Abstract

In this study, titanium dioxide (TiO_2) nanostructured films were synthesized under microwave irradiation through low temperature synthesis (80 °C) and integrated in ultraviolet (UV) photodetectors and as photocatalysts. Bacterial nanocellulose (BNC), tracing paper, and polyester film were tested as substrates, since they are inexpensive, flexible, recyclable, lightweight, and when associated to low temperature synthesis and absence of a seed layer, they become suitable for several low-cost applications. The nanostructured TiO₂ films and substrates were structurally characterized by scanning electron microscopy coupled with energy dispersive X-ray spectroscopy, X-ray diffraction, and Raman spectroscopy. The optical properties of all materials were investigated. The TiO₂ nanostructured films were implemented as a photoactive layer of UV photodetectors and demonstrated significant increase of conductance upon exposed to UV irradiation. The photodetection behaviour of each material was investigated by in-situ Kelvin probe force microscopy experiments, in which the contact potential difference varied under dark or UV irradiation conditions, demonstrating higher shift for the BNC-based UV photodetector. Photocatalytic activity of the films was assessed from rhodamine B degradation under solar radiation, and BNC based devices revealed to be the best photocatalyst. The structural characteristics of the TiO₂ films and substrates were correlated to the differences in the UV photodetection and photocatalytic performances.

1 Introduction

Titanium dioxide (TiO_2) is an extremely versatile material as it can be employed in numerous applications, such as self-cleaning surfaces [1], dye sensitized solar cells [2–4], photocatalysis [5, 6], and photosensors/photodetectors [7, 8]. The interest on the latter application has been increasing with special attention to UV photodetectors. These are of great interest for everyday life especially in terms of sun/UV exposure, as well as for industry with direct applications in environmental safety, flame detection, among others [9]. The most common UV photodetectors used nowadays are the silicon-based ones, however this sort of devices present limitations, mostly associated to their narrow band gap energy (1.1 eV), and high temperature processing [9]. TiO₂-based photodetectors are excellent alternatives as TiO₂ is highly photoactive and stable under UV irradiation due to its band gap [10, 11], 3.00 and 3.21 eV for rutile and anatase, respectively [12]. Regarding brookite's band gap, the values reported in literature are diverse, ranging from 3.13 to 3.40 eV [12, 13]. Moreover, TiO₂ is a highly stable material, earth-abundant, low-cost, non-toxic [5], and it is largely employed as photocatalyst, normally in the anatase and rutile phases, or as mixtures of both phases to increase photocatalytic activity. Brookite, on the other hand is less explored, however its photocatalytic interest has been growing lately [6, 14].

The TiO₂ photoconductivity relies on the electrical conductivity changes under irradiation. The photodetection is governed by a hole-trapping mechanism based on the adsorption/desorption of chemisorbed oxygen molecules at the surface [15]. An analogous mechanism occurs in photocatalysis, where electron-hole pairs are generated. These photogenerated holes and electrons diffuse to the surface, oxidizing and reducing oxygen and water molecules, and creating reactive radicals that will decompose organic and inorganic compounds on the surface of TiO_2 [6, 16]. Kelvin probe force microscopy (KPFM) can be used to map the electronic properties of photoactive materials, measuring the contact potential difference (CPD) shift [17] (CPD with and without irradiation) and the surface potential, thus allowing the correlation with the photosensitivity of the materials [18]. This allows to understand the photosensitivity behaviour of sensing materials. The high sensitivity and stability of the photodetector associated to inexpensive materials and synthesis routes are imperative for obtaining low-cost and efficient devices.

Polymer and biopolymer materials fully fulfil the requirements for producing economically viable and flexible devices, hence the rapid and growing interest concerning the use of these materials as substrates for advanced devices is a reality nowadays. Cellulose is the most abundant biopolymer on earth [19, 20]. Bacterial nanocellulose and tracing paper are valuable materials for the development of disposable and inexpensive devices. BNC displays several advantages over other types of cellulose, in which the main one is the enhanced chemical purity, low surface roughness and porosity. Moreover, BNC displays high crystallinity, a finer and intricate structure, with longer and stronger fiber lengths. The bacteria Gluconacetobacter is normally responsible for the production of BNC membranes in large amounts, becoming an alternative for plant cellulose and thus preserving the environment [21]. Polymer substrates, i.e. polyester films, are also alternative substrates for the development of photodetectors, since they can easily and flexibly adapt to surfaces, are lightweight and impermeable, despite the possibility of recycling plastic waste.

The fabrication route plays a central role on the final cost of the device. Several techniques have been reported to produce TiO₂ nanostructures/films, which included thermal evaporation [22], sputtering [23], hydrothermal or solvothermal synthesis [24, 25], and microwave synthesis [5, 6], and even with waste reuse [26]. Nevertheless, microwave synthesis appears as an attractive option, since it is a simple and fast technique, low-priced, with intrinsic properties that can easily adapt to soft substrates and low temperature synthesis [6]. The efficient heating of solvents and/or reagents [27, 28] is guaranteed, providing accurate temperature control, and assuring homogeneity and uniformity of the produced materials. Moreover, for most of these synthesis routes, a seed layer is usually required. Indeed, the seed layer facilitates nucleation and determines the perfect covering of substrates, together with the crystallization, phase formation, and surface morphology of the growing film [29]. However, the deposition of a seed layer adds to the device extra procedures and in some cases requiring an additional annealing treatment, thus representing an additional cost.

