We study the effect of interactions on 2D fermionic symmetry-protected topological (SPT) phases using the recently proposed braiding statistics approach. We focus on a simple class of examples: superconductors with a Z_2 Ising symmetry. Although these systems are classified by \mathbb{Z} in the noninteracting limit, our results suggest that the classification collapses to \mathbb{Z}_8 in the presence of interactions – consistent with previous work that analyzed the stability of the edge. Specifically, we show that there are at least 8 different types of Ising superconductors that cannot be adiabatically connected to one another, even in the presence of strong interactions. In addition, we prove that each of the 7 nontrivial superconductors have protected edge modes.

Introduction.— Recently it has become apparent that generalizations of topological insulators[1–6] known as “symmetry-protected topological (SPT) phases”[7–15] can be realized in large classes of interacting boson and fermion systems. Loosely speaking, SPT phases are characterized by two properties. First, they support robust gapless boundary modes which are protected by certain symmetries. Second, SPT phases can be adiabatically connected to a “trivial state” (i.e., an atomic insulator or product state) if the relevant symmetries are broken. While significant progress has been made in understanding SPT phases in 1D systems, [8, 9, 12–16] less is known about the higher dimensional case. Several approaches have been developed to understand these higher dimensional systems. One approach, which applies to bosonic SPT phases in general spatial dimension, is the cohomology classification scheme of Ref. [11, 17]. Another approach, which applies to bosonic or fermionic 2D SPT phases with chiral boson edge modes, is to study the edge theories of these systems using the K -matrix formalism[18–20].

In this paper, we discuss a third approach which was introduced in Ref. 21 and applies to 2D SPT phases with unitary symmetry groups. The key idea behind this method is to study SPT phases by “gauging” their symmetries – i.e. coupling them to an appropriate gauge field, thereby transforming their global symmetries into gauge symmetries. One can then probe the structure of the original SPT phases by constructing the excitations of the gauged systems and computing their quasiparticle braiding statistics. This approach has several nice features. First, it provides a simple way to distinguish different SPT phases: if two gauged systems have different quasiparticle statistics then it is clear that the corresponding “ungauged” systems cannot be adiabatically connected without breaking the symmetry. Second, it gives insight into the stability of the edge: as shown in Ref. 21, the quasiparticle braiding statistics of the

gauged system can be used to prove the existence of protected edge modes.

While Ref. 21 focused on bosonic SPT phases, here we explore the fermionic case – a problem of particular interest because the classification of interacting fermionic SPT phases is not understood beyond 1D (although an interesting attempt was made in Ref. 22). We focus on a simple class of examples: 2D superconductors with a Z_2 Ising symmetry. It was previously conjectured[23–25] that while these systems are classified by an integer invariant \mathbb{Z} in the noninteracting limit, the classification collapses to \mathbb{Z}_8 when interactions are included. This claim was supported by an analysis of edge instabilities. Here we obtain further evidence supporting this conjecture. First, we show that there are at least 8 different types of Ising superconductors that cannot be adiabatically connected to one another, even in the presence of strong interactions. Second, we prove that each of the 7 nontrivial superconductors have protected edge modes.

Pseudospin notation.— We begin with some notation. Consider a general fermion system with an on-site, unitary Z_2 symmetry S . Without loss of generality, we can assume that the Hamiltonian is built out of fermion operators that have a definite parity under S . [26] We will label the operators that are even under S with a pseudospin index \uparrow and operators that are odd under S with an index \downarrow . In this notation, the system is composed out of two species of fermions, c_\uparrow and c_\downarrow , where

$$S c_\uparrow S^{-1} = c_\uparrow; \quad S c_\downarrow S^{-1} = -c_\downarrow \quad (1)$$

In addition to the above Z_2 symmetry, locality dictates that the system must also conserve fermion parity P_f , defined by

$$P_f c_\uparrow P_f^{-1} = -c_\uparrow; \quad P_f c_\downarrow P_f^{-1} = -c_\downarrow \quad (2)$$

Putting these two constraints together, we can see that the pseudospin- \uparrow and \downarrow fermions are *separately* conserved modulo 2.

