

non-endocrine systems (TSH, perhaps PRL and gonadotropins, pancreatic and gastrointestinal hormones, growth factors, gastrointestinal exocrine secretions, etc.) (14, 15) that cause several effects, not necessarily untoward, needing further investigation.

This multicenter octreotide study had the following aims: to ascertain the percentage of patients in whom octreotide is able to reduce serum GH levels to less than 2.5 µg/l, clarifying the influence of previous therapy and other possible prognostic factors on drug responsiveness; to evaluate the octreotide effects on GH abnormal responses; and to study octreotide effects on PRL secretion and thyroid function.

With respect to previous trials, particular attention was paid to the study of patients not previously submitted to pituitary radiotherapy, because irradiation may affect GH secretion and decrease tumoral mass for as long as 10 or more years. In addition, because diabetes mellitus, hypertension and dyslipidemia are all more frequent in acromegalic patients than in the general population and can worsen morbidity and mortality, the effects of octreotide therapy on these conditions were investigated.

Patients and methods

A prospective, open label study was performed in 10 Italian centers after having been approved by the local ethic committees. All the patients participating in the study gave their informed written consent.

Patients

Sixty-eight acromegalic patients (43 women and 25 men) 19–70 years old (mean \pm SD – 45.9 \pm 12 years) were included in the study. All had clinically active acromegaly documented by serum GH levels not suppressible below 2 µg/l after the oral glucose tolerance test (OGTT) and elevated insulin like growth factor I (IGF-I) levels.

Twenty patients had not been treated previously, 10 had received only medical treatment with dopaminergic drugs and 38 had been submitted to unsuccessful neurosurgical removal of the GH-secreting adenoma. Ten patients were given postoperative radiotherapy (40–60 Gy) followed by bromocriptine administration 3 months to 15 years (median: 3 years and 6 months) before entering the study, while other 16 patients postoperatively received bromocriptine therapy that was discontinued at least 1 month prior to the start of the study.

Typical signs of acromegaly were present in all patients. With regard to concomitant endocrine diseases, 16 patients (24%) had diabetes mellitus, one had (1.5%) hyperthyroidism, four (6%) had hypothyroidism, two (3%) had adrenal failure and 51 (75%) had goiter. Visual field examination was abnormal in 16 (23%) of the patients. All patients underwent neuroradiological

imaging of the hypothalamic–pituitary region: 48 by computed tomography (CT) scan, nine by magnetic resonance (MR) and 11 by both CT scan and MR. Forty-one examinations (60%) were indicative of the presence of a pituitary adenoma (14 microadenomas and 27 macroadenomas). Among the 27 patients with no radiological evidence of pituitary tumor, 20 were previously operated on and three showed an empty sella. It is likely that in the four remaining patients the tumor was too small to be detected.

Protocol

Octreotide was administered subcutaneously at a dose of 100 µg t.i.d. for 1 year. Compliance was monitored by comparing the number of vials dispensed with those returned. Doses could be adjusted to reduce side effects or to improve hormonal responses: owing to gastrointestinal side effects, the daily doses were reduced to 100–200 µg in six patients temporarily (2 weeks), in one case during the whole study period and in four after the 4th month of therapy. A temporary increase of the dose and frequency of injections to 100 µg q.i.d. was performed in one case from the 5th to the 7th month for relieving severe headache. Because of insufficient hormonal response, the dose was increased after the 4th month in 11 patients (to 400 µg in three cases, to 450 µg in four cases and to 600 µg per day in another four cases).

Pretreatment studies included the following tests: an 8-h saline infusion, with a light, standardized meal given at 4 h; a 4-h OGTT (75 g orally); a TRH test (200 µg iv); and a GnRH test (100 µg iv). During octreotide treatment, the patients were studied every 3 months. At 3 and 12 months an 8-h saline infusion, with octreotide injection given at time zero, was performed. The OGTT was repeated after 6 months of therapy and the TRH and GnRH tests were repeated after 9 months. The OGTT, TRH and GnRH tests were administered 2 h after the morning octreotide injection. Blood was drawn: during saline infusion every hour for serum GH measurement and every 30–60 minutes for glucose and insulin assay; after glucose load every 30 min for serum GH, insulin and glucose determinations; during the TRH test at 0, 20, 30, 60, 120 and 180 min for GH, PRL, TSH, free T₃ (fT₃) and free T₄ (fT₄) measurements; and during the GnRH test at 0, 20, 30 and 60 min for GH evaluation. Additionally, serum levels of IGF-I, fT₃, fT₄, and 24-h urine free cortisol were also evaluated. Patients were considered responsive to the TRH and/or GnRH test when a GH increase of at least 50% and higher than 6 µg/l over the basal value was found, according to worldwide accepted criteria (6). In 42 patients a follow-up study was repeated 1 month after octreotide withdrawal.

