#### Abstract

We propose a compressed self-index based the edit-sensitive parsing (ESP). Given a string $S$, its ESP tree is equivalent to a contextfree grammar deriving just $S$, which can be represented as a DAG $G$. Finding pattern $P$ in $S$ is reduced to embedding $P$ into $G$. Succinct data structures are adopted and $G$ is then decomposed into two LOUDS bit strings and a single array for permutation, requiring $(1+\varepsilon) n \log n+$ $4 n+o(n)$ bits for any $0<\varepsilon<1$ where $n$ corresponds to the number of different symbols in the grammar. The time to count the occurrences of $P$ in $S$ is in $O\left(\frac{\log ^{*} u}{\varepsilon}\left(m \log n+o c c_{c}(\log m \log u)\right)\right)$, where $m=|P|, u=|S|$, and $o c c_{c}$ is the number of occurrences of a maximal common subtree in ESP trees of $P$ and $S$. Using an additional array in $n \log u$ bits of space, our index supports locating $P$ and displaying substring of $S$. Locating time is the same as counting time and displaying time for a substring of length $m$ is $O(m+\log u)$.

## 1 Introduction

We propose a compressed index based on the edit-sensitive parsing (ESP), which was introduced to approximate a variant of string edit distance where a moving operation for any substring with unit cost is permitted. For instance, $a^{n} b^{n}$ is transformed to $b^{n} a^{n}$ by a single operation. This problem called edit distance with move is NP-hard, and the distance was proved to be $O(\log u)$-approximable [9] for strings of length $u$. Moreover, the harder problem, edit distance matching with move, was also proved to be approximable within almost $O(\log u)$ ratio by embedding of string into $L_{1}$ vector space using ESP [3].

When we consider tighter embedding, i.e. a string is embedded into another one as a substring, this problem becomes the pattern matching. In this work we use ESP to represent a grammar which is transformed to a compressed index based on our theoretical results for efficient pattern matching and data structures

[^0]on ESP. The following outlines the proposed data structures and its operations. We first preprocess the text $S$ and build ESP tree $T_{S}$. Given a pattern $P$, we construct $T_{P}$ and decomposes it into a sequence of subtrees, whose roots are labeled by $x_{1}, \ldots, x_{k}$. This sequence is an evidence of occurrence of $P$ in $T: S$ contains an occurrence of $P$ iff there is a sequence $v_{1}, \ldots, v_{k}$ of nodes in $T_{S}$ such that the label of $v_{i}$ is $x_{i}$ and the subtrees rooted by $v_{i}, v_{i+1}$ are adjacent in this order. We should note that $P$ itself is always evidence of $P$. We design algorithms to extract as short evidence as possible by analysis of ESP, and to embed the evidence in $T_{S}$.

Another contribution is to develop compact data structures for the proposed algorithms. An ESP is represented by a restricted CFG, and is equivalent to a DAG $G$ where every internal node has its left and right children. $G$ is then decomposed into two in-branching spanning trees. The one called the left tree is constructed by the left edges, whereas the other, called the right tree, is constructed by the right edges. Both the left and right trees are encoded by LOUDS [4], one of the succinct data structures for ordered trees. Further, correspondence among the nodes of the trees is stored in a single array. Adding the data structure for the permutation [5] over the array makes it possible to traverse $G$. The size of such data structures is at most $(1+\varepsilon) n \log n+4 n+o(n)$ bits of space for arbitrary $0<\varepsilon<1$, where $n$ is the number of variables in $G$.

On the other hand, the compression algorithm should refer to a function, called reverse dictionary to get a name of the variable associated with a digram. For example, if a production rule $Z \rightarrow X Y$ exists, any occurrence of the digram $X Y$ in $P$, which is determined to be replaced, should be replaced by the same $Z$. Taking up the hash function $H(X Y)=Z$ for preprocessing $P$ compels that index size be increased. Thus our algorithm obtains the names of variables for $P$ directly from the compressed $G$ using binary search.

The time to count all occurrences of a pattern $P$ in $S$ is $O\left(\frac{\log ^{*} u}{\varepsilon}(m \log n+\right.$ $\left.\operatorname{occ}_{c}(\log m \log u)\right)$ ) time, where $m=|P|, u=|S|$, and $o c c_{c}$ is the number of occurrences of a core in $T_{S}$, which is the maximal common subtrees of $T_{S}$ and $T_{P}$. The other two operations to locate/display are supported by an additional array requiring $n \log u$ bits of space to store the length of the substring encoded by each variable. This array can be reduced by level-wise sampling because the ESP tree is balanced. The time to display $S[i, j]$ is $O(j-i+\log u)$.