The present work reports the production and characterization of TiO₂ nanostructured films grown on BNC, paper and polyester substrates, under microwave irradiation at low temperature (80 °C) and without any seed layer. The aim is to challenge the present state of the art concerning the exploitation of enhanced TiO₂ photoactive layers produced with low-cost synthesis routes in different substrates but also the fabrication of highly efficient but simple, environmentally friendly, low-cost and disposable UV photodetectors and photocatalysts. Moreover, to the best of the authors' knowledge, TiO₂ films grown under microwave irradiation without any seed layer at low temperature with celluloseand polymer-based substrates to be employed as UV photodetectors and photocatalysts has never been reported before. Structural characterization of the TiO₂ films has been carried out by scanning electron microscopy (SEM) coupled with an energy dispersive X-ray spectroscopy (EDS) detector,

Raman spectroscopy, and X-ray diffraction (XRD). The optical characterization has been also carried out for all materials. In-situ Kelvin probe force microscopy experiments were carried out under UV irradiation.

2 Experimental Procedure

2.1 TiO₂ Film Synthesis

The TiO₂ nanostructured films have been synthesized under microwave irradiation. The TiO₂ microwave solution has been prepared using titanium (IV) isopropoxide (Ti[OCH(CH₃)₂]₄, TTIP, 97% from Sigma Aldrich), hydrochloric acid (HCl, 37%) and deionised water. In a typical synthesis, 50 mL of water was mixed with 10 mL of HCl and stirred for 5 min. Afterwards, 2 mL of TTIP was added and the final mixture stirred for 10 min before microwave synthesis. Microwave synthesis was performed using a CEM Focused Microwave Synthesis System Discover SP. Time, power, temperature and pressure were set at 60 min, 100 W, 80 °C and 17 bar, respectively. The selected proportions of all reagents and synthesis parameters were determined following an analogous study [6] and intending to keep synthesis temperature, power input and acid amount to the minimum to guarantee the TiO₂ nanostructured film formation, and at the same time preventing any damage to the substrates. Solution volumes of 20 mL were transferred into capped quartz vessels of 35 mL, which were kept sealed by the constraining surrounding pressure.

Three types of flexible substrates were used, i.e. bacterial nanocellulose, tracing paper and polyester film. The BNC was synthesized by the bacteria Gluconoacetobacter xylinum in the form of a wet membrane [30]. The nanocellulose is excreted into the aqueous culture medium directly as nanofibers, with a diameter ranging from 25 to 100 nm [31]. This membrane was produced as described elsewhere [32] and then oven dried, forming a membrane with some tens of micrometers. The tracing paper is from Canson with 90 g/cm², translucent and perfectly flat [33]. The polyester substrate has its commercial name as Mylar film and has been purchased from DuPont with one side chemically pretreated for better adhesion. The polyester substrate was used as-purchased, and no other treatment has been carried out. During microwave synthesis, a piece of each substrate (20.0 \times 20.0 mm) was placed at an angle against the vessel and in the case of the polyester, the chemically treated side was facing down [5].

2.2 TiO₂ Film Characterization

X-ray diffraction experiments were performed using a PANalytical's X'Pert PRO MPD diffractometer equipped with a X'Celerator 1D detector and using CuK α radiation. The XRD data were acquired in the 20°–60° 2 θ range with a step size of 0.05°. For comparison, powder diffractograms of rutile, anatase, brookite have been simulated with PowderCell [34] using crystallographic data from reference [35].

Micro-Raman spectroscopy experiments were carried out with a Labram 300 Jobin Yvon spectrometer, equipped with a 17 mW He–Ne laser operating at 532 nm. Surface and cross-section SEM observations were carried out using a Carl Zeiss AURIGA CrossBeam FIB-SEM workstation equipped for EDS measurements. The dimensions of individual nanorods and films have been determined from SEM micrographs using the ImageJ software [36].

Surface potential mapping was measured using the Kelvin probe force microscopy technique in air at room temperature with an MFP-3D Standalone Asylum Research instrument in tapping mode. Olympus AC240 TM platinum coated silicon probes with a natural resonance frequency (f_0) of ~ 70 kHz and a nominal spring constant (k) of ~ 2 N/m have been used. The scanning ranges were 2×2 and $5 \times 5 \ \mu m^2$ with a resolution of at least 256 by 256 lines in all acquisition channels. The KPFM experiments were carried out in a double pass mode, and the second pass was performed at an optimized height of 50 nm above the topographic trace [37]. During UV irradiation, the materials were illuminated with UV ($\lambda = 365$ nm) [38] collimated LEDs from Thorlabs. The root mean square (RMS) roughness of each substrate was obtained from atomic force microscopy (AFM) topography images.

Room temperature reflectance measurements were performed in the 250–800 nm range with a PerkinElmer lambda 950 UV/VIS/NIR spectrophotometer equipped with a 150 mm diameter integrating sphere. The calibration of the system was achieved by using a standard reflector sample (reflectance, R = 1.00 from Spectralon disk). The band gap of the TiO₂ films was estimated from reflectance spectra using the Tauc plot method [39–41].

The pristine substrates were also characterized through XRD, SEM and Raman spectroscopy for understanding their influence on the TiO_2 films produced.