Magnetic resonance or CT of the hypothalamic–pituitary region with contrast media were done at baseline and after 12 months of treatment. Tumor

Effects of treatment with octreotide in acromegalic patients—
a multicentre study

Treatment of acromegaly is effective in reversing the reduced life-span of patients only when serum growth hormone (GH) concentrations are lowered to less than 2.5 ng/L. Useful treatments achieve this

unable to reverse this long-term poor outlook only in those patients whose serum GH concentrations are reduced to less than $2.5 \mu\text{g/L}$ (2). Usual treatments, such as neuropeptide removal of the adenoma and/or pituitary irradiation, are able to achieve this goal in no more than 50–60% of patients (3–5). According to the main clinical trials, medical treatment with dopamine agonists decreases serum GH levels below $5 \mu\text{g/L}$ in about 20% of patients but below $2.5 \mu\text{g/L}$ only in a minority of cases (6). The somatostatin analog octreotide seems to provide a more effective alternative. In fact, several studies, including some multicenter world-wide trials, have shown serum GH normalization in a wide variety of acromegalic patients (7–13). However, the effects of somatostatin analogs are not limited to GH release but also involve several other endocrine and metabolic actions. For example, they reduce insulin resistance, decrease blood pressure, and improve lipid profile (14).

*The Italian Directorate of Health Study Group comprised the following participants: Bruno Marzio, Institute of Internal Medicine; Giacomo Sartori, University of Milan; Gianni Saccoccia, Department of Endocrinology, University of Padova; Guido Tamburro, Department of Endocrinology, University of Rome; Romano Bazzucchi, Department of Endocrinology, University of Florence; Giacomo Cicchetti, Department of Endocrinology, University of Naples; Gianni Guido, Department of Endocrinology, University of Palermo; Gianni Sciacqua, Department of Endocrinology, University of Genoa; Gianni Vassalli, Department of Endocrinology, University of Pavia; Gianni Zamboni, Department of Endocrinology, University of Parma; Gianni Zamboni, Department of Endocrinology, University of Bologna; Gianni Zamboni, Department of Endocrinology, University of Perugia; Gianni Zamboni, Department of Endocrinology, University of Roma La Sapienza; Gianni Zamboni, Department of Endocrinology, University of Roma Tor Vergata; Gianni Zamboni, Department of Endocrinology, University of Roma Tre.

Women with malignant breast cancer have a reduced life-span and able to reverse this long-term poor outlook only in those patients whose serum GH concentrations are reduced to less than 2.5 ng/L (2). usual treatments, such as neutro-

No statistical differences in GII responsiveness to somatosatin were found between patients submitted to previous treatments or not. In fact, the mean percentage decrease of serum GH levels was 56 ± 23% in operated patients (n = 55) compared to non-operated patients (n = 55) ($P < 0.05$).

No correlation between the GH premenstrual decrease and pre-treatment GH levels was found. However, in the 16 patients who had a fall in serum GH levels to 2.5 μ g/l or less, pre-treatment GH levels were significantly lower than those found in the 17 patients with serum GH levels still higher than 5 μ g/l (12 ± 10 vs 6 ± 9 μ g/l).

Sixty-five patients completed the first 3 months of the study, 64 taking a dose of 300 µg/day. Serum GH levels mean of nine samples taken hourly during saline infusion) decreased from 32.5 ± 54 to 13.2 ± 26 µg/L ($p < 0.001$). Mean serum GH levels below 2.5 µg/L concentrations (67% of total). Mean serum GH levels below 2.5 µg/L were observed in 16 patients (25%), of whom 15 had previously been GH levels below 2.5 µg/L. When excluding previously irradiated cases, 63% of patients decreased serum GH levels by more than 50%, while a reduction to less than 2.5 µg/L was achieved in 24% of patients. One patient that received a dose of 50 µg/day twice a day because of gastrointestinal side effects had only a temporary effect on GH secretion after each injection.

Effects on

All results are expressed as mean \pm sd, unless exact test. All tumor shrinkage were evaluated by Fisher's exact test. The continuity tables (2×2) related to GH levels vs tumor shrinkage were evaluated by Fisher's exact test. The symmetry between pretreatment and the end of the study was tested by McNemar's test of agreement. Symptom scores (more than two measures), symptoms and treatment's test (more than two measures), symptoms and side effects non-parametric statistics within treatment's Wilcoxon's signed rank test (two means comparison) or Kruskal-Wallis' test (more than two means). Arteries and the mean GH and PRL levels were compared under the curves (AUC) using the trapzoidal method. T₃ and PRL, were quantified by measuring the area beneath the curve (GH, glucose, insulin, TSH, TRH-stimulated basal levels of variance. Data with multiple observations for each subject were analyzed by factorial analysis of variance (ANOVA).