We compare the performance of ESP-index with other practical self-indexes [68] under several reasonable parameters. Beyond that, we give an experimental result for maximal common substring detection. These common substrings are obtained to find common variables in compressed $T_{S}$ and $T_{P}$. In these experiments, we conclude that the proposed index is efficient enough for cases where the pattern is long.

## 2 Pattern Matching on ESP

The set of all strings over an alphabet $\Sigma$ is denoted by $\Sigma^{*}$. The length of a string $w \in \Sigma^{*}$ is denoted by $|w|$. A string $a^{k}(k \geq 1)$ is also denoted by $a^{+}$, and is called
a repetition, denoted by $a^{++}$, if $k \geq 2 . S[i]$ and $S[i, j]$ denote the $i$-th symbol of $S$ and the substring from $S[i]$ to $S[j]$, respectively. We let $\log ^{(1)} u=\log u$, $\log ^{(i+1)} u=\log \log ^{(i)} u$, and $\log ^{*} u=\min \left\{i \mid \log ^{(i)} u \leq 1\right\}$, i.e. $\log ^{*} u \leq 5$ for $u \leq 2^{65536}$. Thus We can treat any $\log ^{*} u$ as constant in a practical sense.

We assume that any context-free grammar $G$ is admissible, i.e., $G$ derives just one string and for each variable $X$, exactly one production rule $X \rightarrow \alpha$ exists. The set of variables is denoted by $V(G)$, and the set of production rules, called dictionary, is denoted by $D(G)$. We also assume that for any $\alpha \in(\Sigma \cup V(G))^{*}$ at most one $X \rightarrow \alpha \in D(G)$ exists. We use $V$ and $D$ instead of $V(G)$ and $D(G)$ when $G$ is omissible. The string derived by $D$ from a string $S \in(\Sigma \cup V)^{*}$ is denoted by $S(D)$. For example, when $S=a Y Y$ and $D=\{X \rightarrow b c, Y \rightarrow X a\}$, we obtain $S(D)=a b c a b c a$.

### 2.1 Edit-sensitive parsing (ESP)

We start with the outline of ESP. For any string, it is uniquely partitioned to $w_{1} a_{1}^{++} w_{2} a_{2}^{++} \ldots w_{k} a_{k}^{++} w_{k+1}$ by maximal repetitions, where each $a_{i}$ is a symbol and $w_{i}$ is a string containing no repetition. Each $a_{i}^{++}$is called Type1 metablock, $w_{i}$ is called Type 2 metablock if $\left|w_{i}\right| \geq \log ^{*} n$, and other short $w_{i}$ is called Type 3 metablock, where if $\left|w_{i}\right|=1$, this is attached to $a_{i-1}^{++}$or $a_{i}^{++}$, with preference $a_{i-1}^{++}$when both are possible. Any metablock is longer than or equal to two.

Let $S$ be a metablock and $D$ be a current dictionary starting with $D=\emptyset$. We set $\operatorname{ESP}(S, D)=\left(S^{\prime}, D \cup D^{\prime}\right)$ for $S^{\prime}\left(D^{\prime}\right)=S$ and $S^{\prime}$ described as follows:

1. In case $S$ is Type1 or Type 3 of length $k \geq 2$,
(a) If $k$ is even, let $S^{\prime}=t_{1} t_{2} \cdots t_{k / 2}$, and make $t_{i} \rightarrow S[2 i-1,2 i] \in D^{\prime}$.
(b) If $k$ is odd, let $S^{\prime}=t_{1} t_{2} \cdots t_{(k-3) / 2} t$, and make $t_{i} \rightarrow S[2 i-1,2 i] \in D^{\prime}$, $t \rightarrow S[k-2] t^{\prime}$, and $t^{\prime} \rightarrow S[k-1, k] \in D^{\prime}$, where $t_{0}$ denotes the empty string for $k=3$.
2. In case $S$ is Type2,
(c) for the partitioned $S=s_{1} s_{2} \cdots s_{k}\left(2 \leq\left|s_{i}\right| \leq 3\right)$ by alphabet reduction, let $S^{\prime}=t_{1} t_{2} \cdots t_{k}$, and make $t_{i} \rightarrow X Y \in D^{\prime}$ if $s_{i}=X Y$ and make $t_{i} \rightarrow X Y^{\prime}, Y^{\prime} \rightarrow Y Z \in D^{\prime}$ if $s_{i}=X Y Z$.