2.3 TiO₂ UV Photodetectors Production and Characterization

The TiO₂ nanostructured films grown on all flexible substrates were tested as photoactive layers on UV photodetectors. For the assembly of the complete device, a shadow mask was used for patterning interdigitated contacts [42] and an Au/Pd film of 100 nm was then sputtered at room temperature (Fig. 1). The Au/Pd interdigitated contacts were selected since a Schottky interface is expected to be formed between metals with large work function (such as Pd and Au) and *n*-type TiO₂ [43]. The formed junction

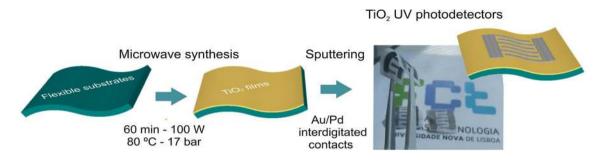

Fig. 1 Scheme of the TiO₂ UV photodetector production stages and photograph of the final devices showing high flexibility

has a rectifying electrical transport behaviour, resulting in efficient charge separation of the photogenerated electron-hole pairs, and thus preventing the electron-hole recombination [43].

The devices characterization has been carried out using a potentiostat model 600 from Gamry Instruments, Inc. in a chronoamperometry configuration, with a constant applied voltage of 10 V. The photodetectors were subjected to UV irradiation using two ultraviolet lamps, model TK-2028 from Hongguang Optics International Industry Co. Ltd., with 6 W (each) at a wavelength of 360 nm. The produced photodetectors were irradiated for 15 min followed by 30 min in off state. The *I*–*V* characteristics of the flexible photodetectors were measured by sweeping the voltage from – 5 to 5 V with a step of 10 mV/s.

2.4 Photocatalytic Activity

The photocatalytic activity of the TiO₂ nanostructured films was evaluated at room temperature from the degradation of rhodamine B from Sigma Aldrich under a solar light simulating source. The experiments were not carried out with the direct exposure to sunlight. The experiments considered the International standard ISO 10678. The TiO_2 films were placed on the bottom of the reaction recipient and for each experiment, 50 ml of the rhodamine B solution (5 mg/L) was stirred for 30 min in the dark to establish absorption-desorption equilibrium. The photocatalytic activity experiments used a Xe lamp at room temperature with intensity of 100 mW cm² and AM1.5 spectrum [6]. Absorption spectra were recorded using a PerkinElmer lambda 950 UV/VIS/ NIR spectrophotometer with intervals of 60 min for the first 8 h, and after with intervals of 120 min up to 12 h, then a 180 min exposure was carried out to complete a total exposure time of 15 h. To perform reusability experiments, the material was dried after the first exposure, at 50 °C for 1 h, and the liquid was discarded. The reusability tests were carried out by the repeated solar radiation exposure of the same sample in fresh solutions for different intervals of time up to 15 h.

3 Results and Discussion

 TiO_2 nanostructured films were successfully synthesized under microwave irradiation using cellulose- and polymerbased substrates at low temperatures and without any seed layer. The distinct substrates were selected due to their specific characteristics, i.e. BNC is transparent and together with tracing paper, both have lack of porosity when compared to other types of papers, making them suitable for optoelectronic devices. The polymer-based material is highly flexible and resistant being also largely integrated in such devices. The TiO₂ films, substrates and final devices were systematically investigated including their behavior under UV irradiation and dark conditions.

3.1 Structural Characterization

Figure 2 shows the SEM images of TiO₂ nanostructured films presented together with the pristine substrates for comparison. A clear difference is observed between the substrates before and after microwave irradiation. The pristine BNC substrate appears with a well-organized 3D structure, forming a closed packed cellulose nanofiber network with irregular interconnected pores (Fig. 2a). AFM measurements revealed a RMS roughness value of 58 nm (see Supplementary Information Fig. S1). The tracing paper and polyester substrates are more compact materials without any defined structures (Fig. 2c, e), despite the higher roughness of tracing paper. In fact, AFM showed that tracing paper displayed a rougher surface with a RMS value of 312 nm (Fig. S1). The polyester film has a chemically pre-treated surface, however no particular pattern/roughness could be discerned by SEM. AFM measurements revealed a RMS roughness value of 11 nm (Fig. S1).

Microwave irradiation resulted in uniformly covered substrates, forming continuous TiO_2 films with two distinct film characteristics. Individual nanostructured particles with an undefined structure (ranging from small sized squares to rod-like structures) covered mostly of the cellulosed-based substrates and fine nanorod aggregates forming TiO_2 flower-like structures were also observed (higher extent on

show the TiO_2 films and the nanorod flower-like structures with a higher magnification

the BNC material when compared to the paper substrate). After microwave synthesis, the nanofiber network can still be noticed on the BNC-based material, however completely covered with the TiO_2 film (see Fig. S2a). On the polyester substrate, these flower-like structures were grown side-byside appearing as a continuous material formed by densely and closely packed nanorod aggregates. Nevertheless, some cracks along the film could be observed (Fig. 2f). In all materials, the average nanorod widths were similar with 11 ± 3 nm (magnified SEM image of the nanorods is presented in Fig. S2b). These fine aggregated nanorods have been reported previously [5, 44]. These reports suggest that the fine nanorods have the rutile phase and a [001] growth direction [5, 44], moreover they tend to combine and thus reduce the surface energy [45] forming the aggregates. This undefined nanostructures has also been previously reported in an analogous work and identified as having the brookite phase [6].