Effects on GH and IGF-1 levels after 3 months of

Statistical analyses of pretreatment and end-of-study results were performed only for patients for whom

Statistical analyses

Hormone measurements were carried out by RIA and IRMA methods at each study center (see Appendix). The standards utilized by six of the ten centers were calibrated against the WHO 1st NRP IIGM-NRC 96/217. However, four centers used standards calibrated against NIH RRP 80/505. The equivalence between the two standards is clearly stated by the manufacturers ($1 \text{ ng of } 80/505 = 0.85 \text{ ng of } 96/217$). The laboratory gave a CV below 20% for all the concentrations tested (1.5, 20 and $40 \text{ }\mu\text{g/l}$). Owing to the differences in the absolute values given for IGF-I assays (some reporting some difference in the normal range, no absolute values were given for IGF-I concentrations, in each individual laboratory was referred to).

Hotphone adspssp sfip

Adverse events were evaluated by assessing symptoms and by measuring hematological and biochemical parameters at baseline and at each control, balloon-ladder ultrasoundography was done at baseline and repeated at 6 and 12 months of therapy. Asymptomatic gallstones were not considered a contraindication to the admittance of octreotide; however, two patients were submitted to therapy with bile acids alone who had a history of gallbladder stricture or dilation of the common bile duct. In addition, the two patients with gallbladder stricture had a history of cholangitis and were submitted to therapy with bile acids alone.

Volume was calculated by measuring the three major diameters (a,b,c) and applying the formula $\frac{4}{3}\piabc^2$. Tumor shrinkage was defined as at least 10% volume reduction. Visual field examination was performed at baseline and after 12 months of treatment using either Goldmann's perimeter or computer-assisted static perimetry, depending on the local practice in each study center. The baseline examination was repeated after 12 months. The examination was done in 54 patients at baseline. The examination was repeated after 12 months.

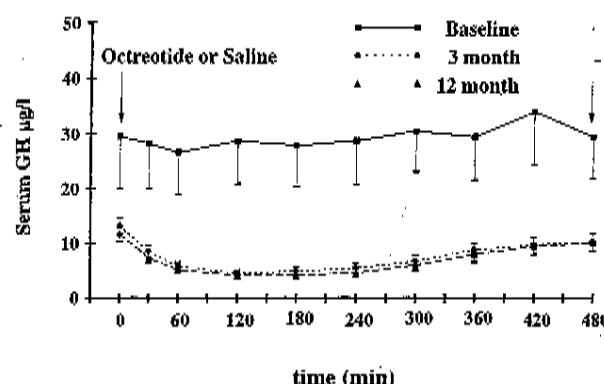

Fig. 1 Mean serum GH levels (\pm SEM) during an 8-h saline control before treatment and during chronic octreotide therapy in 50 acromegalic patients who completed 12 months of treatment. Serum GH concentrations at 3 months of therapy were superimposable to those found at 12 months.

submitted to other forms of therapy reached absolute GH concentrations lower than untreated patients.

After 3 months of therapy the IGF-I levels normalized in about 40% of patients (21/53), a percentage that does not change when considering only non-irradiated patients (19/48). The IGF-I levels normalized in all the patients with mean GH concentrations $\leq 2.5 \mu\text{g/l}$ and in 10 out of 18 patients with serum GH levels between 2.6 and 7.0 $\mu\text{g/l}$. A positive correlation between IGF-I and GH percentage decrease was found ($r = 0.38$, $p < 0.01$).

Effects on GH and IGF-I levels after 12 months of therapy and during the follow-up

Fifty patients completed the study and received octreotide therapy for 12 months. In these patients, mean GII levels were not significantly different from those observed at 3 months (7.0 ± 5.9 vs $7.7 \pm 6.2 \mu\text{g/l}$, respectively) (Fig. 1), with a percentage mean decrease of $58 \pm 33\%$. Mean GH concentrations lower than $2.5 \mu\text{g/l}$ were found in 20% of patients. However, in some patients a further decrease in serum GH levels was seen between the 3rd and the 12th month; in particular, two patients who were unresponsive at the 3rd month showed a 50% decrease in serum GH levels at the 12th month. On the contrary, one patient became completely refractory.