Case (a) and (b) denote a typical left aligned parsing. For example, in case $S=a^{6}, S^{\prime}=x^{3}$ and $x \rightarrow a^{2} \in D^{\prime}$, and in case $S=a^{9}, S^{\prime}=x^{3} y$ and $x \rightarrow$ $a^{2}, y \rightarrow a y^{\prime}, y^{\prime} \rightarrow a a \in D^{\prime}$. In Case (c), we omit the description of alphabet reduction [3] because the details are unnecessary in this paper.

Finally, we define ESP for any string $S \in(\Sigma \cup V)^{*}$ that is partitioned to $S_{1} S_{2} \cdots S_{k}$ by $k$ metablocks; $\operatorname{ESP}(S, D)=\left(S^{\prime}, D \cup D^{\prime}\right)=\left(S_{1}^{\prime} \cdots S_{k}^{\prime}, D \cup D^{\prime}\right)$, where $D^{\prime}$ and each $S_{i}^{\prime}$ satisfying $S_{i}^{\prime}\left(D^{\prime}\right)=S_{i}$ are defined in the above.

Iteration of ESP is defined by $E S P^{i}(S, D)=E S P^{i-1}(E S P(S, D))$. In particular, $E S P^{*}(S, D)$ denotes the iterations of ESP until $|S|=1$. After computing $E S P^{*}(S, D)$, the final dictionary represents a rooted ordered binary tree deriving $S$, which is denoted by $E T(S)$. We refer to several characteristics of ESP, which are bases of our study.

Lemma 1. (Cormode and Muthukrishnan [3]) The height of $E T(S)$ is $O(\log |S|)$ and $E T(S)$ can be computed in time $O\left(|S| \log ^{*}|S|\right)$ time.

Lemma 2. (Cormode and Muthukrishnan [3]) Let $S=s_{1} s_{2} \cdots s_{k}$ be the partition of a Type 2 metablock $S$ by alphabet reduction. For any $1 \leq j \leq|S|$, the block $s_{i}$ containing $S[j]$ is determined by at most $S\left[j-\log ^{*}|S|-5, j+5\right]$.

### 2.2 Pattern embedding problem

We focus on the problem to find occurrences of $P$ by embedding of $P$ into a parsing tree. Given a parsing tree $T_{S}=E T(S)$ by $D_{S}$ and a pattern $P$, the key idea is to compute $\operatorname{ESP}\left(P, D_{S}\right)$ and find an embedding of resulting tree $T_{P}$ into $T_{S}$. The label of node $v$ is denoted by $L(v) \in \Sigma \cup V$, and $L\left(v_{1} \cdots v_{k}\right)=L\left(v_{1}\right) \cdots L\left(v_{k}\right)$. Let yield $(v)$ denote a substring of $S$ derived by $L(v)$, and yield $\left(v_{1} \cdots v_{k}\right)=$ yield $\left(v_{1}\right) \cdots \operatorname{yield}\left(v_{k}\right)$. We note that $T_{S}$ and $T_{P}$ are ordered binary trees.

Let us define some notations for ordered binary tree. The parent and left/right child of node $v$ are denoted by parent $(v)$ and $\operatorname{left}(v) / \operatorname{right}(v)$, respectively. For an internal node $v$, edges $(v, \operatorname{left}(v))$ and $(v, \operatorname{right}(v))$ are called left edge and right edge. Node $v$ is called the lowest right ancestor of $x$, denoted by $\operatorname{lra}(x)$, if $v$ is the lowest ancestor satisfying that the path from $v$ to $x$ contains at least one left edge. If $x$ is a rightmost descendant, $\operatorname{lra}(x)$ is undefined. Otherwise, $\operatorname{lra}(x)$ uniquely exists. The lowest left ancestor of $x$, denoted by $l l a(x)$, is similarly defined. Let $v_{1}, v_{2}$ be different nodes. If $\operatorname{lra}\left(v_{1}\right)=l l a\left(v_{2}\right)$, we call that $v_{1}, v_{2}$ are adjacent in this order, and we also call that $v_{1}$ is left adjacent to $v_{2}$ (or $v_{2}$ is right adjacent to $v_{1}$ ). We can derive the following characterization immediately.
fact $1 v_{1}$ is left adjacent to $v_{2}$ iff $v_{2}$ is a leftmost descendant of right $\left(\operatorname{lra}\left(v_{1}\right)\right)$, and $v_{2}$ is right adjacent to $v_{1}$ iff $v_{1}$ is a rightmost descendant of left (lla $\left.\left(v_{2}\right)\right)$.