EDS analyses were carried out in the material crosssections and revealed that the TiO_2 film was grown on both

sides of the cellulose-based substrates, while for the polyester material, just the chemically pre-treated side formed a continuous film (Fig. 3). Some residual traces of TiO₂ could be observed on the untreated side, however, no continuous film could be observed. The chemically treated surface of the polyester substrate is expected to facilitate the fixation of the film during synthesis. The TiO₂ growth on cellulose-based substrates without any seed layer or chemical treatment for adhesion are expected to be due to substrate roughness facilitating nucleation and fixation of the TiO₂ structures. Other metal-oxide based materials have been shown to grow on cellulose-based substrates, however, a seed layer was required for this process to occur [46-48]. The thickness of the films grown on BNC and tracing paper could not be inferred precisely due to heterogeneities of the structures formed, while the TiO₂ nanorod film grown on the polyester substrate revealed a thickness average of 167 ± 9 nm (see Fig. 3i). The substrate thickness differences are evident, corresponding to $15 \pm 1 \mu m$ (BNC), $62 \pm 9 \mu m$ (tracing paper) and $21 \pm 1 \,\mu m$ (polyester).

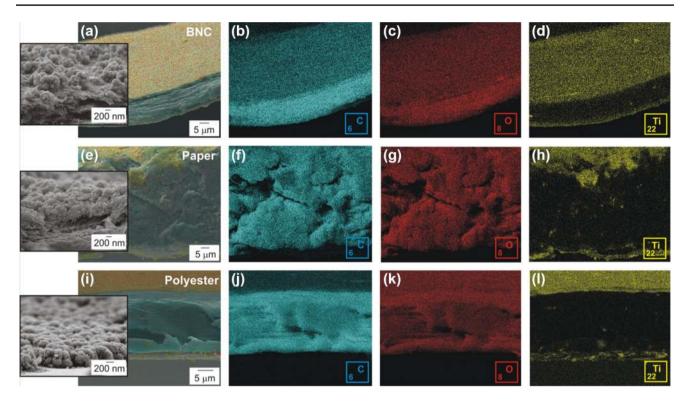

Fig.3 SEM images of the TiO_2 films grown on BNC (a), tracing paper (e) and polyester (i) substrates together with their corresponding EDS maps of C (b, f and j), O (c, g and k) and Ti (d, h and l). The insets show the cross-section SEM images of all materials

Raman spectroscopy and X-ray diffraction measurements were carried out for the TiO_2 nanostructured films together with their pristine substrates. A substantial contribution from the substrates was observed on XRD diffractograms, hindering the TiO_2 signal (Fig. S3). Raman spectroscopy was able to overcome this difficulty, allowing the precise identification of the TiO_2 phases present [49] (Fig. 4). The pristine substrate Raman spectra are presented for comparison.

The Raman spectra showed the presence of both brookite and rutile phases for all materials. The Raman bands associated to brookite were detected from 100 to 400 cm⁻¹, which can be assigned to A_{1g} (152 cm⁻¹) and B_{2g} (355 cm⁻¹) [49]. The Raman bands associated to rutile can be assigned to B_{1g} (103 cm⁻¹), E_g (244 and 439 cm⁻¹) and A_{1g} (604 cm⁻¹). The characteristic Raman band of ~ 518 cm⁻¹ [49] associated to the presence of anatase was not detected in any material. No additional bands could be found in the spectra. In the TiO₂ films grown on polyester, the substrate peaks (*) are more intense, unlike in the case of the cellulose-based ones (such as in XRD results), an effect that might be related to differences in thickness between the TiO₂ films (which could not be estimated for the cellulose-based materials).

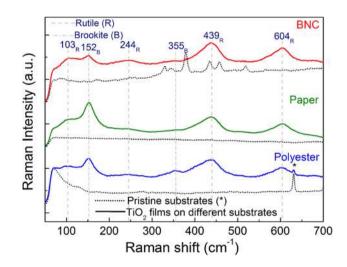

Fig. 4 Raman spectra of the TiO_2 films together with their pristine substrates (dot lines). Dashed lines indicate the rutile bands and dot/ dashed ones point out to the brookite ones

3.2 Optical Characterization

Optical band gaps have been evaluated from reflectance data through the Tauc plot. The optical band gap is related to the optical absorption coefficient and the incident photon energy as follows [40, 50]:

$$\alpha h v = A \left(h v - E_{\rm g} \right)^n \tag{1}$$

where α is the linear absorption coefficient of the material, $h\nu$ is the photon energy, A is a proportionality constant and n is a constant exponent which determines the type of optical transitions (n = 1/2) for direct allowed transition and n = 2 for indirect ones). Moreover, for determining the band gap, the $(\alpha h\nu)^2$ against $h\nu$ is plotted, and extracted through the intersection of the extrapolation of the linear portion with 0. The band gaps were estimated to be 3.28, 3.27, and 3.12 eV for the TiO₂ films grown on BNC, tracing paper and polyester substrates, respectively (Fig. 5). The evaluated band gaps are within the reported values for the different TiO₂ phases [12, 51, 52], i.e. for the rutile phase (3.00 eV) and brookite (3.13–3.4 eV) [12, 13]. The band gap is strongly dependent on crystallite size [53, 54], phase present [5], defects [42], residual strain [55], degree of compactness and densification [56], among other factors. No significant band gap differences were observed between the cellulose-based materials, while the band gap value of the TiO₂ film grown on polyester substrate revealed to be slightly lower. This difference can be justified by the structural properties of the polyester-based TiO₂ films, such as film thickness [55] and compactness [5].