As far as modifications of octreotide doses are concerned, a loss of efficacy was observed in two of the four patients who had a reduced daily dose of octreotide. In none of the nine cases in whom the daily dose was increased (up to 600 $\mu\text{g/day}$) were serum GH levels normalized (9.9 ± 3.3 vs $8.6 \pm 3.5 \mu\text{g/l}$; NS). Another two patients discontinued the drug: one for ineffectiveness and one due to non-compliance.

One month after therapy withdrawal, mean serum GH levels returned to baseline in the majority of patients

while 40% of irradiated patients and 25% of untreated patients maintained reduced GH concentrations (50–85% of pretreatment levels); 14% of untreated patients showed GII concentrations 60–120% higher than baseline.

The mean IGF-I levels measured in 42 patients after 12 months of therapy were not significantly different from those found after 3 months. However, six patients normalized the IGF-I level between the 3rd and the 12th month of therapy, out of a total of 24 (57%) patients with normal IGF-I levels (three dropped out during the same period).

Abnormal GII responses to TRH, GnRH and OGTT

Before starting octreotide treatment 35/65 patients (54%) increased serum GII levels from 22.6 ± 32 to $83.2 \pm 11 \mu\text{g/l}$ after TRH administration and 10/63 (16%) from 15.2 ± 7 to $40.8 \pm 22 \mu\text{g/l}$ after GnRH administration. After 9 months of therapy the abnormal GII responses to TRH and GnRH were reduced from 54% to 24% and from 16% to 12%, respectively. The TRH test became negative in 17 out of 28 retested patients, showing an abnormal GH increase before therapy (Fig. 2). Mean serum GH levels were slightly, although not significantly, lowered in 17 patients in whom the abnormal response disappeared, in comparison to 11 patients in whom the response was maintained (5.1 ± 6 vs $8.8 \pm 6.9 \mu\text{g/l}$; $p = 0.06$). The GnRH test became negative in two out of eight retested patients, although mean GII levels were still elevated. Responsiveness to octreotide evaluated as percentage mean GII decrease after 3 months of therapy, was $58 \pm 27\%$ and $67 \pm 18\%$ in patients who at baseline had shown a paradoxical GH increase after TRH and GnRH, respectively, and $51 \pm 27\%$ and $52 \pm 26\%$, respectively, in patients who did not. These differences were not statistically significant.

In 18 out of 35 patients (51%) GH levels decreased to less than $2 \mu\text{g/l}$ after a glucose load. Fourteen of these patients had reached mean GH levels below $5 \mu\text{g/l}$ during the 3-month evaluation.

Effects on tumor mass

Twenty-six patients with pituitary imaging positive for tumor (17 macroadenomas and nine microadenomas) had a comparative CT or MR study at 12 months. None had received previous pituitary radiotherapy. Thirteen (50%) of these patients showed a reduction of tumor mass: in four cases the image of a microadenoma completely disappeared; in three cases (two macroadenomas and one microadenoma) the tumor shrinkage was greater than 50% and in the remaining patients (three macroadenomas and three microadenomas) the tumor size was reduced by 10–15%. In two cases with a decrease lower than 20% a radiological examination performed 1 month after the withdrawal of octreotide therapy

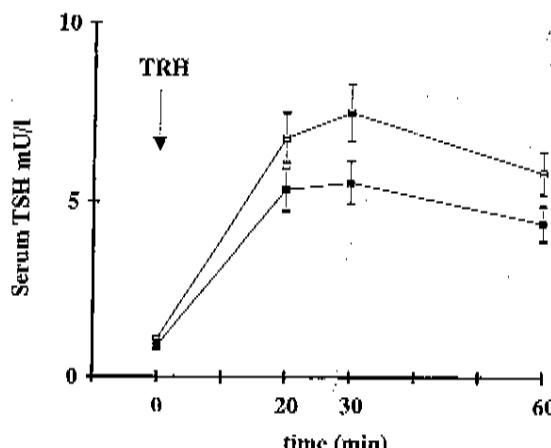

Fig. 4. Thyrotropin response (+ SEM) to TRH before (□) and after 9 months of octreotide therapy (■) in 32 acromegalic patients. A significant reduction was seen during chronic therapy.

TRH-stimulated TSH secretion was seen at 9 months (Fig. 4).

No significant modifications of basal levels of fT_3 and fT_4 , evaluated every 3 months during therapy in 30 patients, were seen. Free T_4 and fT_3 responses to TRH was evaluated only in 14 patients: a small, though not significant, decrease of fT_4 response was found (47.5 ± 14.2 vs $42.8 \pm 11.3 \text{ pmol l}^{-1} \text{ h}^{-1}$).

