanna Kumar, 2006) coupled with marginal river discharge during spring intermonsoon (Fig.14a). SST during spring intermonsoon along the central Bay transect was 1°C warmer in the north, but towards the south it was 2°C warmer. However, along the western boundary SST remained similar in both seasons. Though the warm SST in spring intermonsoon is capable of stratifying the upper ocean, the higher surface salinity in spring than in fall intermonsoon could counteract this, as

can be seen from the stability profiles (note the break in scale during fall intermonsoon).

As mentioned earlier, these cold-core eddies are capable of pumping subsurface waters to the upper layers. Eddy-pumping could cause an upward displacement of the nutricline along constant density surfaces and inject growth-limiting macro- (such as nitrate, phosphate and silicate) and micro- (such as iron) nutrients to an impoverished euphotic zone (Falkowski et al., 1991; Olaizola et al., 1993; McGillicuddy and Robinson, 1997; McGillicuddy et al., 1998; Seki et al., 2001). If there is enough sunlight this will lead to enhanced rates of biological productivity and export out of the euphotic zone. We see enhanced levels of nitrate and silicate during both fall and spring intermonsoons in the region of eddies. The observed co-located high concentrations of chlorophyll *a* during fall and spring intermonsoons are the response of nutrient injection into the euphotic zone by these eddies. Eddy-pumping of nutrients increased the chlorophyll *a* concentrations to more than 1½ times. Another effect of eddy pumping is that the subsurface chlorophyll maximum (SCM), which is generally located between 40 and 70 m, is pushed upward. In fact, in spring intermonsoon SCM is even deeper, between 60 and 90 m, and the eddy-pumping not only shallows the SCM but increases the chlorophyll *a* in the SCM to more than double. In an earlier study Murty et al. (2000) reported the depth of the SCM in the open-sea region of the Bay of Bengal between 50 and 100 m based on May-June 1996 measurements. However, their chlorophyll *a* concentrations were extremely low compared to earlier measurements (Radhakrishna et al., 1982, Devassy et al., 1983; Sarma and Kumar, 1991; Prasanna Kumar et al., 2002; Madhupratap et al., 2003), especially in the SCM, where they were ~0.1 mg/m³.

Apart from the nutrient enhancement in the eddy region, we also note enhancement of nitrate and silicate in the surface layer along the western boundary during fall intermonsoon towards 20°N and 11°N (see 0.5- and 1.5- μ M contours in Fig.6 c & d respectively). In the case of silicate the surface concentrations in the north were as high as 15 μ M. This indicated that the nutrient source in the north must be the river input. As the river discharge peaks during August (Fig.14a), it is quite likely that the surface enhancement of nutrients brought by river influx will be felt in the fall intermonsoon. Since the surface circulation at this time of the year is southward from the head of the Bay along the western boundary (Fig.5), there are more chances for the nutrients brought by the river input to be advected along the western boundary than in the offshore region. Hence, we see this signal as enhanced nutrients in the northern part of the western boundary rather than in the northern part of the open-ocean transect. Consistent with this the chlorophyll *a* in the upper 30 m in northern part of the western boundary was 0.4 mg/m³, while it was only 0.15 mg/m³ in the northern part of the open-ocean transect. Again, in the south (11°N) the runoff from southern rivers could explain the enhanced levels of nutrients and associated elevated chlorophyll.

Eddies enhanced the biological productivity by more than 1½ times during both fall and spring intermonsoons. Interestingly, during fall intermonsoon the column-integrated biological productivity in the north was about 2½ times less than that in the south along the open ocean transect. In contrast, along the western boundary the northern part was about 1½ times more productive than the south. This low biological productivity in the north along the central Bay transect, in spite of nutrient availability in the upper water column, points to the possibility of light limitation due to the

suspended sediment load brought in by the river runoff. Along the northern part of the western boundary, however, the quantity of nutrient in the surface layer is more than that in the northern part of the open-ocean transect. Note that along the western boundary the surface productivity in the north is more than 7 times that in the south (Table 1). Hence, though there could be light limitation in the northern part of the western boundary, comparatively high nutrient levels in the upper layer leads to an overall high productivity in comparison to the south. During spring intermonsoon, however, the enhanced biological productivity is entirely controlled by eddy-pumping of nutrients to the euphotic zone.