3.3 TiO₂ UV Photodetectors

 TiO_2 UV photodetectors have been studied over the years, especially the ones based on nanomaterials, due to their large surface-to-volume ratios assuring high responsivity [57]. The TiO₂ phase present on the device also plays a key role on its final behaviour. It is known that poor charge separation is achieved in materials with one single TiO₂ phase [10], thus this drawback can be overpassed with mixtures of TiO₂ phases [10]. TiO₂ UV sensing devices

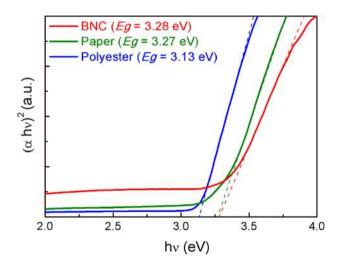

Fig. 5 $(\alpha h\nu)^2$ variation versus photon energy $h\nu$ for the TiO₂ films grown on BNC, tracing paper and polyester substrates

based on mixtures of anatase and rutile have been reported [10, 58], nevertheless devices based on brookite/rutile phases are rare, and to our best knowledge brookite/rutile UV photodetectors have never been reported, particularly producing flexible devices based on cellulose or polymer substrates. The relatively low stability of brookite can be responsible for this lack of investigation. In fact, brookite can be converted to rutile by a proper thermal treatment [13]. Yet, the combination of both rutile and brookite is expected to produce devices with high performance as both phases have wide band gaps and are excellent UV absorbers [10, 13].

The sensitivity of a UV photodetector is also governed by other factors besides the ones already mentioned, i.e. shape, reduced grain size and phase present. Thus, substrate morphology, surface state, oxygen adsorption quantity, oxygen adsorption active energy, lattice defects, and connectivity between grains also contribute to the final device performance [42, 59].

The TiO₂ films grown on BNC, tracing paper and polyester substrates were tested as UV photodetectors, and the results are presented in Fig. 6. Nevertheless, the heterogeneous structure observed at each material reverberated to their photosensitivity and final UV photodetector behaviour. The time resolved photocurrent of TiO₂ films was measured at room temperature in response to the on/ off switching of UV irradiation (Fig. 6a). Despite the heterogeneity, the behaviour observed for several UV photodetectors produced with all the substrates was consistent, with the TiO₂ film grown on bacterial nanocellulose displaying enhanced photosensitivity when compared to the other substrates. Under the bias voltage of 10 V, the photocurrent exponentially increased from 0.15 µA (dark condition) to 3.78 µA (UV irradiation) for the TiO₂ film grown on BNC substrate, while for the tracing paper one, it increased from 0.06 to 1.99 µA and polyester substrate from 0.01 to 0.83 µA. When the UV irradiation was turned off, the current decreased to its initial current value. Moreover, the photocurrent could be reproducibly switched from on to off states several times maintaining the characteristics over time indicating the enhanced stability of all the UV photodetectors. Figure 6b shows the typical current versus voltage (I-V) curves of the TiO₂ film UV photodetectors in the dark and under UV irradiation measured at a bias voltage ranging from -5 to 5 V and at room temperature. The I-V curves revealed an Ohmic contact between the Au/Pd electrodes and the TiO₂ films. Upon UV irradiation, and as exhibited on Fig. 6a, the current significantly increased especially for the cellulose-based materials, and the difference between measurements with UV irradiation and dark condition are evident (see inset in Fig. 6b).

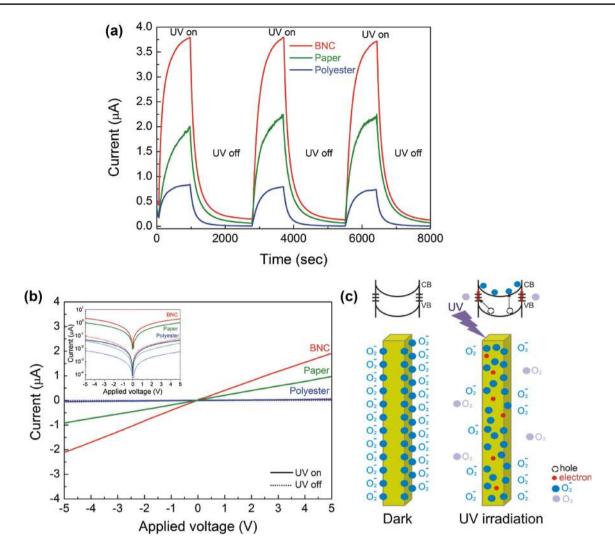

Fig. 6 a Cycling behaviour of TiO_2 film photodetectors at 10 V and under a 360 nm UV source. b *I–V* curves showing the dark current and photocurrent of the produced devices. c Schematic diagrams of dark and UV irradiation processes. The top drawing shows the schematic of the energy band diagrams, where VB and CB are the valence and conduction band, respectively. The bottom drawing shows the