Thyroid ultrasonography at baseline showed the presence of goiter in 76% of patients: simple in 46% of patients and multinodular in 30% of patients. When reinvestigated after 1.2 months of therapy, six patients (18%) showed a reduction in goiter size while eight patients (25%) showed an increase in goiter size and/or the appearance of new nodules. No correlation between the modifications of thyroid size or morphology and IGF-I/GH levels was found.

Effects on insulin and glucose metabolism in non-diabetic patients

Twenty acromegalic patients without overt diabetes mellitus had hourly determinations of glucose and insulin levels at baseline, 3 and 12 months. While no modifications of fasting morning glucose concentrations were seen (4.88 ± 0.5 , 4.72 ± 0.6 and $4.77 \pm 0.6 \text{ mmol/l}$ respectively, at baseline, 3 and 12 months), a slight increase of both pre-prandial and post-prandial mean glucose levels reaching statistical significance at 3, but not at 12 months, was observed during octreotide therapy (8-h AUC: 44.4 ± 5 , 47 ± 4 and $45.4 \pm 5 \text{ mmol/l}^2 \text{ h}^{-1}$, respectively). The increase in blood glucose concentrations was accompanied by a significant reduction in insulin levels (8-h AUC: 1643 ± 1226 vs 1018 ± 502 vs $975 \pm 466 \text{ pmol l}^{-1} \text{ h}^{-1}$, respectively; baseline vs 3 months, $p < 0.05$; baseline vs 12 months, $p < 0.01$; 3 vs 12 months, NS).

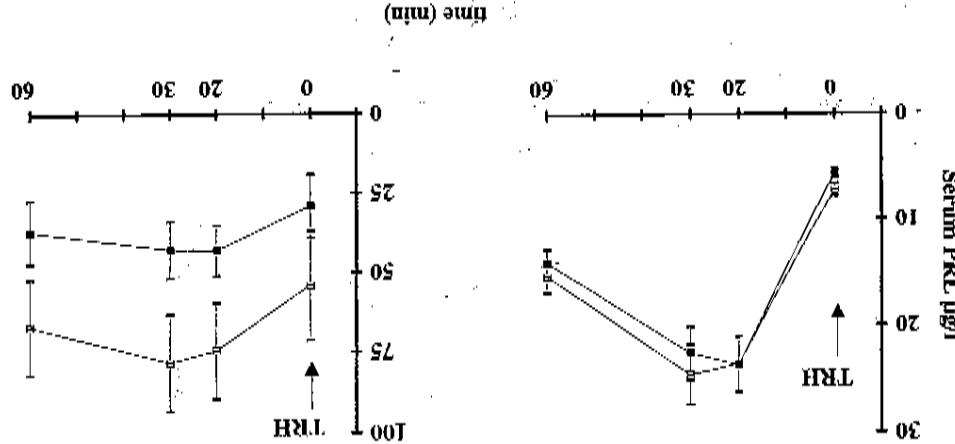

As far as the response to the OGTT is concerned, during treatment both the blood glucose peak at 2 h and the AUC were increased in comparison with the baseline test (glucose peak: 9.8 ± 2.8 vs $6.9 \pm 2.2 \text{ mmol/l}$, $p < 0.01$; AUC: 32.4 ± 6 vs $26 \pm 5.8 \text{ mmol l}^{-1} \text{ h}^{-1}$, $p < 0.01$). Individual data showed a worsening of the response in about one-third of patients (according to the National Diabetes Data Group criteria, eight previously normal patients fulfilled the criteria of impaired glucose tolerance, and seven patients the diabetes mellitus classes), while a normalization of the response was seen in three patients. In none of the patients was reactive hypoglycemia seen. Insulin release after glucose load was significantly reduced during octreotide therapy with respect to baseline (1076 ± 767 vs $1765 \pm 1348 \text{ pmol l}^{-1} \text{ h}^{-1}$, $p < 0.01$). No significant changes of glycosylated hemoglobin were observed during octreotide therapy in the 34 patients having the evaluation performed (5.2 ± 0.9 at baseline vs $5.1 \pm 1.1\%$ at 12 months).

Effects on insulin and glucose metabolism in diabetic patients

Fifteen acromegalic patients had non-insulin-dependent diabetes mellitus, while one had insulin-dependent diabetes mellitus before starting octreotide therapy. In four of these patients a clear worsening of metabolic control was observed: one required a threefold increase in his daily insulin dose, one had to be treated with insulin therapy at high doses and two patients had octreotide withdrawn because of worsening of serum glucose levels. In contrast, in two patients an improvement was seen because glycosylated hemoglobin normalized without changing daily doses of oral antidiabetic drugs and diet. Three dropped out for unrelated reasons and in the remaining seven patients no significant modifications of carbohydrate control and drug requirement were seen.