It is now evident that cyclonic eddies exist and enhance biological productivity of the Bay of Bengal, not only in summer monsoon (Prasanna Kumar et al., 2004) but also in fall and spring intermonsoons. Though the surface chlorophyll concentrations as detected by satellite remote sensing may be perennially low, these cyclonic eddies, which appear to be ubiquitous in the Bay of Bengal, enhance biological productivity by 1½-2 times its ambient value through eddy-pumping of nutrients. This has an overall implication for the basin-wide new production and export flux. The comparable rates of the annual fluxes of organic carbon between the high-productivity Arabian Sea and what has traditionally been considered to be the low-productivity Bay of Bengal could be, at least in part, explained by enhancement of biological productivity in the Bay of Bengal by cyclonic eddies. However, we need more eddy-targeted measurements and modeling efforts to quantify the impact of the eddies on the biological pump in the Bay of Bengal.

Note that the PP measurements along the central Bay (88°E) during fall intermonsoon were at 18°N while those during spring intermonsoon were at 17°N. * The unusually low surface PP is inexplicable. However, at 10 m depth it was $2.88 \text{ mg C m}^{-2} \text{ d}^{-1}$ though the chlorophyll *a* was around 0.06 mg m^{-3} at both depths. Mean±SE (standard error) was calculated using ^{14}C counts (disintegration per minute; dpm) of 3 light-bottles (triplicate sample). The dark bottle dpm was subtracted from each light-bottle dpm before calculating the mean±SE.

Fig.1 Location map showing the BOBPS sampling stations along central (88°E) and western Bay of Bengal during fall (14 September -12 October, 2002) and spring (12 April - 7 May, 2003) intermonsoons overlying the annual mean surface salinity distribution (Levitus et al., 1994). Dark circles indicate 1-degree CTD stations while hollow circles are the biological stations for *in-situ* incubation for primary production. Rivers Ganges-Brahmaputra, Godavari, Krishna, Cauvery and Irrawady are also shown. Depth contours are in meters.

Fig.2 Vertical section of (a) temperature ($^{\circ}\text{C}$), (b) salinity, and (c) sigma-t (kg/m^3) along the central Bay of Bengal (88°E) during fall intermonsoon 2002. Filled inverted triangles (\blacktriangledown) indicate the location of CTD stations. Note the change in contour interval <32 in (b).

Fig.3 Vertical section of (a) temperature ($^{\circ}\text{C}$), (b) salinity, and (c) sigma-t (kg/m^3) along the western boundary of the Bay during fall intermonsoon 2002. Filled inverted triangles (\blacktriangledown) indicate the location of CTD stations. Note the change in contour interval <32 in (b).

Fig.4 Vertical section of geostrophic velocity (cm/s) w.r.t. 1000 m along (a) central and (b) western boundary of the Bay of Bengal during fall intermonsoon 2002. Shading indicates westward flow while the flow in the rest of the region is eastward.