The sensing process of the TiO_2 photodetectors can be explained as follows:

- On dark conditions, the oxygen molecules adsorbed on the TiO₂ surface capture the free electrons present in the *n*-type semiconductor, forming a low conductivity depletion layer near the surface [O₂(g) + e⁻ → O₂⁻ (ads)] (Fig. 6c).
- Under UV irradiation at a photon energy above its *Eg*, electron-hole pairs are photogenerated, and the holes migrate to the surface along the potential slope. This potential slope is produced by band bending and discharge of negatively charged adsorbed oxygen ions through surface electron-hole recombination, leading

dark and UV irradiation mechanisms, where in dark, the oxygen molecules adsorbed at the surface capture the free electron present in the *n*-type semiconductor forming a low-conductivity depletion layer near the surface. Under UV irradiation, photogenerated holes migrate to the surface and are trapped, leaving behind unpaired electrons that contribute to the photocurrent [60, 61]

to oxygen photo desorption [42, 60] $[h^+ + O_2^-(ads) \rightarrow O_2(g)]$ (Fig. 6c). This hole-trapping mechanism through oxygen adsorption and desorption enhances the high density of trap states due to the dangling bonds at the surface and thus enhances the photoresponse [61].

The TiO_2 UV photodetector responsivities were also estimated according to the Eq. (2) [42]:

$$R = \frac{I_{ph} - I_{dark}}{P_{UV}} \tag{2}$$

where I_{ph} is the UV device photocurrent, I_{dark} is the dark current, and P_{UV} is the UV light power. The calculated

responsivity was 0.33, 0.16 and 0.07 μ A/W for the TiO₂ films grown on BNC, tracing paper and polyester substrates, respectively. The responsivity was calculated taking into account the current value when the device reaches 95% of its stable value [33, 62]. Thus, the TiO₂ film grown on BNC substrate displayed the highest responsivity among the other substrates used.

As previously mentioned, several parameters dictate the UV photodetector responsivity. For the present case, no clear relation between the band gaps and the responsivity can be established for all materials, as no significant differences were detected. No significant TiO₂ phase differences are expected between all the materials, however BNC revealed enhanced performance. Thus, no direct input resultant from the TiO₂ phases at each material could be directly inferred. Nevertheless, the present study demonstrated that TiO₂ UV photodetectors based on mixtures of brookite/rutile can be effectively produced with enhanced performance (Fig. 6a). Some contribution can be expected from lattice defects, such as oxygen vacancies, which are believed to contribute to the enhanced photosensitivity of materials [61].

The observed UV photodetector performances were then justified regarding the structural properties of the TiO₂ nanostructured films and their substrates. In fact, films with different structural characteristics, such as crystal structure, particle size and film thickness, could significantly influence the transport and recombination properties of the photogenerated carriers and thus the UV photodetector performance [63]. In the present case, no direct conclusions could be determined from the TiO₂ film thicknesses, since the thickness could not be estimated, due to heterogeneities of the cellulose-based materials. Nevertheless, a considerable contribution for UV photodetection can be expected due to film thickness [63, 64]. Moreover, the nanorods observed in all materials displayed similar widths, thus this parameter seems not to be responsible for the differences in photosensitivity observed.

Regarding the substrate morphology input, clear structural differences between the substrates studied were observed by SEM and AFM measurements (see Figs. 2 and S1). In the case of BNC-based materials, significant contribution can be suggested from the substrate structure, as nanocellulose displays high surface-to-volume ratio [65]. The enhanced BNC surface-to volume property can tune the TiO₂ nanostructured film features and thus its sensing behaviour. In fact, this could be observed with the nanofibers covered with the TiO₂ film after microwave synthesis (Fig. S2a). Moreover, BNC is a closed packed cellulose nanofiber network with the lowest RMS roughness value among the cellulose-based materials studied. This intrinsic surface characteristic guarantees the growth of continuous nanostructured films without any abrupt gap among the structures formed, which would lead to current loss. The higher roughness of tracing paper, on the other hand, can contribute to discontinuities in the nanostructured film, which decrease the photodetector performance. Regarding the polyester-based materials, the cracks observed along the film can be responsible for the poorest behaviour among the materials tested. In Ref. [33], a wrinkled material after microwave synthesis was assumed to difficult current flow through the sample, decreasing its performance.

3.4 Kelvin Probe Force Microscopy

Kelvin probe force microscopy is a powerful technique capable of determining electronic properties of materials at the nanometer scale, such as contact potential differences (CPD) [37]. The CPD (or V_{CPD}) can be related to the material surface potential, through the following equation [60, 66]:

$$V_{CPD} = \frac{\left(\varphi_p - \varphi_s\right)}{e} \tag{3}$$

where φ_p and φ_s are the work functions of probe and sample, respectively, and *e* is the electronic charge. For a semiconductor, it is defined φ as the surface potential [60]. In general, the local surface potential is due to the charge density on the material surface, depending on the presence of charges on the surface but also beneath it, surface dipoles, and polarization effects [67].

Figures 7 and S4 show the CPD averaged profiles together with the corresponding topography and surface potential images carried out in air and with/without UV irradiation of the TiO_2 films grown on BNC, tracing paper and polyester substrates. The CPD of all TiO_2 films increased with the UV irradiation. Nevertheless, from the CPD averaged profiles, the shift under UV irradiation is not linear and changed regarding the material tested.