Effects on lipid metabolism

Mean serum total and LDL cholesterol levels significantly decreased after 3 months of octreotide treatment: from 5.35 ± 1 to $4.88 \pm 1 \text{ mmol/l}$ ($p < 0.05$) and from 3.33 ± 1 to $2.71 \pm 0.9 \text{ mmol/l}$ ($p < 0.05$), respectively, in 35 patients studied. No further significant modifications of both parameters were seen between 3 and 12 months of therapy. Mean HDL cholesterol levels were unaffected by octreotide treatment (pretreatment: $1.29 \pm 0.4 \text{ mmol/l}$; 3 months: $1.34 \pm 0.3 \text{ mmol/l}$; 12 months: $1.34 \pm 0.3 \text{ mmol/l}$). Individual data show that 22/35 patients had basal serum total cholesterol levels $> 5.2 \text{ mmol/l}$, which were normalized by treatment in 14 patients, remained unchanged in six and slightly increased in two patients. As far as triglyceride levels are concerned, a slight but not significant decrease was

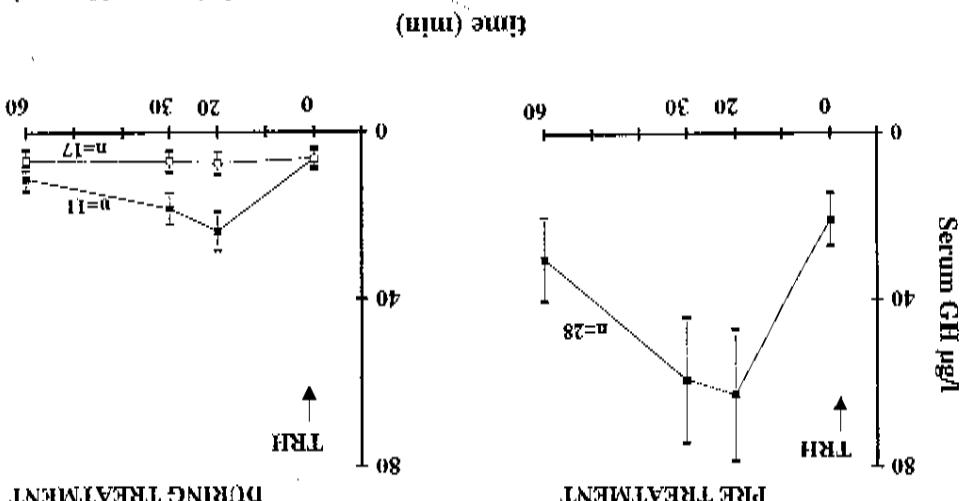

No significant changes of TSH secretion were found during chronic treatment with octreotide in 32 euthyroid patients not taking thyroid hormone therapy (8-h AUC: 6.4 ± 3.3 at baseline; 5.8 ± 3.4 at 3 months and 6.5 ± 4.1 μ M $^{-1}$ h $^{-1}$ at 12 months). A significant reduction of

Effects on thyroid function and ultrasonography

111 hyperprolactinemic patients from 53.6 ± 45 (range 20-184) to 26.7 ± 26.4 µg/L (range 8-103) at 3 months (p < 0.01) and normalized in five patients. The LTH test was repeated after 9 months of octreotide therapy in nine cases and showed a significant reduction in PRL response (AUC = 39.1 ± 27.9 vs 70.3 ± 49.2 µg⁻¹·h⁻¹; p < 0.01). On the contrary, no significant modification of either basal or TRH-stimulated serum PRL levels was seen in 34 normoprolactinemic patients (AUC after TRH:

Fig. 2. Growth hormone response (± SEM) to TRT before (on the left) and during chronic octreotide therapy in 28 retested patients showing an abnormal GH increase before treatment. The abnormal response disappeared in 17 patients (□) and was maintained in 11 (■).