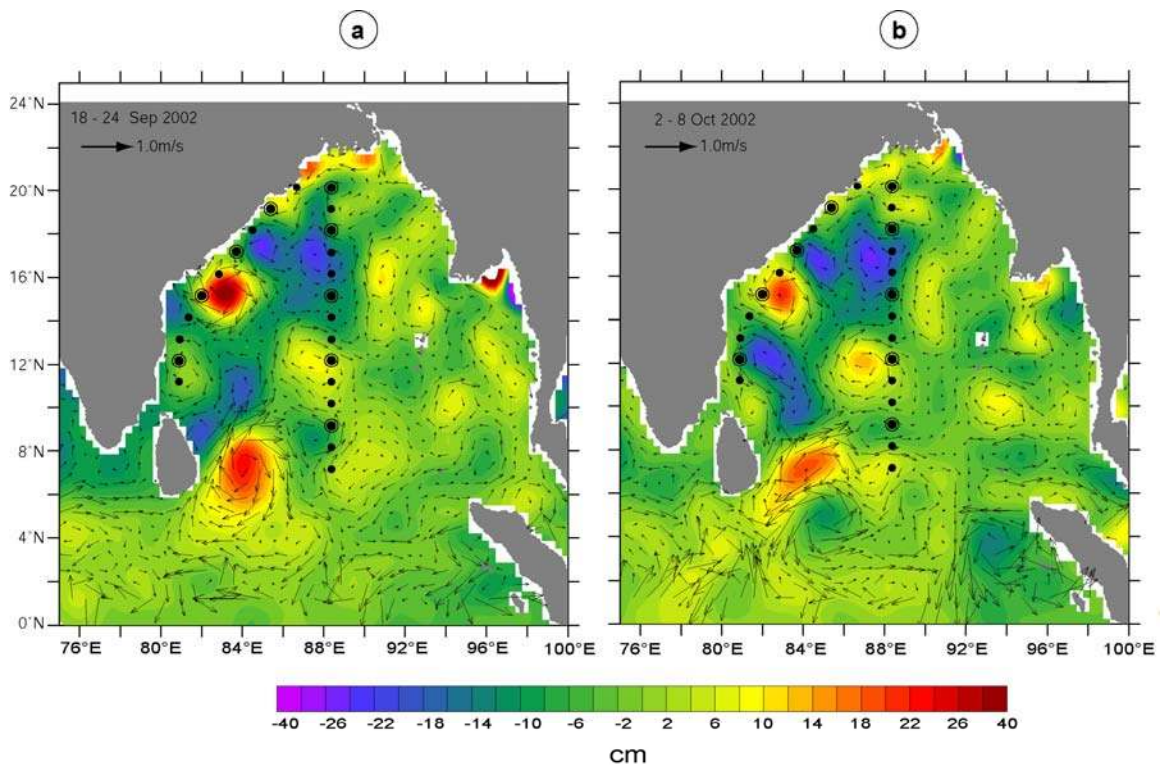

Fig.5 7-day snapshot of Topex/Poseidon ERS 1/2 merged sea-level anomalies overlaid with geostrophic velocities during (a) 18-24 September 2002 and (b) 2-8 October 2002 which is close to the period of CTD measurements along central (a) and western boundary (b) of the Bay of Bengal. Dark circles indicate CTD stations while open circles indicates the biological stations.

Fig.6 Vertical section of (left) nitrate ($\mu\text{mol L}^{-1}$) (a,c) and (right) silicate ($\mu\text{mol L}^{-1}$) (b,d) along (top) the central Bay of Bengal (88°E) (a,b) and (bottom) the western boundary (c,d) during fall intermonsoon 2002. Zero (0) indicates concentrations below detection level. Note the change in contour interval of dashed line which is $0.5 \mu\text{mol L}^{-1}$. Dark circles indicate sample locations.

Fig.7 Vertical distribution of chlorophyll *a* (mg/m^3) along (left) the central Bay of Bengal (88°E) (a,c) and (right) the western boundary (b,d) during (top) fall intermonsoon 2002 (a,b) and (bottom) spring intermonsoon 2003 (c,d). Dark circles indicate sample locations. Note that shading is removed for chlorophyll *a* concentration $< 0.2 \text{ mg}/\text{m}^3$ in (a,b) and for concentrations $> 0.4 \text{ mg}/\text{m}^3$ and $< 0.2 \text{ mg}/\text{m}^3$ in (c,d).