The film surface potential, which is related to CPD, depends on its own characteristics such as thickness; however, some contribution also comes from the substrate [67] below the film. In the present case, the substrates are completely distinct, with different surfaces, roughness and thicknesses, leading to different surface potential contributions. This behaviour has been previously reported with different substrates, leading to distinct surface potentials of the deposited films [67]. For that reason, the averaged CPD measured cannot be linearly comparable between the materials, but instead its shift detected with and without UV irradiation. Moreover, considering Eq. (3) and using the same calibrated probe during UV on/off measurements, it can be assumed that the CPD shift is equal to the surface potential shift.

Several KPFM measurements in distinct TiO_2 photodetectors were performed and the results are presented in

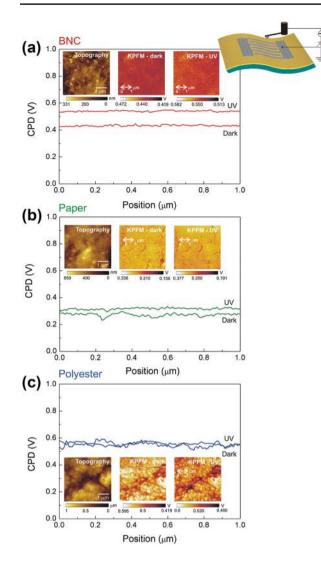

Fig. 7 CPD averaged profiles together with the corresponding topography and surface potential images with and without UV irradiation at room temperature for the TiO_2 films grown on **a** BNC, **b** tracing paper and **c** polyester substrates. The profiles were carried out in regions that represented the average surface potential of the image. The scheme of the KPFM measurement is presented

Figs. 7 and S4. In Fig. 7, the averaged CPD for the TiO_2 film grown on BNC substrate increased from 420 mV in dark to 530 mV under UV, while the film grown on tracing paper increased from 280 to 320 mV, dark and UV, respectively, and the one grown on polyester substrate increased from 525 to 550 mV, dark and UV, respectively. In Fig. S4, different devices were tested, which revealed that the averaged CPD for the BNC-based material increased from 20 mV in the dark to 380 mV under UV irradiation, while for tracing paper it increased from 700 to 920 mV, (dark and UV, respectively) and from 550 to 600 mV (dark and UV, respectively) in the case of the polyester-based material. The CPD increase under UV irradiation for all

materials indicates that the surface potential is shifted under UV exposure. Differences in CPD between the TiO_2 UV photodetectors with the same substrate were observed and expected to be due to the heterogeneities of the structures formed and substrate contributions.

The BNC-based devices revealed the highest CPD/surface potential shift among the materials studied for all measurements. As previously mentioned, the oxygen molecules adsorbed on TiO₂ surface capture electrons in air, and a low conductivity depletion layer is formed at its surface. Under UV irradiation, electron-hole pairs are generated, where holes migrate to the surface along the potential slope created by band bending and release the electron adsorbed oxygen ions, lowering the upward bent banding near the TiO₂ surface and increasing electron concentration. Consequently, the surface potential decreases, while the contact potential difference increases [60, 68]. Moreover, the clear photoresponse of the surface potential detected for all materials strongly suggest a change in the effective Fermi level of the TiO₂ films under UV irradiation [60].

Previous reports assumed that higher surface potential shift under UV irradiation are related to enhanced photocatalytic activity and proof of photogenerated electron-hole pairs separation [43, 60, 69]. This assumption can be extrapolated to the photosensitivity observed for the materials investigated. The contact potential difference shift detected for all materials can indicate the separation of photogenerated electron-hole pairs [69], and the highest shift observed for the BNC-based material suggests that this substrate possesses better charge separation ability than the other materials studied.

3.5 Photocatalytic Activity

Photocatalysis is a vast research field, with several distinct photocatalyst materials reported so far [70-82]. Nevertheless, TiO₂ continues to be one of the most widely embraced photocatalysts nowadays. TiO_2 is a wide band gap material [6, 83], which makes it active under UV light irradiation and thus it is expectable that TiO₂ films have higher photocatalytic activity under UV than under solar radiation [6]. In fact, all the above results confirm that the materials are effectively active under UV irradiation (Figs. 6, 7). Nevertheless, the solar UV radiation that reaches the earth surface is relatively small (3–5%) [84], turning pollutant degradation with UV activation extremely limited. On the other hand, the use of the complete solar spectrum is highly sought in terms of flexibility, sustainability and cost effectivity [85, 86]. Several studies reported the TiO₂ photocatalytic activity under visible/solar radiation [87–91], and also difference approaches to increase its performance under these conditions, i.e. doping, surface modification [90, 92]. Concerning

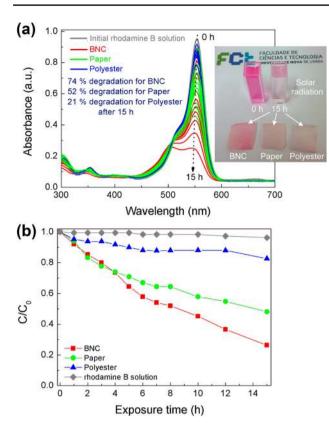

Fig.8 a Rhodamine B absorbance spectra at different solar light exposure times up to 15 h. The images of rhodamine B solutions at 0 h and after 15 h are presented together with the materials after the photocatalytic experiments. **b** Rhodamine B degradation ratio (C/C_0) versus solar simulating light exposure time

the substrates, photocatalytic papers have been reported over the years, however normally under UV irradiation [93, 94].