The noninteracting limit.— We next review the classification of *noninteracting* fermion SPT phases with Z_2 Ising symmetry. The key observation is that quadratic pseudospin mixing terms, e.g. $c_{\uparrow}^{\dagger}c_{\downarrow}$, are prohibited by the Z_2 symmetry. Therefore the c_{\uparrow} and c_{\downarrow} fermions are completely decoupled in the non-interacting limit. Applying the known integer classification of 2D topological superconductors[27, 28], it follows that the different free fermion phases are classified by a pair of integers $(\nu^{\uparrow}, \nu^{\downarrow})$. Here, $(\nu^{\uparrow}, \nu^{\downarrow}) \in \mathbb{Z}^2$ corresponds to a phase where the pseudospin- \uparrow and pseudospin- \downarrow fermions form two decoupled topological superconductors with ν^{\uparrow} and ν^{\downarrow} chiral Majorana edge modes, respectively. (The sign of $\nu^{\uparrow}, \nu^{\downarrow}$ indicates the chirality of the edge mode – left or right moving).

In this paper, we only consider a *subset* of the above phases – namely those satisfying $\nu^{\uparrow} = -\nu^{\downarrow}$. The reason for this restriction is that our definition for SPT phases requires that they be adiabatically connected to a trivial band insulator if the symmetry is broken, and only phases with $\nu^{\uparrow} = -\nu^{\downarrow}$ obey this condition. Hence, according to our definition, the noninteracting SPT phases are classified by a single integer $\nu = \nu^{\uparrow} = -\nu^{\downarrow}$.

The effect of interactions.— While the Z_2 symmetry requires that the pseudospin \uparrow and \downarrow fermions decouple from one another in the non-interacting limit, interspecies coupling is allowed once we add interactions into the system. (For example, the four fermion term $c_{i\uparrow}^{\dagger}c_{j\uparrow}^{\dagger}c_{j\downarrow}c_{i\downarrow}$ is Z_2 symmetric, but mixes the two species). Thus, we might expect that the \mathbb{Z} classification will collapse once we include interactions: i.e. it may be possible to adiabatically connect phases with different values of ν . The question we will now investigate is: how many distinct phases survive in the presence of interactions?

For concreteness, we focus our analysis on a free fermion Hamiltonian with nearest neighbor (NN) hopping and pairing terms:

$$H^{\nu} = \sum_{\lambda=1}^{\nu} \sum_{\sigma} \sum_{\langle ij \rangle} t_{ij\sigma} c_{i\sigma;\lambda}^{\dagger} c_{j\sigma;\lambda} + h.c. \\ + \sum_{\lambda=1}^{\nu} \sum_{\sigma} \sum_{\langle ij \rangle} t_{ij\sigma} \Delta_{ij\sigma} c_{i\sigma;\lambda}^{\dagger} c_{j\sigma;\lambda}^{\dagger} + h.c. \quad (3)$$

Here i runs over lattice sites, while $\lambda = 1, \dots, \nu$ describes different orbital states on each lattice site. We choose the pairing term $\Delta_{ij;\uparrow(\downarrow)}$ so as to describe a $p+ip$ ($p-ip$) superconductor, with an edge containing a single right (left) moving chiral Majorana mode. Our task is to determine which H^{ν} describe distinct phases, and which can be adiabatically connected to one another. Our strategy for answering this question is to couple the pseudospin \uparrow and \downarrow fermions to two independent Z_2 gauge fields, $(Z_2^{\uparrow} \times Z_2^{\downarrow})$ and then study the braiding statistics of the Z_2 flux excitations in the gauged model. We will show that some values of ν exhibit different braiding statistics

and therefore must represent distinct phases.

The gauged model that we will analyze can be formally written as

$$H^{\text{gauge}} = \sum_{\lambda=1}^{\nu} \sum_{\sigma} \sum_{\langle ij \rangle} t_{ij\sigma} c_{i\sigma;\lambda}^{\dagger} \tau_{ij\sigma}^z c_{j\sigma;\lambda} + h.c. \\ + \sum_{\lambda=1}^{\nu} \sum_{\sigma} \sum_{\langle ij \rangle} \Delta_{ij\sigma} c_{i\sigma;\lambda}^{\dagger} \tau_{ij\sigma}^z c_{j\sigma;\lambda}^{\dagger} + h.c. - H_{\sigma}^{\text{flux}} \quad (4)$$