Fig.8 Vertical section of (a) temperature ($^{\circ}\text{C}$), (b) salinity, and (c) sigma- t (kg/m^3) along the central Bay of Bengal (88°E) during spring intermonsoon 2003. Filled inverted triangles (\blacktriangledown) on the top indicate the locations of CTD stations.

Fig.9 Vertical section of (a) temperature ($^{\circ}\text{C}$), (b) salinity, and (c) $\sigma\text{-}t$ (kg/m^3) along the western boundary of the Bay of Bengal during spring intermonsoon 2003. Filled inverted triangles (\blacktriangledown) on the top indicate the locations of CTD stations.

Fig.10 Vertical section of geostrophic velocity (cm/s) w.r.t. 1000 m along (a) central (b) western boundary of the Bay of Bengal during spring intermonsoon 2003. Shading indicates westward flow, while the flow in the rest of the region is eastward.

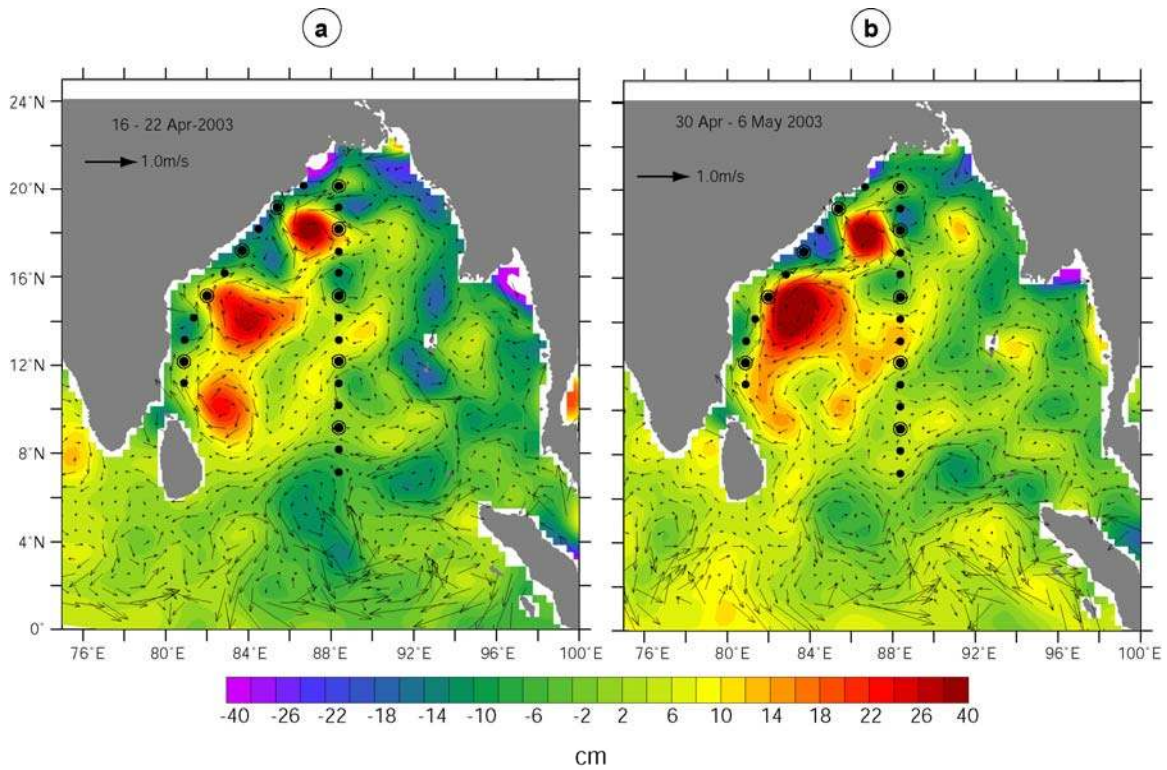

Fig.11 7-day snapshot of Topex/Poseidon ERS 1/2 merged sea-level anomalies overlaid with geostrophic velocities during (a) 16-22 April 2003 and (b) 30 April-6 May 2003 which is close to the period of CTD measurements along central (a) and western boundary (b) of the Bay of Bengal. Dark circles indicate CTD stations while open circles indicates the biological stations.