Using this adjacency, we define an embedding of sequence of nodes, $v_{1}, \ldots, v_{k}$ $(k \geq 2)$, as follows: if $v_{i}, v_{i+1}$ are adjacent in this order $(1 \leq i \leq k-1)$ and $z$ is the lowest common ancestor of $v_{1}$ and $v_{k}$ denoted by $z=l c a\left(v_{1}, v_{k}\right)$, we state that the sequence is embedded in $z$ and it is denoted by $\left(v_{1}, \ldots, v_{k}\right) \prec z$. For such $z$, if yield $\left(v_{1} \cdots v_{k}\right)=P, z$ is called an occurrence node of $P$. We introduce a special type of strings to guarantee occurrences of $P$ in $S$.

Definition 1. A string $Q \in(\Sigma \cup V)^{*}$ of length $k$ satisfying the following condition is called an evidence of $P$ : node $z$ in $T_{S}$ is an occurrence node of $P$ iff there is a sequence $v_{1}, \ldots, v_{k}$ such that $\left(v_{1}, \ldots, v_{k}\right) \prec z$, $\operatorname{yield}\left(v_{1} \cdots v_{k}\right)=P$, and $L\left(v_{1} \cdots v_{k}\right)=Q$.

For any $T_{S}$ and $P$, at least one evidence of $P$ exists because $P$ itself is an evidence of $P$. We propose an algorithm to find as short evidence as possible for given $T_{S}$ and $P$; we also propose another algorithm to find all occurrences of $P$ in $S$ using obtained evidence.

Fig. 1. Algorithm to find evidence of pattern $P$ using dictionary $D_{S}$ from $E S P^{*}(S, D)$.

## 3 Algorithms and Data Structures

We propose two algorithms: one generates an evidence $Q$ of pattern $P$ from preprocessed $E S P^{*}(S, D)=\left(S^{\prime}, D_{S}\right)$, and the other algorithm finds the occurrence node $z$ of $P$ such that $\left(v, v_{1} \ldots, v_{k}\right) \prec z$ for given $Q$ and $v$ in $T_{S}$ satisfying $L(v)=Q[1]$. Finally, we propose data structures to access the next node $v^{\prime}$ satisfying $L\left(v^{\prime}\right)=L(v)$ for each $v$ in $T_{S}$. By this, all occurrences of $P$ are found to check if $\left(v, v_{1} \ldots, v_{k}\right) \prec z$ for all candidates $v$ satisfying $L(v)=Q[1]$.

### 3.1 Finding evidence of pattern

The algorithm to generate evidence $Q$ of pattern $P$ is described in Fig. 1. An outline follows. Input is a pair of pattern $P$ and final dictionary $D_{S}$ from $E S P^{*}(S, D) . P$ is partitioned to $P=\alpha \beta \gamma$ for the first metablock $\alpha$ and the last metablock $\gamma$. Depending on the type of metablocks, $P$ is further partitioned to $P=\alpha_{p} \alpha_{s} \beta \gamma_{p} \gamma_{s}$. The algorithm then updates current $Q=Q_{p} Q_{s}$ by $Q_{p} \leftarrow Q_{p} \alpha_{p}$ and $Q_{s} \leftarrow \gamma_{s} Q_{s}$, and $P \leftarrow P^{\prime}$ such that $P^{\prime}$ is the string produced by $\operatorname{ESP}\left(\alpha_{s} \beta \gamma_{p}, D_{S}\right)$. This is continued until $P$ is entirely deleted.

Lemma 3. Let $Q$ be an output string of Find_evidence $\left(P, D_{S}\right)$ and let $Q=$ $Q_{1} \cdots Q_{k}, Q_{i} \in\left\{q_{i}^{+}\right\}$for some symbol $q_{i}$ and $q_{i} \neq q_{i-1}, q_{i+1}$. Then $Q$ is an evidence of $P$ satisfying $k=O\left(\log m \log ^{*} u\right)$ for $m=|P|$.

Proof. For $P=\alpha \beta \gamma$ by the first/last metablock $\alpha / \gamma$, if $\alpha, \gamma$ are Type1 or $3, \alpha \beta \gamma$ is clearly an evidence of $P$. In this case, any occurrence of $\beta$ inside $S[n, m]=\alpha \beta \gamma$ is transformed to a same $\beta^{\prime}$ in this while loop. Thus, $\alpha \beta^{\prime} \gamma$ is an evidence of $P$.