In the present study, the photocatalytic activity of all TiO₂ nanostructured films were evaluated through the rhodamine B degradation under solar radiation to mimic ambient conditions. The degradation ratio (C/C_0) versus exposure time is presented in Fig. 8, where C is the absorbance of the rhodamine B solution at each exposure time and C_0 is the initial solution absorbance. The gradual rhodamine B degradation under solar radiation could be observed, however the TiO_2 film grown on BNC substrate showed the highest photocatalytic activity. This material reached values of 74% after 15 h, while the other TiO_2 films achieved 52 and 21% for the tracing paper and polyester, respectively. A blank rhodamine B solution was also measured, where it has been observed that the blank solution was not influenced under the solar simulating light source, so all the photocatalytic effect is due to the presence of the catalyst. The photodegradation of rhodamine B has been attributed to the oxidation by different reactive oxygen species [95, 96], and its degradation mechanism has been reported in several studies [95-99], including for TiO2 photocatalysts. The degradation under visible/solar light radiation is the result of the chromophore structure destruction or N-deethylation [99], passing through the formation of intermediate species, that despite being controversial in literature, have in phthalic acid and benzoic acid well accepted intermediates [96, 98]. UV/VIS/ NIR spectroscopy measurements can be used to infer the mechanisms occurring during rhodamine B photodegradation [99, 100].

The photocatalytic activity depends on several properties like band gap, crystallite size, crystalline phase, specific surface area, defects and active facets [5, 6, 101]. A clear relation between the band gaps of all the materials and their photocatalytic behavior cannot be stated as no significant band gap differences were observed between the cellulosebased materials, and the TiO₂ film grown on polyester substrate revealed a slightly lower value which can be justified by the structural properties of this material. The TiO₂ active facets are $\{110\} > \{001\} > \{100\}$ for rutile, and $\{210\}$ for brookite [13]. In this study, contributions can be expected from active facets in all materials. The mixture of TiO₂ phases also can contribute to the increase of photocatalytic performance [6, 102]. In this study, Raman measurements (Fig. 4) revealed a mixture of TiO₂ phases (brookite and rutile) for all the materials produced, which can have an expressive contribution to the photocatalytic activity of all materials under solar light simulating source. An analogous study also revealed that the mixture of TiO₂ phases (brookite and rutile) largely increased the photocatalytic performance under UV and solar radiation [6]. In fact, it has been previously described that brookite has higher photocatalytic activity than anatase or rutile [49]. Another study reported a mixture of TiO₂ phases, i.e. anatase-rutile system, which exhibited enhanced visible light activity, promoting the effective transfer of photoexcited electrons and favoring electron-hole separation [90].

The nanocellulose based material demonstrated higher photocatalytic activity than the other materials, thus the structural differences of the TiO₂ nanostructured films and substrates play a key role on the behavior observed. The cellulose-based materials are expected to have higher specific surface area than the ones of the polyester material, in which the latter presented a closed structure with closely packed nanorods [6]. In fact, the cellulose based materials formed a continuous film and presented individual nanostructured particles having nanorod flower-like structures with a more open structure (Fig. 2), which can lead to the higher surface area [103]. Regarding the substrates, the nanocellulose substrate has a 3D structure which can effectively enhance the photocatalytic activity. The 3D closed packed cellulose nanofiber network of nanocellulose fully covered by TiO₂, not only can provide more active sites for the photoreaction, but also facilitate the species transport and electrons collection [104].

These materials exhibited resistance to water immersion, and after the photocatalytic experiments even the cellulosebased materials could be recovered and dried as shown on Fig. 8a. Reusability experiments were carried out for the best photocatalyst, see Fig. S5, and it can be observed that the BNC-based material can be reutilized despite the activity deterioration observed over the exposures [105, 106]. Thus, these experiments demonstrated that the materials produced, which have been thought to be fully disposable but showing now that they can be reused, are able to effectively degrade pollutant model dyes, and at some point, contribute to the environmental protection, while reducing production costs.

4 Conclusions

TiO₂ nanostructured films were successfully grown on lowpriced substrates using microwave synthesis at low temperature, producing flexible and disposable UV photodetectors and photocatalysts with minimal production stages, as it does not require the use of seed layers for the photoactive layer growth, thus reducing the total cost of the device. A mixture of rutile and brookite was identified in all materials, forming continuous films with nanostructures that were arranged distinctively regarding the substrate used. The devices composed by the TiO₂ film grown on BNC tended to display enhanced photosensitivity when compared to the other substrates, nevertheless all devices studied revealed remarkable stability after switching from on to off states several times. The photodetection behaviour and photocatalytic activity were shown to depend on the structural characteristics of the TiO₂ nanostructured films and substrates. KPFM data also demonstrated the enhanced BNC-based material behaviour with the highest contact potential difference shift among the materials investigated. The present work demonstrated that the simple approach developed is an effective and attractive alternative for producing flexible, low-cost, and disposable devices that can be employed in multifunctional applications as photodetectors and photocatalysts.
