## Abstract

This chapter provides an econometric methodology for inference in large-dimensional conditional factor models in finance. Changes in the business cycle and asset characteristics induce time variation in factor loadings and risk premia to be accounted for. The growing trend in the use of disaggregated data for individual securities motivates our focus on methodologies for a large number of assets. The beginning of the chapter outlines the concept of approximate factor structure in the presence of conditional information, and develops an arbitrage pricing theory for large-dimensional factor models in this framework. Then we distinguish between two different cases for inference depending on whether factors are observable or not. We focus on diagnosing model specification, estimating conditional risk premia, and testing asset pricing restrictions under increasing cross-sectional and time series dimensions. At the end of the chapter, we review some of the empirical findings and contrast analysis based on individual stocks and standard sets of portfolios. We also discuss the impact on computing time-varying cost of equity for a firm, and summarize differences between results for developed and emerging markets in an international setting.

# 1 Introduction

The objective of this chapter is to provide an econometric methodology for inference in conditional factor models in finance. We focus on diagnosing model specification, estimating conditional risk premia, and testing asset pricing restrictions under increasing cross-sectional and time series dimensions.

Financial and macroeconomic variables influence the risk-return trade-off. Conditional linear factor models aim at capturing their time-varying influence in a simple setting (see e.g. Shanken (1990), Cochrane (1996), Ferson and Schadt (1996), Ferson and Harvey (1991, 1999), Lettau and Ludvigson (2001), Petkova and Zhang (2005)). Time variation in risk biases time-invariant estimates of alphas and betas, and therefore asset pricing test conclusions (Jagannathan and Wang (1996), Lewellen and Nagel (2006), Boguth et al. (2011)). Ghysels (1998) discusses the pros and cons of modeling time-varying betas.

Risk premia measure financial compensation asked by investors for bearing systematic risk. The workhorse to estimate equity risk premia in a linear multi-factor setting is the two-pass cross-sectional regression method developed by Black, Jensen, and Scholes (1972) and Fama and MacBeth (1973). A series of papers address its large and finite sample properties for linear factor models with time-invariant coefficients, see e.g. Shanken (1985, 1992), Jagannathan and Wang (1998), Shanken and Zhou (2007), Kan, Robotti and Shanken (2013), and the review paper of Jagannathan, Skoulakis and Wang (2009). That early literature did not formally address statistical inference for equity risk premia in conditional linear factor models despite its empirical relevance.

In this chapter, we study how we can infer the time-varying behaviour of equity risk premia from large stock returns databases under conditional linear factor models. Our approach is inspired by the recent trend in macro-econometrics and forecasting methods trying to extract cross-sectional and time-series information simultaneously from large panels (see e.g. Stock and Watson (2002a,b), Bai (2003, 2009), Bai and Ng (2002, 2006), Forni, Hallin, Lippi and Reichlin (2000, 2004, 2005), Pesaran (2006)). Ludvigson and Ng (2007, 2009) exemplify this promising route when studying bond risk premia. Connor, Hagmann, and Linton (2012) show that large cross-sections exploit data more efficiently in a semiparametric characteristic-based factor model of stock returns. The theoretical framework underlying the Arbitrage Pricing Theory (APT) also inspires our approach relying on individual stocks returns. In this setting, approximate factor structures with nondiagonal error covariance matrices (Chamberlain and Rothschild (1983)) answer the

potential empirical mismatch of exact factor structures with diagonal error covariance matrices underlying the original APT of Ross (1976). Under weak cross-sectional dependence among idiosyncratic error terms, such approximate factor models generate no-arbitrage restrictions in large economies where the number of assets grows to infinity. This chapter develops an econometric methodology tailored to the APT framework. Indeed, we let the number of assets grow to infinity mimicking the large economies of financial theory.