where $\tau_{ij\sigma}^z$ is the Z_2 gauge field strength associated with pseudospin σ fermions and where $H_{\sigma}^{\text{flux}} = \sum_{\langle ijkl \rangle} \tau_{ij\sigma}^z \tau_{jk\sigma}^z \tau_{kl\sigma}^z \tau_{li\sigma}^z$ is a flux energy term that gives an energy cost to flux excitations of the gauge fields. (H_{σ}^{flux} is the analogue of the \mathbf{B}^2 term in Maxwell electromagnetic dynamics). The Hamiltonian H^{gauge} is defined in a Hilbert space consisting of gauge invariant states – that is, all states satisfying the constraint $\prod_{j \in NN(i)} \tau_{ij\sigma}^x = (-)^{\sum_{\lambda} n_{i\sigma;\lambda}}$. This constraint can be thought of as a Z_2 analogue of Gauss' law, $\nabla \cdot \mathbf{E} = \rho$.

The next step is to compare the quasiparticle braiding statistics of the gauged system Eq. (4) for different values of ν . To this end, it is useful to first think about a simpler system with only one pseudospin component and ν chiral edge modes. The quasiparticle braiding statistics of such a chiral superconductor were worked out by Kitaev in Ref. 29. That calculation showed that the quasiparticle braiding statistics of the superconductor depends on the number of chiral edge modes ν , modulo 16. For example, if ν is even, the Z_2 gauge fluxes (i.e. superconducting vortices) are Abelian anyons with an exchange phase factor $e^{\frac{\pi}{8}i\nu}$. If ν is odd, the Z_2 -fluxes are non-Abelian anyons with an exchange phase $(-)^{\frac{(\nu^2-1)}{8}} e^{\frac{\pi}{8}i\nu}$ when the two non-Abelian anyons are in the vacuum fusion channel.

Now, let us consider the full system, which consists of a pseudospin \uparrow component with ν right moving edge modes and a pseudospin \downarrow component with ν left moving edge modes. Naively, one might guess that the braiding statistics of this system also depends on ν modulo 16, since it is made up of two independent chiral superconductors. However, this guess is incorrect: the braiding statistics of the “doubled” system only depends on ν modulo 8. To see this, we need to show that the braiding statistics for $\nu = 0, 1, \dots, 7$ are all different while the $\nu = 0$ case is equivalent to the $\nu = 8$ case. One way to establish the first statement is to compute the exchange phases of all the different types of Z_2^{\downarrow} (or Z_2^{\uparrow}) flux excitations. Here, a Z_2^{\downarrow} flux is defined to be any quasiparticle excitation that acquires a phase of -1 when braided around a pseudospin- \downarrow fermion and acquires no phase when braided around a pseudospin- \uparrow fermion. Using the results of Ref. 29, it is easy to see that for even ν there are 4 types of Z_2^{\downarrow} fluxes with exchange statistics $\pm e^{\frac{\pi}{8}i\nu}$, while for odd ν there are 2 types of Z_2^{\downarrow} fluxes with exchange statistics $\pm e^{-\frac{\pi}{8}i\nu}$. (In the latter case, we assume

the fluxes are in the vacuum fusion channel). In particular, we see that the exchange statistics of the Z_2 fluxes are different for each of the eight possibilities $\nu = 0, 1, \dots, 7$.

On the other hand, to see that $\nu = 0$ and $\nu = 8$ have the same braiding statistics, we need to construct an explicit isomorphism between the quasiparticles in the two systems. To this end, we consult Ref. 29 and note that for both $\nu = 0, 8$ the gauge theory Eq.(4) has four quasiparticles $1, e_\sigma, m_\sigma, \varepsilon_\sigma$ for each pseudospin direction, $\sigma = \uparrow, \downarrow$. Including all possible composites of pseudospin \uparrow and \downarrow excitations, there are $4 \cdot 4 = 16$ quasiparticles

$\nu = 0$	1	e_\uparrow	m_\uparrow	e_\downarrow	m_\downarrow	$e_\uparrow e_\downarrow$	$m_\uparrow m_\downarrow$	$\varepsilon_\uparrow \varepsilon_\downarrow$	$e_\uparrow m_\downarrow$	$m_\uparrow e_\downarrow$	ε_\uparrow	ε_\downarrow	$e_\uparrow \varepsilon_\downarrow$	$\varepsilon_\uparrow e_\downarrow$	$m_\uparrow \varepsilon_\downarrow$	$\varepsilon_\uparrow m_\downarrow$
$\nu = 8$	1	$e_\uparrow \varepsilon_\downarrow$	$m_\uparrow \varepsilon_\downarrow$	$\varepsilon_\uparrow e_\downarrow$	$\varepsilon_\uparrow m_\downarrow$	$m_\uparrow m_\downarrow$	$e_\uparrow e_\downarrow$	$\varepsilon_\uparrow \varepsilon_\downarrow$	$m_\uparrow e_\downarrow$	$e_\uparrow m_\downarrow$	ε_\uparrow	ε_\downarrow	e_\uparrow	e_\downarrow	m_\uparrow	m_\downarrow