Serum PRL levels were affected differently by octreotide treatment, depending on patients being hyper- or normo-

HOYSSDOSIST

were observed in the four patients who had gallstones

Diarhoea and abdominal pain were reported by 53% and 26% of the patients at the beginning of treatment. These symptoms required permanent or temporary withdrawal of octreotide therapy in seven cases. However, in the other patients they spontaneously remitted after 7-14 days. At 12 months, diarrhoea and abdominal pain occurred in only 6% and 8% of patients, respectively. Nausea was reported by about 8% of patients during all the study and pain at the site of injection by 4-10% of patients, five patients (10%) showed the appear-

Side effects and drop-outs

Bordy mass index significantly decreased during octreotide therapy from 26.6 ± 3.7 to 25.7 ± 3.2 at 12 months ($p < 0.01$). A slight, but not significant, decrease of both systolic and diastolic blood pressure was seen (from 131 ± 16 to 127 ± 13 mmHg and from 83 ± 9 to 80 ± 9 mmHg, respectively). An improvement of the disappearance rate of the main symptoms of acromegaly was reported by the majority of patients; about 80% for hypothyroidism, paracapillaries and headache and about 70% for fatigue and musculoskeletal ache. In whom mean GH levels decreased by 50% or more, but also in some patients with a very slight and short-lasting octreotide effect on GH secretion, type-2 diabetes improved in $5/14$ patients (two with GH levels below 2.5 ng/L , two with GH levels between 2.5 and 5 ng/L and one with immobile GH concentrations) and worsened in one case in spite of a 65% GH decrease.

Aftertreatments of the menstrial cycle, loss of libido and loss of potency were not influenced by the treatment. The circumference of the middle phalanx of the left hand increased in 15%, and it increased in 5% of patients who maintained GH levels below 2.5 ng/L . During octreotide therapy, during octreotide therapy, visual acuity improved in about 80% of patients, while four patients deteriorated in about 80% of patients, while it was unchanged in 15%. And it increased in 5% of patients who discontinued therapy despite GH levels being decreased by about 50%.

Conclusion: Our results show that octreotide is effective in the treatment of acromegaly, especially in those patients with a low baseline GH level. The effectiveness of octreotide in acromegaly seems to be related to the degree of the disease, as well as to the patient's age. The effectiveness of octreotide in acromegaly seems to be related to the degree of the disease, as well as to the patient's age.

Other clinical effects

seen in the whole group (pretreatment: 1.63 ± 0.9 mmol/L; 3 months: 1.55 ± 1 mmol/L; 12 months: 1.37 ± 0.5 mmol/L), while a significant reduction (2.13 ± 0.3 mmol/L vs 1.38 ± 0.5 vs 1.44 ± 0.3 mmol/L; $p < 0.01$) was seen in 10 patients who had pretreatment plasma triglycerides levels > 1.8 mmol/L. Normal triglyceride levels were reached in nine of these patients.

It has been hypothesized that the magnitude of GH reduction during octreotide therapy is dependent on time (10, 13). This is not confirmed by our data. In fact, apart from a few exceptions, mean GH concentrations after 12 months of treatment were fully comparable to those found after 3 months. However, because previous studies were carried out for 18–24 months, it cannot be excluded that a longer course of therapy is necessary before obtaining a further reduction of GH levels. In one case an escape from octreotide suppression was observed at 12 months.

On the whole, IGF-I levels were normalized in 40% of patients. It is worth mentioning that several patients normalized their IGF-I levels in spite of the persistence of pathological serum GH levels. This is in agreement with previous studies (8, 9, 13, 16, 17) and supports the hypothesis of a direct effect of octreotide on IGF-I production and IGF-I binding proteins (18, 19). A crucial issue is the relative importance of GH levels below 2.5 µg/l with respect to normalized IGF-I levels for clinical and lifespan benefits in acromegalic patients. This point could be clarified only by specific studies.

Our finding of a reduction of tumor size in 50% of 26 non-irradiated patients with identifiable tumor is in agreement with previous reports (7–14). In our experience, microadenomas had a greater probability to be reduced than macroadenomas, which is at variance with previous observations (12). The degree of reduction of the tumor volume did not correlate with the magnitude of GH suppression, as already observed by others (9). In addition, no statistical difference between patients with or without GH reduction by 50% or more and with and without GH reduction to below 2.5 µg/l was achieved, thus suggesting that the control of GH secretion does not offer better chances for a tumor to shrink.

No significant modifications of either basal or TRH-stimulated PRL levels was seen in 34 normoprolactinemic patients, confirming that octreotide does not act on normal lactotroph cells. On the contrary, a significant octreotide-induced reduction of basal PRL levels was seen in hyperprolactinemic patients, as already described (12, 20, 21). It is widely recognized, as also confirmed by our own data, that elevated PRL levels in acromegalic patients maintain responsiveness to TRH stimulus (22, 23), at variance with the high PRL levels of patients with pure PRL-secreting adenomas in whom a lack of effect of octreotide was also described (20). Following octreotide administration we observed a significant reduction of PRL response to TRH in the hyperprolactinemic patients. These findings suggest that octreotide is able to suppress PRL release from mixed GH- and PRL-secreting adenomas. This is in agreement with previous observations in patients in whom the presence of mammosomatotrophs cells has been documented by *in vitro* studies of the tumor (20).