If $\alpha, \gamma$ are Type2, by alphabet reduction, the prefix $\alpha$ of $P$ is partitioned to $\alpha=\alpha_{1} \cdots \alpha_{\ell}\left(2 \leq\left|\alpha_{i}\right| \leq 3\right)$. Then $j=\min \left(\log ^{*} u+5, \ell\right)$ is determined and $\alpha_{1} \cdots \alpha_{j}$ is appended to current $Q$, and a short suffix of $\gamma$ is similarly appended to $Q$. By Lemma 2, for any $S=x \beta y\left(|x| \geq \log ^{*} u+5,|y| \geq 5\right)$, any occurrence of $\beta$ inside $S[n, m]=x \beta y$ is transformed to a same $\beta^{\prime}$ in this while loop. The selected $j$ for $\alpha$ satisfies either $\left|\alpha_{1} \cdots \alpha_{j}\right| \geq \log ^{*} u+5$ or $\alpha_{1} \cdots \alpha_{j}=\alpha$ and the selected $j$ for $\beta$ similarly satisfies either $\left|\gamma_{r-j} \cdots \gamma_{r}\right| \geq 3$ or $\gamma_{r-j} \cdots \gamma_{r}=\gamma$. Thus we can obtain an evidence $\alpha_{1} \cdots \alpha_{j} \beta^{\prime} \gamma_{r-j} \cdots \gamma_{r}$ of $P$, and the other cases, one of $\alpha, \gamma$ is Type 1 or 3 and the other is Type2, are similarly proved.

Applying the above analysis to $\beta^{\prime}$ until its length becomes one, we can finally obtain $Q$ as an evidence of $P$. The number of iterations of $\operatorname{ESP}(P, D)=\left(P^{\prime}, D \cup\right.$ $\left.D^{\prime}\right)$ is $O(\log m)$ because $\left|P^{\prime}\right| \leq|P| / 2$. In $i$-th iteration, if current $Q=Q_{p} Q_{s}$ is updated to $Q_{p} \alpha_{p} \gamma_{s} Q_{s}, \alpha_{p} \gamma_{s}$ contains $O\left(\log ^{*} u\right)$ different symbols. Therefore we conclude $k=O\left(\log m \log ^{*} u\right)$.

### 3.2 Finding pattern occurrence

The algorithm to find an occurrence node of $P$ is described in Fig. 2. Using Find_evidence $\left(P, D_{S}\right)$ as subroutine, the algorithm Find_pattern $\left(Q, D_{S}, v, T_{S}\right)$ finds an embedding $\left(v, v_{1}, \ldots, v_{\ell}\right) \prec z$ satisfying $\operatorname{yield}\left(v v_{1} \cdots v_{\ell}\right)=P$ for fixed $v$ having the label $Q[1]$. By Lemma 3, such $z$ exists iff $z$ is an occurrence node of $P$. We show the correctness of this algorithm and the time complexity.

Lemma 4. Find_pattern $\left(Q, D_{S}, v, T_{S}\right)$ outputs node $z$ in $T_{S}$ iff $z$ is an occurrence node of $P$ satisfying $\left(v, v_{1}, \ldots, v_{\ell}\right) \prec z$ for some $v_{1}, \ldots, v_{\ell}$ and fixed $v$ in $T_{S}$. The time complexity is $O\left(\log m \log u \log ^{*} u\right)$ for $m=|P|$ and $u=|S|$.

Proof. We outline the proof. For any node $v$ in $T_{S}$ and $q \in \Sigma \cup V$, we can check if $\left(v, v^{\prime}\right) \prec z$ and $L\left(v^{\prime}\right)=q$ for some nodes $v^{\prime}, z$ in $O(\log u)$ time because such $v^{\prime}$ must be a leftmost descendant of $\operatorname{right}(\operatorname{lra}(v))$ and the height of $T_{S}$ is $O(\log u)$.

Let $Q=Q_{1} \cdots Q_{k}$ and $Q_{i} \in\left\{q_{i}^{++}\right\}$for some $q_{i} \in \Sigma \cup V$. If $Q$ contains no repetition and we assume that $\left(v_{1}, \ldots, v_{j}\right) \prec z$ is found for $Q_{1} \cdots Q_{j}=q_{1} \cdots q_{j}$. From $\left(v_{j}, v_{j+1}\right) \prec z^{\prime}$ and $L\left(v_{j+1}\right)=q_{j+1}$, we obtain $\left(v_{1}, \ldots, v_{j+1}\right) \prec l c a\left(z, z^{\prime}\right)$ in $O(\log u)$ time because $z, z^{\prime}$ must be in a same path. Thus an embedding of length at most $O\left(\log m \log ^{*} u\right)$ from $v$ is computed in $O\left(\log m \log u \log ^{*} u\right)$ time.