Here, the table is organized so that the first ten quasiparticles are all bosons while the other six are all fermions. We can see that the correspondence not only preserves braiding statistics and fusion rules, but also preserves the $Z_2^\uparrow \times Z_2^\downarrow$ gauge structure, mapping the \downarrow fermions (ε_\downarrow) of one system onto the corresponding fermions in the other system, and likewise mapping the Z_2^\downarrow fluxes ($e_\downarrow, m_\downarrow, \varepsilon_\uparrow e_\downarrow, \varepsilon_\uparrow m_\downarrow$) of one system onto the Z_2^\downarrow fluxes of the other system (and similarly for \uparrow).

Two conclusions follow from the above analysis. First, we conclude that the Hamiltonians H^ν with $\nu = 0, 1, \dots, 7$ cannot be adiabatically connected to one another without breaking the Z_2 symmetry. Indeed, if there existed a gapped path connecting these Hamiltonians, then there would have to be a corresponding path connecting the gauged systems H^{gauge} – an impossibility, since we have seen that they have different quasiparticle braiding statistics. The second conclusion is that it is at least *plausible* that H^0 and H^8 can be adiabatically connected to one another in the presence of interactions, since the corresponding $Z_2^\uparrow \times Z_2^\downarrow$ gauge theories share the same statistics and gauge structure.

The instability of $\nu = 8$ edge. – In this section, we give additional evidence that the $\nu = 8$ system is a trivial SPT phase: we show that the $\nu = 8$ edge can be gapped out by appropriate interactions, without breaking the Z_2 symmetry (explicitly or spontaneously). We note that a similar result was obtained previously in Refs. 23–25.

Our approach is based on bosonization. We note that the edge of the $\nu = 8$ free fermion Hamiltonian Eq.(3) contains 8 pseudospin- \uparrow Majorana modes and 8 pseudospin- \downarrow Majorana modes moving in opposite directions. Pairing up the Majorana modes to form complex fermions, we can equivalently describe the edge using 4 pseudospin- \uparrow and 4 pseudospin- \downarrow complex fermions. We then bosonize these fermions, using 4 boson modes Φ_1, \dots, Φ_4 for the pseudospin- \uparrow fermions, and 4 boson

all together. We can think of the ε_σ as the constituent fermions while e_σ and m_σ are different types of Z_2^σ gauge fluxes which differ from one another by the addition of a fermion: $e_\sigma = m_\sigma \cdot \varepsilon_\sigma$. Using the results of Ref. 29, we can see that for both $\nu = 0, 8$, the three particles $\varepsilon_\sigma, e_\sigma, m_\sigma$ acquire a phase of -1 when braided around each other. The only difference is that e_σ and m_σ are *bosons* for the case $\nu = 0$ while they are *fermions* for the case $\nu = 8$. With these properties in mind, one can easily see that the following map gives an isomorphism between the quasiparticles in the two systems:

modes Φ_5, \dots, Φ_8 for the pseudospin- \downarrow fermions. The edge is then described by the chiral boson Lagrangian

$$\mathcal{L}_{\text{edge}} = \frac{1}{4\pi} (K_{IJ} \partial_x \Phi_I \partial_x \Phi_J - V_{IJ} \partial_x \Phi_I \partial_x \Phi_J) \quad (5)$$

where $K = \text{diag}(1, 1, 1, 1, -1, -1, -1, -1)$, and V_{IJ} is the velocity matrix. Here we use a normalization convention where the fermion creation operators are of the form $e^{i\Phi_k}$, $k = 1, \dots, 8$. In this language, the symmetry transformation is given by $S^{-1} \Phi S = \Phi + \pi K^{-1} \chi$ where $\chi^T = (0, 0, 0, 0, 1, 1, 1, 1)$.