As already mentioned, empirical work in asset pricing vastly relies on linear multi-factor models with either time-invariant coefficients (unconditional models) or time-varying coefficients (conditional models). The factor structure is often based on observable variables (empirical factors) and supposed to be rich enough to extract systematic risks while idiosyncratic risk is left over to the error term. Linear factor models are rooted in the Arbitrage Pricing Theory (Ross (1976), Chamberlain and Rothschild (1983)) or come from a loglinearization of nonlinear consumption-based models (Campbell (1996)). A central and practical issue is to determine whether there are one or more factors omitted in the chosen specification. If the set of observable factors is correctly specified, the errors are weakly cross-sectionally correlated, namely the covariance matrix of the error terms in the factor model has a fastly vanishing largest eigenvalue. If the set of observable factors is not correctly specified, the no-arbitrage restrictions derived from APT do not hold, and the risk premia estimated by the two-pass regression approach are meaningless. Even if the omitted factors are not priced, i.e., their associated risk premia are nil, direct computations of the limits of first pass and second pass estimators under misspecification show that second pass estimates do not converge to the risk premia of the priced factors, and that biases on betas and risk premia do not compensate each other. Besides, since the no arbitrage restrictions do not hold, we cannot simply say that the risk premia are the expected factor returns for models with traded factors. Hence detecting an omitted factor is also important in that case to produce correct expected excess returns from the no arbitrage restrictions. Given the large menu of factors available in the literature (the factor zoo of Cochrane (2011), see also Harvey et al. (2016), Harvey and Liu (2016)), we need a simple diagnostic criterion to decide whether we can feel comfortable with the chosen set of observable factors before proceeding further in the empirical analysis of large cross sectional equity data sets under the APT setting. For example, if the factor model passes the diagnostic, and we reject that alphas are zero using a GRS-type statistic (Gibbons et al. (1989)), it will not be because of an omitted factor. This chapter also aims at providing with such a diagnostic criterion.

This outline of this chapter is as follows. In Section 2, we consider a general framework of conditional linear factor model for asset returns in large economies. Section 3 presents inference in models with observable factors. Those two sections are largely inspired by Gagliardini, Ossola, Scaillet (2016, GOS) and Gagliardini, Ossola, Scaillet (2019, GOS2). We focus on diagnosing model specification, estimating conditional risk premia, and testing asset pricing restrictions under increasing cross-sectional and time series dimensions. In Section 4, we investigate models with unobservable factors. We look at empirical findings in Section 5. There we contrast analysis based on individual stocks and standard sets of portfolios. We also summarize differences between results for developed and emerging markets in an international setting. Section 5 gathers concluding remarks.

## 2 Large dimensional factor models

In this section, we consider a conditional linear factor model with time-varying coefficients. We work in a multi-period economy (Hansen and Richard (1987)) under an approximate factor structure (Chamberlain and Rothschild (1983)) with a continuum of assets as in GOS. Such a construction is close to the setting advocated by Al-Najjar (1995, 1998, 1999a) in a static framework with an exact factor structure. He discusses several key advantages of using a continuum economy in arbitrage pricing and risk decomposition. A key advantage is robustness of factor structures to asset repackaging (Al-Najjar (1999b); see GOS for a proof).

Let  $\mathcal{F}_t$ , with  $t = 1, 2, \dots$ , be the information available to investors. Without loss of generality, the continuum of assets is represented by the interval  $[0, 1]$ . The excess returns  $R_t(\gamma)$  of asset  $\gamma \in [0, 1]$  at dates  $t = 1, 2, \dots$  satisfy the conditional linear factor model:

$$R_t(\gamma) = a_t(\gamma) + b_t(\gamma)' f_t + \varepsilon_t(\gamma), \quad (1)$$

where vector  $f_t$  gathers the values of  $K$  factors at date  $t$ . The intercept  $a_t(\gamma)$  and factor sensitivities  $b_t(\gamma)$  are  $\mathcal{F}_{t-1}$ -measurable. The error terms  $\varepsilon_t(\gamma)$  have mean zero and are uncorrelated with the factors conditionally on information  $\mathcal{F}_{t-1}$ , and satisfy a weak cross-sectional dependence condition in the form of an upper bound on the largest eigenvalue of the error variance-covariance matrix (Assumption APR.3 in GOS). Moreover, we exclude asymptotic arbitrage opportunities in the economy: there are no portfolios that approximate arbitrage opportunities when the number of assets increases. In this setting, GOS show that the following

asset pricing restriction holds:

$$a_t(\gamma) = b_t(\gamma)' \nu_t, \text{ for almost all } \gamma \in [0, 1], \quad (2)$$

almost surely in probability, where random vector  $\nu_t \in \mathbb{R}^K$  is unique and is  $\mathcal{F}_{t-1}$ -measurable. The asset pricing restriction (2) is equivalent to  $E[R_t(\gamma)|\mathcal{F}_{t-1}] = b_t(\gamma)' \lambda_t$ , where  $\lambda_t = \nu_t + E[f_t|\mathcal{F}_{t-1}]$  is the vector of the conditional risk premia.