Let $Q_{j}=q^{\ell}$ for some symbol $q$ and $\ell \geq 2$. In ESP, any repetition is transformed to a shorter string by the left aligned parsing, and this transformation is continued as long as the resulting string contains a repetition. Thus, by $T_{S}$, an occurrence $S[s, t]=q^{\ell}$ is partitioned to $S[s, t]=S\left[s_{1}, t_{1}\right] S\left[s_{2}, t_{2}\right] \cdots S\left[s_{k}, t_{k}\right]$ such that $\left|S\left[s_{i}, t_{i}\right]\right|=2^{\ell_{i}} \geq 1, v_{i}$ in $T_{S}$ is the root of the complete binary tree deriving $S\left[s_{i}, t_{i}\right]$, and $k=O(\log \ell)$. Let $S\left[s_{i}, t_{i}\right]$ be the longest segment. We note that all symbols in current string are replaced by the next iteration of ESP. By this characteristic, when $S\left[s_{i}, t_{i}\right]$ is transformed to $S^{\prime}[j]$, the adjacent digram

                    \(v \leftarrow v_{a}, z \leftarrow l c a\left(z, z^{\prime}\right), \quad \ell \leftarrow \ell-2^{d} ;\)
            \}/* next complete binary tree until whole \(q_{j}^{++}\)is covered */
            else return 0 ;
        \(\} j \leftarrow j+1 ;\)
    \}
\}return \(z\);
```

Fig. 2. Algorithm to find occurrence node of $P$ starting with a given node $v$.
$S^{\prime}[j-2, j-1]$ derives a string containing $S\left[s_{1}, t_{1}\right] \cdots S\left[s_{i-1}, t_{i-1}\right]$ as its suffix. Thus, we can check if $\left(v_{1}, \ldots, v_{i-1}\right) \prec v_{p}$ for some $v_{p}$ in $O(\log \ell+\log u)=$ $O(\log m+\log u)$ time. The time to check if $\left(v_{p}, v_{i}\right) \prec z$ is $O(\log u)$. Hence, the time to embed $q^{\ell}$ is $O(\log m+\log u)$. Therefore, we find the occurrence of $P$ in $O\left(\log m \log ^{*} u(\log m+\log u)\right)=O\left(\log m \log u \log ^{*} u\right)$ time.

### 3.3 Data structures

We develop compact data structures for $\operatorname{Find}$ _pattern $\left(Q, D_{S}, v, T_{S}\right)$ to access a next occurrence of $v$ satisfying $L(v)=q$ for any $q \in \Sigma \cup V$. These improvements are achieved by two techniques: one is decomposition of DAG into left tree and right tree; the other is simulation of the reverse dictionary for pattern compression. First we treat decomposition of DAG $G$, which is a graph representation of $D_{S}$. Introducing a super $\operatorname{sink} v_{0}$ together with left and right edges from any sink of $G$ to $v_{0}, G$ can be modified to have the unique source/sink.
fact 2 Let $G$ be a DAG with single source/sink such that any node except the sink has exactly two children. For any in-branching spanning tree of $G$, the graph defined by the remaining edges is also an in-branching spanning tree of $G$.

Fig. 3. Succinct representation of a CFG by left tree and right tree in LOUDS bit-string with a permutation array.

In-branching spanning tree of $G$ constructed by left edges only is called left tree of $G$ and denoted by $T_{L}$. Thus the complementary tree is called right tree of $G$ and denoted by $T_{R}$. An example of $G$ and its left/right tree is shown in Fig. 3 with its succinct representation proposed hereafter.

When a DAG is decomposed into $T_{L}$ and $T_{R}$, the two are represented by succinct data structures for ordered trees and permutations. The bit-string by LOUDS in [4] for an ordered tree is defined as shown below. We visit any node in level-order from the root. As we visit a node $v$ with $d \geq 0$ children, we append $1^{d} 0$ to the bit-string beginning with the empty string. Finally, we add 10 as the prefix corresponding to an imaginary root, which is the parent of the root of the tree. For the $n$-node tree, LOUDS uses $2 n+o(n)$ bits to support constant time access to the parent, the $i$-th child, and the number of children of a node.