We now construct interaction terms that gap out the edge without breaking the Z_2 symmetry (either explicitly or spontaneously). We consider backscattering terms of the form $U(\Lambda) = U(x) \cos(\Lambda^T K \Phi - \alpha(x))$. In order for $U(\Lambda)$ to be invariant under S , we require that

$$\Lambda^T \chi \equiv 0 \pmod{2} \quad (6)$$

In order to gap out the edge, we need to add 4 backscattering terms $\sum_i U(\Lambda_i)$: each term can gap out a pair of counter-propagating edge modes. Such terms can gap out the edge as long as the $\{\Lambda_i\}$ vectors satisfy [30]

$$\Lambda_i^T K \Lambda_j = 0 \quad (7)$$

for all i, j . This “null-vector” condition guarantees that we can make a suitable change of variables mapping L_{edge} onto a system of 4 decoupled Luttinger liquids with 4 backscattering terms. It is then easy to see that the backscattering terms will gap out the corresponding Luttinger liquids (at least for large U [31]).

We now claim that the following $\{\Lambda_i\}$ will do the job:

$$\begin{aligned} \Lambda_1^T &= (1, -1, 0, 0, 1, -1, 0, 0); \\ \Lambda_2^T &= (1, 0, -1, 0, 1, 0, -1, 0); \\ \Lambda_3^T &= (1, 0, 0, -1, 1, 0, 0, -1); \\ \Lambda_4^T &= (1, 0, 1, 0, 0, -1, 0, -1). \end{aligned} \quad (8)$$

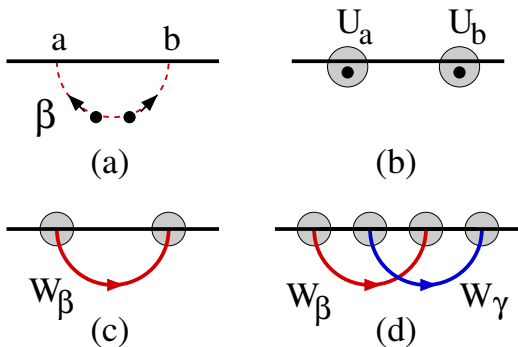

FIG. 1. (a) We consider a thought experiment in which we create two Z_2^\perp fluxes in the bulk and then move them along a path β to points a, b at the edge. (b) We argue that the two fluxes can be annihilated at the boundary by applying local operators U_a, U_b . (c) We define \mathbb{W}_β to be an operator which describes a process in which the fluxes are created in the bulk, brought to the edge, and then annihilated. (d) To obtain a contradiction, we consider two paths β, γ that intersect one another, and we investigate the commutation algebra of the corresponding operators $\mathbb{W}_\beta, \mathbb{W}_\gamma$.

Indeed, it is easy to check that these $\{\Lambda_i\}$ obey the null vector criterion (7), as well as the symmetry condition (6). To complete the argument, we need to check that the perturbation corresponding to $\{\Lambda_i\}$ does not spontaneously break the Z_2 symmetry. However, as explained in Ref. [18], we can rule out the possibility of spontaneous symmetry breaking if the $\binom{8}{4}$ 4×4 minors of the 8×4 matrix with columns $\Lambda_1, \dots, \Lambda_4$ have no common factor. This property of $\Lambda_1, \dots, \Lambda_4$ can be verified by direct calculation.

Protected edge states for $\nu \neq 0 \pmod{8}$. — On the other hand, we now show that the edge of H^ν is *protected* if $\nu \neq 0 \pmod{8}$. To state our result more precisely, let us consider a disk geometry and a Hamiltonian of the form $H = H_{\text{bulk}} + H_{\text{edge}}$, where $H_{\text{bulk}} = H^\nu$, and H_{edge} is an arbitrary interacting Hamiltonian acting on fermions near the edge. In this setup, what we will show is that the ground state $|0\rangle$ cannot be both Z_2 symmetric and “short-range entangled.” [32] We believe that this result rules out the possibility of a Z_2 symmetric, gapped edge, and in this sense proves that the gapless edge excitations are protected.

As in Ref. [21], our argument is a proof by contradiction: we assume that $|0\rangle$ is short-range entangled and Z_2 symmetric and we show that these assumptions lead to a contradiction. The first step is to couple the pseudospin- \uparrow and pseudospin- \downarrow fermions to two independent Z_2 gauge fields as in (4). We then imagine creating a pair of Z_2^\perp (or Z_2^\uparrow) fluxes in the bulk. After creating the Z_2^\perp fluxes, we separate them and move them along some path β to points a, b at the boundary (Fig. 1a). Formally, this process can be implemented by applying a unitary (string-like) operator W_β to $|0\rangle$.