To have an empirically workable version of Equations (1) and (2), we define how the conditioning information is generated and how the model coefficients depend on it via simple functional specifications. The conditioning information  $\mathcal{F}_{t-1}$  contains  $Z_{t-1}$  and  $Z_{t-1}(\gamma)$ , for all  $\gamma \in [0, 1]$ , where the vector of lagged instruments  $Z_{t-1} \in \mathbb{R}^p$  is common to all stocks, the vector of lagged instruments  $Z_{t-1}(\gamma) \in \mathbb{R}^q$  is specific to stock  $\gamma$ , and  $Z_t = \{Z_t, Z_{t-1}, \dots\}$ . Vector  $Z_{t-1}$  may include the constant and past observations of the factors and some additional variables such as macroeconomic variables. Vector  $Z_{t-1}(\gamma)$  may include past observations of firm characteristics and stock returns. To end up with a linear regression model, we assume that: (i) the vector of factor loadings  $b_t(\gamma)$  is a linear function of lagged instruments  $Z_{t-1}$  (Shanken (1990), Ferson and Harvey (1991), Dumas and Solnik (1995)) and  $Z_{t-1}(\gamma)$  (Avramov and Chordia (2006)); (ii) the vector of risk premia  $\lambda_t$  is a linear function of lagged instruments  $Z_{t-1}$  (Dumas and Solnik (1995), Cochrane (1996), Jagannathan and Wang (1996)); (iii) the conditional expectation of  $f_t$  given the information  $\mathcal{F}_{t-1}$  depends on  $Z_{t-1}$  only and is linear (as e.g. if  $Z_t$  follows a Vector Autoregressive (VAR) model of order 1). Hence:

$$b_t(\gamma) = B(\gamma)Z_{t-1} + C(\gamma)Z_{t-1}(\gamma), \quad \lambda_t = \Lambda Z_{t-1}, \quad E(f_t|\mathcal{F}_{t-1}) = FZ_{t-1}, \quad (3)$$

for some unknown parameter matrices  $B(\gamma)$ ,  $C(\gamma)$ ,  $\Lambda$  and  $F$ .

To ensure that cross-sectional limits exist and are invariant to reordering of the assets, we introduce a sampling scheme as in GOS. We formalize it so that observable assets are random draws from an underlying population (Andrews (2005)). In particular, we rely on a sample of  $n$  assets by randomly drawing i.i.d. indices  $\gamma_i$  from the population according to a probability distribution  $G$  on  $[0, 1]$ . For any  $n, T \in \mathbb{N}$ , the excess returns are  $R_{i,t} = R_t(\gamma_i)$ . Similarly, let  $a_{i,t} = a_t(\gamma_i)$  and  $b_{i,t} = b_t(\gamma_i)$  be the coefficients,  $\varepsilon_{i,t} = \varepsilon_t(\gamma_i)$  be the error terms, and  $Z_{i,t} = Z_t(\gamma_i)$  be the stock specific instruments. By random sampling, we get a random coefficient panel model (e.g. Hsiao (2003), Chapter 6). Such a formalisation is key to

reconcile finance theory and econometric modelling. Without drawings, cross-sectional averages such as  $\frac{1}{n} \sum_i b_i$  correspond to deterministic sequences since the  $b_i$ s are then parameters. Working with the standard arbitrage pricing theory with approximate factor models has three issues as discussed in GOS. First, cross-sectional limits depend in general on the ordering of the financial assets, and there is no natural ordering between assets (firms). Second, we cannot exploit either a law of large numbers to guarantee existence of those limits, nor a central limit theorem to get distributional results. Third, the asset pricing restrictions derived under no arbitrage are not testable, the so-called Shanken critique (Shanken (1982)).

In available datasets, we do not observe asset returns for all firms at all dates due to entry and exit from the panel. Thus, we account for the unbalanced nature of the panel through a collection of indicator variables  $I_{i,t}$ , for any asset  $i$  at time  $t$ . We define  $I_{i,t} = 1$  if the return of asset  $i$  is observable at date  $t$ , and 0 otherwise (Connor and Korajczyk (1987)). In GOS and GOS2, we assume independence between the observability and return generating processes conditionally on observed variables, which amounts to a missing-at-random hypothesis (Rubin (1976)). A more general assumption would imply model nonlinearities.