As far as the effects of octreotide on TSH secretion and thyroid function are concerned, our study confirms that

basal serum TSII, fT₃ and fT₄ release are not modified by chronic octreotide therapy, in agreement with previous studies (9, 21, 24–26). A reduction in circulating total T₃ levels, suggesting a decreased peripheral conversion of T₄ to T₃, has been described (24, 26). These variations are probably very transitory (26), while our first measurements of thyroid hormone levels were performed after 3 months of treatment. We found a significant reduction of TRH-stimulated TSH secretion after 9 months of treatment. Blunting of TSH response to TRH has been described previously after short-term octreotide administration (25). However, these subtle octreotide-induced alterations of the hypophyseal-thyroid axis do not seem to provoke abnormalities in thyroid function.

Goiter is far more frequent in acromegalic patients than in normal subjects. In our series goiter was found in 76% of patients, a percentage higher than reported previously (27). This may result from either the high prevalence of endemic goiter in Italy or the use of thyroid ultrasonography for diagnosis. The results of 12-month octreotide therapy on the goiter size and/or the number or size of thyroid nodules show a great individual variability but, on the whole, no significant changes were observed. These results seems to disprove the role of IGF-I in the pathogenesis of goiter (28).

Octreotide treatment was very effective in improving other symptoms typical of acromegaly. Even if serum GII levels were halved in only 60% of patients, hyperhidrosis, headache, fatigue and paresthesias improved in about 80% of patients, perhaps better reflecting the effect on tissue IGF-I levels. Hypertension improved in 10% of patients. Only a few previous studies report on serum lipid changes in acromegalic patients treated with octreotide. A slight, but not significant, reduction in serum cholesterol levels has already been described (29). In our series the reduction of total and LDL cholesterol was significant and a decrease in serum triglycerides was observed in hypertriglyceridemic patients, in agreement with other reports (12, 29). Owing to the increased prevalence of cardiovascular diseases in acromegaly, the observed lipid changes are of particular importance and deserve further investigation. In fact, although the explanation of the observed changes could be partly ascribed to a reduction of fat absorption (12, 30), it probably also involves other still unknown effects of octreotide.

In accordance with other studies we have at first observed a high incidence of gastrointestinal complaints, particularly diarrhea, but this tended to subside. An initial lower dosage of octreotide, gradually increasing to the full dose, or alternatively, a temporary reduction of the dosage might be useful in order to overcome the problem. In our series, 9% of patients showed evidence of asymptomatic cholelithiasis before entering the study. The observation is comparable to what is seen in non-acromegalic individuals in the Italian population (31). However, the presence of

formulations (35, 36)

In conclusion, we confirm that octocotide is an effective tool in the medical treatment of acromegaly, improving the clinical symptoms in the majority of patients and normalizing GH levels in about 40% of cases. Lower concentrations and IGF-I levels in about one-half of patients also prove the usefulness of this drug in acromegalic patients. One of the major limitations of octocotide therapy appears to be the timing of admissions. Preliminary data show that this limitation could be overcome in the future by the use of depot injections. Preliminary data show that this limitation of administration; the requirement for frequent daily admissions, the most frequent cause of death in acromegalic patients. One of the major limitations of octocotide therapy appears to be the timing of admissions.

The influence of elevation on carbohydrate metabolism appears more complex. On the whole we observed a variation with others (33, 34), and increase of mean blood glucose levels during octocapide therapy in non-diabetic patients. In patients with overt diabetes mellitus we found an impairment of metabolic control about 25%, while two patients disclosed effects on carbohydrate metabolism in acromegalic patients with diabetes mellitus, while beneficial effects on carbohydrate metabolism were observed in one patient with acromegaly.

asympomatic hallusions does not seem to represent a contraindication to cognitive therapy, because no impairment of ultrasonography or appearance of specific symptoms was seen during the course of the study. Conversely, hallucinations were new to the patients during the course of therapy, because no impairment of ultrasonography or appearance of specific symptoms was seen during the course of therapy, because no other studies similar to that reported in our cases (10%), an incidence of 32%, 14, 9, 7, 32). Suppression of the mesial-stimulated release of cholecystokinin, gallbladder and sympathetic activity, development of superstitiated bile and absorption of cholesterol in the liver may all be involved in the pathogenesis of cholelithiasis during octocotide treat-