Next, we claim that the Z_2^\perp fluxes can be annihilated at the boundary if we apply appropriate local operators. That is, there exist local operators U_a, U_b , acting near points a, b such that $U_a U_b W_\beta |0\rangle = |0\rangle$ (Fig. 1b). Establishing this claim is the hardest step in the argument, and here we merely outline its proof.[33] The basic point is that when we bring the Z_2^\perp fluxes to the boundary, we effectively create two Z_2^\perp domain walls at a and b . Given that the ground state is Z_2^\perp symmetric, these domain walls are *local* excitations: they only affect expectation values in the neighborhood of a and b . It then follows that these domain walls can be annihilated by local operators since local excitations of a short-range entangled state can always be annihilated locally.

In the third step, we consider a creation and annihilation process in which two Z_2^\perp fluxes are created in the bulk, moved to the boundary and then annihilated. Let \mathbb{W}_β be a unitary operator describing this process (Fig. 1c). (Formally, $\mathbb{W}_\beta = U_a U_b W_\beta$). Now, consider a second path γ with the geometry shown in Fig. 1d and define \mathbb{W}_γ in the same way. By construction, we have $\mathbb{W}_\beta |0\rangle = \mathbb{W}_\gamma |0\rangle = |0\rangle$. Hence

$$\mathbb{W}_\beta \mathbb{W}_\gamma |0\rangle = \mathbb{W}_\gamma \mathbb{W}_\beta |0\rangle = |0\rangle \quad (9)$$

In the final step, we show that (9) leads to a contradiction if $\nu \neq 0 \pmod{8}$. It is useful to consider separately the case where ν is even and ν is odd. First, suppose ν is even. In this case, the Z_2^\perp fluxes are abelian anyons and it follows from a general analysis of abelian quasiparticle statistics (see e.g. Refs. 21 and 34) that

$$\mathbb{W}_\beta \mathbb{W}_\gamma |0\rangle = e^{2i\theta} \mathbb{W}_\gamma \mathbb{W}_\beta |0\rangle \quad (10)$$

where $e^{i\theta}$ is the exchange phase of the Z_2^\perp fluxes. According to the braiding statistics calculation outlined above, the four types of Z_2^\perp fluxes have exchange statistics $\theta = \pm \frac{\pi\nu}{8}$. Hence if $\nu \neq 0 \pmod{8}$ then $e^{2i\theta} \neq 1$ for any of the four types of fluxes and equations (9), (10) are in contradiction.

Now suppose ν is odd. In this case, the Z_2^\perp fluxes are non-abelian anyons, so the above braiding statistics analysis is more complicated. However, we can avoid these complications using an alternative argument. We note that if ν is odd then each Z_2^\perp flux carries an *unpaired Majorana mode*. Thus, the state $W_\beta |0\rangle$ has unpaired Majorana modes localized near points a and b . But then it is clearly impossible for $U_a U_b W_\beta |0\rangle = |0\rangle$ since unpaired Majorana modes cannot be destroyed by any local operation. Once again, we encounter a contradiction, implying that our assumption is false and $|0\rangle$ cannot be both Z_2 symmetric and short-range entangled.

Conclusion. — In this paper we have studied SPT phases in interacting fermion systems using a braiding statistics approach. As a simple example, we considered superconductors with a Z_2 (Ising) symmetry. Although in the noninteracting case these Ising superconductors

are classified by an integer invariant $\nu \in \mathbb{Z}$, we give evidence that the classification collapses to \mathbb{Z}_8 in the presence of interactions. We also give a general argument proving that the edge excitations are protected when $\nu \neq 0 \pmod{8}$ and unprotected when $\nu = 0 \pmod{8}$.

- [31] Note that it is not important to us whether these terms are relevant or irrelevant in the renormalization group sense. The reason is that we are not interested in the *perturbative* stability of the edge, but rather whether it is stable to arbitrary perturbations that do not break the symmetry, explicitly or spontaneously.
- [32] Here, a fermionic state is said to be “short-range entangled” if it can be transformed into an atomic insulator by a local unitary transformation – a unitary operator generated from the time evolution of a local Hamiltonian over a finite time t .