Fig.12 Vertical section of (left) nitrate ($\mu\text{mol L}^{-1}$) (a,c) and (right) silicate ($\mu\text{mol L}^{-1}$) (b,d) along (top) the central Bay of Bengal (88°E) (a,b) and (bottom) the western boundary (c,d) during spring Intermonsoon 2003. Zero (0) indicates concentration below detection level. Note the change in contour interval of dashed line, which is 0.5 $\mu\text{mol L}^{-1}$. Dark circles indicate sample location.

Fig. 13 Profiles of upper ocean static stability parameter (E, m^{-1}) at (a) $18^\circ\text{N}, 84.5^\circ\text{E}$ and $14^\circ\text{N}, 88^\circ\text{E}$ during fall intermonsoon 2002 and (b) $19^\circ\text{N}, 88^\circ\text{E}$ and $14^\circ\text{N}, 81^\circ\text{E}$ during spring intermonsoon 2003.

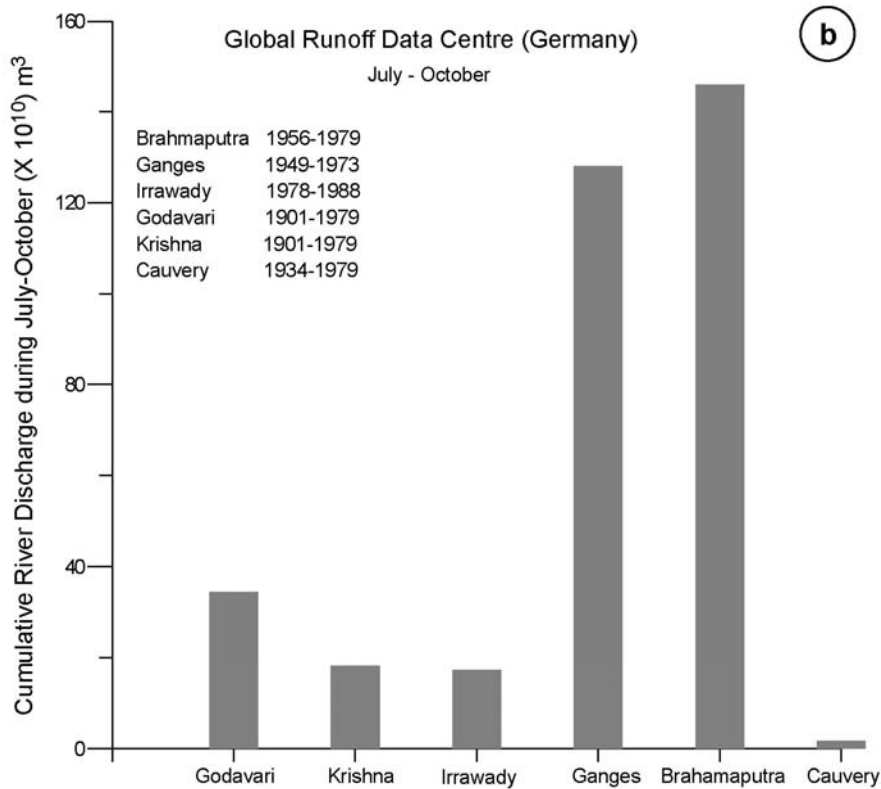

Fig. 14 Climatology of (a) monthly mean river discharge (m^3/s) and (b) cumulative discharge (m^3) during July to October of rivers Ganges, Brahmaputra, Irrawady, Godavari, Krishna and Cauvery. The river discharge data was obtained from Global Runoff Data Center, Germany (<http://grdc.bafg.de/servlet/is/2781/>).