To traverse $G$ equivalent to $T_{S}$, we also need the correspondence of nodes in one tree to the other. For this purpose, we employ the succinct data structure for permutation in [5]. For a given permutation $\pi$ of $N=(0, \ldots, n-1)$, using $(1+\varepsilon) n \log n+o(n)$ bits of space, this data structure supports access to $\pi[i]$ in $O(1)$ time and $\pi^{-1}[i]$ in $O(1 / \varepsilon)$ time. For instance, if $\pi=(2,3,0,4,1)$, then $\pi[2]=0$ and $\pi^{-1}[4]=3$; that is, $\pi[i]$ is the $i$-th member of $\pi$ and $\pi^{-1}[i]$ is the position of the member $i$. For each node $i$ in $\operatorname{LOU} D S\left(T_{L}\right)$ and the corresponding node $j$ in $\operatorname{LOU} D S\left(T_{R}\right)$, we can get the relation by $\pi[i]=j$ and $\pi^{-1}[j]=i$.

We introduce another preprocess for $G$. For each iteration $\operatorname{ESP}(S, D)=$ $\left(S^{\prime}, D \cup D^{\prime}\right)$, we rename new variables in $D^{\prime}$ and $S^{\prime}$ by sorting ${ }^{1}$ all production rules $X \rightarrow X_{i} X_{j} \in D^{\prime}$ by $(i, j)$ : If the rank of $X \rightarrow X_{i} X_{j}$ is $k$, all occurrences of $X$ in $D^{\prime}$ and $S^{\prime}$ are renamed to $X_{k}$. For example, $D^{\prime}=\left\{X_{1} \rightarrow a b, X_{2} \rightarrow\right.$

[^1]$\left.b c, X_{3} \rightarrow a c, X_{4} \rightarrow a X_{2}\right\}$ and $S^{\prime}=X_{1} X_{2} X_{3} X_{4}$ are renamed to $D^{\prime}=\left\{X_{1} \rightarrow\right.$ $\left.a b, X_{2} \rightarrow a c, X_{3} \rightarrow a X_{4}, X_{4} \rightarrow b c\right\}$ and $S^{\prime}=X_{1} X_{4} X_{2} X_{3}$. Thus, variable $X_{i}$ in $G$ coincides with node $i$ in LOUDS of $T_{L}$ because they are both named in level-order. The $G$ in Fig. 3 is already renamed. By this improvement, the size of the array required for node correspondence is reduced to $n \log n$ bits of space.

Finally we simulate the reverse dictionary using $G$ for pattern compression. When $E S P^{*}(S, D)$ is computed, the naming function $H_{S}(X Y)=Z$ defined by $Z \rightarrow X Y \in D$ is realized by a hash function. However, because our index does not contain this data structure, we must simulate $H_{S}$ by only $G$ to obtain an evidence of $P$. By preprocessing, variable $X_{k}$ corresponds to the rank of its left hand side $X_{i} X_{j}$ for $X_{k} \rightarrow X_{i} X_{j}$. Conversely, given $X_{i}$, the children of $X_{i}$ in $T_{L}$ are already sorted by the ranks of their parents in $T_{R}$. Because LOUDS supports referring to the number of children and $i$-th child, $H_{S}\left(X_{i} X_{j}\right)=X_{k}$ is obtained by binary search in the following time complexity.

Lemma 5. The function $H_{S}(X Y)=Z$ is computable in $O\left(\frac{1}{\varepsilon} \log k\right)=O\left(\frac{1}{\varepsilon} \log n\right)$ time, where $k$ is the maximum degree and $n$ is the number of nodes of $T_{L}$.

Theorem 1. The size of ESP-index for string $S$ is $(1+\varepsilon) n \log n+4 n+o(n)$ bits of space, where $n$ is the number of variables in $T_{S}$. With pattern $P$, the number of its occurrence in $S$ is computable in $O\left(\frac{\log ^{*} u}{\varepsilon}\left(m \log n+o c c_{c}(\log m \log u)\right)\right.$ ) time for any $0<\varepsilon<1$, where $u=|S|, m=|P|$, and $o c c_{c}$ is the number of occurrences of a maximal common subtree in $T_{S}$ and $T_{P}$.

Proof. We can modify Find_pattern to find $\left(v_{1}, \ldots, v_{k}\right) \prec z$ from $v_{k}$ to $v_{1}$. Thus, starting with $v_{\ell}$ labeled by $q$ which encodes a longest string, we can find $z$ by $\left(v_{1}, \ldots, v_{\ell}\right) \prec z_{1},\left(v_{\ell}, \ldots, v_{k}\right) \prec z_{2}$, and $\left(v_{1}, \ldots, v_{k}\right) \prec l c a\left(z_{1}, z_{2}\right)=z$. This derives the time bound.

Locating and displaying are realized by an additional array to store the length of each variable. Since ESP tree is balanced, we obtain the bound below.

Corollary 1. With additional $n \log u+o(n)$ bits of space, ESP-index supports locating $P$ and displaying $S[i, j]$. The time to locate is the same as the case of counting, and the time to display a substring of length $m$ is $O(m+\log u)$.

## 4 Experiments

The environment is OS:CentOS 5.5 (64-bit), CPU:Intel Xeon E5504 2.0GHz (Quad) $\times 2$, Memory:144GB RAM, HDD:140GB, and Compiler:gcc 4.1.2. Datasets of English texts and DNA sequences of 200 MB each are obtained from the text collection in Pizza\&Chili Corpus. ${ }^{2}$