Through appropriate redefinitions of the regressors and coefficients, GOS show that we can rewrite the model for Equations (1) and (2) as a generic random coefficient panel model:

$$R_{i,t} = x'_{i,t} \beta_i + \varepsilon_{i,t}, \quad (4)$$

where the regressor  $x_{i,t} = (x'_{1,i,t}, x'_{2,i,t})'$  has dimension  $d = d_1 + d_2$  and includes vectors  $x_{1,i,t} = (\text{vech}[X_t]', Z'_{t-1} \otimes Z'_{i,t-1})' \in \mathbb{R}^{d_1}$  and  $x_{2,i,t} = (f'_t \otimes Z'_{t-1}, f'_t \otimes Z'_{i,t-1})' \in \mathbb{R}^{d_2}$  with  $d_1 = p(p+1)/2 + pq$  and  $d_2 = K(p+q)$ . In vector  $x_{2,i,t}$ , the first components with common instruments take the interpretation of scaled factors (Cochrane (2005)), while the second components do not since they depend on  $i$ . The symmetric matrix  $X_t = [X_{t,k,l}] \in \mathbb{R}^{p \times p}$  is such that  $X_{t,k,l} = Z_{t-1,k}^2$ , if  $k = l$ , and  $X_{t,k,l} = 2Z_{t-1,k}Z_{t-1,l}$ , otherwise,  $k, l = 1, \dots, p$ , where  $Z_{t,k}$  denotes the  $k$ th component of the vector  $Z_t$ . The vector-half operator  $\text{vech}[\cdot]$  stacks the elements of the lower triangular part of a  $p \times p$  matrix as a  $p(p+1)/2 \times 1$  vector (see Chapter 2 in Magnus and Neudecker (2007) for properties of this matrix tool). The vector of coefficients  $\beta_i$  is a function of asset specific and common instrument parameters defining the dynamics of  $a_{i,t}$  and  $b_{i,t}$  in (2) and (3). We give their explicit forms in Section 3.2 where we first need them. Those forms are compatible

with restrictions from asymptotic no arbitrage. In matrix notation, for any asset  $i$ , we have

$$R_i = X_i \beta_i + \varepsilon_i, \quad (5)$$

where  $R_i$  and  $\varepsilon_i$  are  $T \times 1$  vectors. Regression (4) contains both explanatory variables that are common across assets (scaled factors) and asset-specific regressors. It includes models with time-invariant coefficients as a particular case. In such a case, the regressor reduces to  $x_t = (1, f_t')'$  and is common across assets, and the regression coefficient vector is  $\beta_i = (a_i, b_i)'$  of dimension  $d = K + 1$ .

### 3 Inference in models with observable factors

In Section 3.1, we first develop the diagnostic criterion for omitted factors before looking at the determination of the number of omitted factors. In Section 3.2, we discuss how to estimate risk premia via the two-pass regression methodology. We dedicate Section 3.3 to testing asset pricing restrictions. Throughout this chapter we assume a joint asymptotics in which the cross-sectional dimension  $n$  and time series dimension  $T$  grow such that:

$$n, T \rightarrow \infty, \quad n = O(T^{1/\underline{\gamma}}), \quad T = O(n^{\bar{\gamma}}), \quad (6)$$

with  $0 < \underline{\gamma} \leq \bar{\gamma} \leq \infty$ . Our asymptotics accommodate, among others, schemes such that  $T$  is much smaller than  $n$  (i.e.,  $\bar{\gamma} < 1$ ), or  $n$  and  $T$  are comparable ( $\underline{\gamma} = \bar{\gamma} = 1$ ). We omit technical details and refer the reader to GOS and GOS2 which give all required assumptions and proofs.

#### 3.1 Model diagnostic

In order to build the diagnostic criterion for the set of observable factors, we consider the following rival models:

$\mathcal{M}_1$  : the linear regression model (4), where the errors  $(\varepsilon_{i,t})$  are weakly cross-sectionally dependent,

and

$\mathcal{M}_2$  : the linear regression model (4), where the errors  $(\varepsilon_{i,t})$  satisfy a factor structure.

Under model  $\mathcal{M}_1$ , the observable factors fully capture the systematic risk, and the error terms do not feature pervasive forms of cross-sectional dependence (see GOS2 for a formal definition). This zero-factor case in the error terms should hold when we choose factors and instruments in a time-varying setting to build the variables  $x_{i,t}$ , so that their explanatory power for excess returns achieves weak cross-sectional correlation in the noise terms. Working with weak cross-sectional dependence, namely an approximate factor structure, avoids the stronger assumption of zero cross-sectional correlations, namely an exact factor structure. Under model  $\mathcal{M}_2$ , the following error factor structure holds

$$\varepsilon_{i,t} = \theta_i' h_t + u_{i,t}, \quad (7)$$

where the  $m \times 1$  vector  $h_t$  includes unobservable (i.e., latent or hidden) factors, and the  $u_{i,t}$  are weakly cross-sectionally correlated. The latent factors may include scaled factors to cover latent time-varying factor loadings with common instruments. Such scaled factors may come from misspecification of the functional form of the time-varying betas. Since the factors  $h_t$  are unobservable by definition, we cannot tell from the output of the diagnostic criterion whether they are pure or scaled factors. We cannot allow for latent time-varying factor loadings with stock-specific instruments in our setting because of identification issues in disentangling time-varying loadings and latent factors. This lack of identification means that we cannot estimate a generic time-varying unobservable structure from the spectral properties of a covariance matrix alone. A recent proposal in the direction of a functional specification for a time-varying  $\theta_{i,t}$  is the Instrumented Principal Components Analysis (IPCA) of Kelly et al. (2017, 2019), which we review in Section 4 together with other inference approaches for latent factor models with time-varying betas. IPCA works with linear loading specifications, with balanced panels, and without observable factors. The  $m \times 1$  vector  $\theta_i$  corresponds to the factor loadings, and the number  $m$  of common factors is assumed unknown. In vector notation, we have:

$$\varepsilon_i = H\theta_i + u_i, \quad (8)$$

where  $H$  is the  $T \times m$  matrix of unobservable factor values, and  $u_i$  is a  $T \times 1$  vector. In Equation (7), the  $\theta_i$ s and  $h_t$ s are also called interactive fixed effects in the panel literature (Pesaran (2006), Bai (2009), Moon and Weidner (2015)). King et al. (1994) use them to capture the correlation between the unanticipated innovations in observable descriptors of economic performance (e.g. industrial production, inflation, etc.)

and stock returns. Gobillon and Magnac (2016) use them to get treatment effect estimates in regional policy evaluation and characterize the generic bias induced by the popular difference-in-differences procedure. To diagnose the absence of omitted interactive effects is clearly important when applying the difference-in-differences procedure.

To compute the diagnostic criterion that checks whether the error terms are weakly cross-sectionally correlated or share at least one common factor, we estimate the generic panel model (4) by OLS applied asset by asset, and we get estimators

$$\hat{\beta}_i = \hat{Q}_{x,i}^{-1} \frac{1}{T_i} \sum_t I_{i,t} x_{i,t} R_{i,t}, \quad i = 1, \dots, n, \quad (9)$$

where  $\hat{Q}_{x,i} = \frac{1}{T_i} \sum_t I_{i,t} x_{i,t} x_{i,t}'$ . We get the residuals  $\hat{\varepsilon}_{i,t} = R_{i,t} - x_{i,t}' \hat{\beta}_i$ , where  $\hat{\varepsilon}_{i,t}$  is observable only if  $I_{i,t} = 1$ . In available panels, the random sample size  $T_i$  for asset  $i$  can be small, and the inversion of matrix  $\hat{Q}_{x,i}$  can be numerically unstable. To avoid unreliable estimates of  $\beta_i$ , we apply a trimming approach as in GOS. We define  $\mathbf{1}_i^X = \mathbf{1} \left\{ CN \left( \hat{Q}_{x,i} \right) \leq \chi_{1,T}, \tau_{i,T} \leq \chi_{2,T} \right\}$ , where  $CN \left( \hat{Q}_{x,i} \right) = \sqrt{\mu_1 \left( \hat{Q}_{x,i} \right) / \mu_d \left( \hat{Q}_{x,i} \right)}$  is the condition number of the  $d \times d$  matrix  $\hat{Q}_{x,i}$ ,  $\mu_1 \left( \hat{Q}_{x,i} \right)$  and  $\mu_d \left( \hat{Q}_{x,i} \right)$  are its largest, resp. its smallest, eigenvalue and  $\tau_{i,T} = T/T_i$ . We assume that the two sequences  $\chi_{1,T} > 0$  and  $\chi_{2,T} > 0$  diverge asymptotically. The first trimming condition  $\{CN \left( \hat{Q}_{x,i} \right) \leq \chi_{1,T}\}$  keeps in the cross-section only assets for which the time-series regression is not too badly conditioned. A too large value of  $CN \left( \hat{Q}_{x,i} \right)$  indicates multicollinearity problems and ill-conditioning (Belsley et al. (2004), Greene (2008)). The second trimming condition  $\{\tau_{i,T} \leq \chi_{2,T}\}$  keeps in the cross-section only assets for which the time series is not too short. We also use both trimming conditions in the proofs of the asymptotic results.