We first show how a long string is encoded by evidence of pattern in Fig. 4. This figure shows the maximum length of a string encoded by a symbol in evidence $Q$ according to the pattern length. We call this symbol in $Q$ a core. By

[^2]

Fig. 4. Encoded String Length by Core / Pattern Length.

Fig. 5. Index Size

Fig. 6. Construction Time
this result, sufficiently long common substrings in $S_{1}$ and $S_{2}$ are extracted as common variables in $E T\left(S_{1}\right)$ and $E T\left(S_{2}\right)$.

We next compare our ESP-index with other compressed indexes referred to as LZ-index (LZI) ${ }^{3}$, Compressed Suffix Array, and FM-index (CSA and FMI) ${ }^{4}$. These implementations are based on [6-8]. Due to the trade-off between construction time and index size, the indexes referred to above are examined with respect to reasonable parameters.

For ESP-index, we set $\varepsilon=1,1 / 4$ for permutation. In CSA, the option (-P1:L) means that the $\psi$ function is encoded by the gamma function and L specifies the block size for storing $\psi$. In FMI, (-P4:L) means that BW-text is represented by a Huffman-shaped wavelet tree with compressed bit-vectors and L specifies the sampling rate for storing rank values; (-P7:L) is the uncompressed version. In addition, these CSA and FMI do not make indexes for occurrence position.

The result of index size is shown in Fig. 5, where the space for locating is removed in all indexes except LZI; total index size including the space for locating/displaying is shown in the last two tables. Fig. 5 reveals that ESP-index is compact enough and comparable to CSA(-P1:64). The result of construction time is shown in Fig. 6. It is deduced from this result that ESP-index is comparable with FMI and CSA in the parameters in construction time, and slower than LZI. Further, a conspicuous difference is not seen in construction time.

[^3]

Fig. 7. Counting Time.

Fig. 7 shows the time to count the occurrences of pattern for both types of English and DNA. Random ${ }^{5}$ selection of pattern from the text was made 1000 times for each fixed pattern length; the search time indicates the average time. In this implementation, we modified our search algorithm so that the core $q$ is extracted by preprocessing a short prefix of $P$. And an occurrence of $P$ in $S$ is examined by finding $q$ and the exact match of the remaining substrings by partial decoding of the compressed $S$. By preliminary experiments, we determine the length of preprocessed prefix to be $1 \%$ of $u=|P|$ in practice. In DNA and ENGLISH, our method is faster than LZI and CSA in case of long patterns.

Finally, we show the results of locating and displaying in Table 1 and Table 2 respectively. Locating is achieved with an additional array to store the length of the encoded string for each variable. Because ESP tree is balanced, the size of this array is reduced by level-wise sampling; in this experiment, the array is developed only for variables produced in odd level of ESP. In CSA/FMI, option $-\mathrm{I}:\{\mathrm{D}\}:\{\mathrm{D} 2\}$ indicates sampling parameter D for suffix array and D2 for the reverse array. We get better results for $m=100$ than for $m=1000$. This is because the frequency of longer pattern becomes one and the search time is thus proportional to $m$. For comparison of theoretical time/space bound, see e.g. [2].

## 5 Discussion

We have another motivation to apply our data structures to practical use. Originally, ESP was proposed to solve a difficult variant of the edit distance by finding the maximal common substrings of two strings. Thus, our method will exhibit its ability if both strings are sufficiently long. Such situations are found in the framework of normalized compression distance [1] to compare two long strings directly. Improving $\log m \log u$ in time complexity is also an important work.