We consider the following diagnostic criterion:

$$\xi = \mu_1 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^X \bar{\varepsilon}_i \bar{\varepsilon}_i' \right) - g(n, T), \quad (10)$$

where the vector  $\bar{\varepsilon}_i$  of dimension  $T$  gathers the values  $\bar{\varepsilon}_{i,t} = I_{i,t} \hat{\varepsilon}_{i,t}$ , the penalty  $g(n, T)$  is such that  $g(n, T) \rightarrow 0$  and  $C_{n,T}^2 g(n, T) \rightarrow \infty$ , when  $n, T \rightarrow \infty$ , for  $C_{n,T}^2 = \min\{n, T\}$ . Bai and Ng (2002) consider several simple potential candidates for the penalty  $g(n, T)$ . In vector  $\bar{\varepsilon}_i$ , the unavailable residuals are replaced by zeros. Then we use the following model selection rule: we select  $\mathcal{M}_1$  if  $\xi < 0$ , and we select  $\mathcal{M}_2$  if  $\xi > 0$ , since (a)  $Pr(\xi < 0 \mid \mathcal{M}_1) \rightarrow 1$ , and (b)  $Pr(\xi > 0 \mid \mathcal{M}_2) \rightarrow 1$ , when

$n, T \rightarrow \infty$  under the asymptotics (6) with  $\bar{\gamma} \leq 1$ . This characterizes an asymptotically valid model selection rule, which treats both models symmetrically. The model selection rule is valid since (a) and (b) imply  $Pr(\mathcal{M}_1|\xi < 0) = Pr(\xi < 0|\mathcal{M}_1) Pr(\mathcal{M}_1) [Pr(\xi < 0|\mathcal{M}_1) Pr(\mathcal{M}_1) + Pr(\xi < 0|\mathcal{M}_2) Pr(\mathcal{M}_2)]^{-1} \rightarrow 1$ , as  $n, T \rightarrow \infty$ , by Bayes Theorem. Similarly, we have  $Pr(\mathcal{M}_2|\xi > 0) \rightarrow 1$ . The diagnostic criterion (10) does not deliver a testing procedure since we do not use a critical region based on an asymptotic distribution and a chosen significance level. The zero threshold corresponds to an implicit critical value yielding a test size asymptotically equal to zero since  $Pr(\xi < 0|\mathcal{M}_1) \rightarrow 1$ . The selection procedure is conservative in diagnosing zero factor by construction. We do not allow type I error under  $\mathcal{M}_1$  asymptotically, and really want to ensure that there is no omitted factor as required in the APT setting. This also means that we will not suffer from false discoveries related to a multiple testing problem (see e.g. Barras et al. (2010), Harvey et al. (2016)) in our empirical application where we consider a large variety of factor models on monthly and quarterly data. However, a possibility to achieve  $p$ -values is to use a randomisation procedure as in Trapani (2018) (see Bandi and Corradi (2014) and Corradi and Swanson (2006) for recent applications in econometrics). This type of procedure controls for an error of the first type, conditional on the information provided by the sample and under a randomness induced by auxiliary experiments.

The proof of the validity of the selection rule in GOS2 shows that the largest eigenvalue in (10) vanishes at a faster rate than the penalization term under  $\mathcal{M}_1$  when  $n$  and  $T$  go to infinity. Under  $\mathcal{M}_1$ , we expect a vanishing largest eigenvalue because of a lack of a common signal in the error terms. The negative penalizing term  $-g(n, T)$  dominates in (10), and this explains why we select the first model when  $\xi$  is negative. On the contrary, the largest eigenvalue remains bounded from below away from zero under  $\mathcal{M}_2$  when  $n$  and  $T$  go to infinity. Under  $\mathcal{M}_2$ , we have at least one non vanishing eigenvalue because of a common signal due to omitted factors. The largest eigenvalue dominates in (10), and this explains why we select the second model when  $\xi$  is positive. We can interpret the criterion (10) as the adjusted gain in fit including a single additional (unobservable) factor in model  $\mathcal{M}_1$ . We can rewrite (10) as  $\xi = SS_0 - SS_1 - g(n, T)$ , where  $SS_0 = \frac{1}{nT} \sum_i \sum_t \mathbf{1}_i^X \bar{\varepsilon}_{i,t}^2$  is the sum of squared errors and  $SS_1 = \min \frac{1}{nT} \sum_i \sum_t \mathbf{1}_i^X (\bar{\varepsilon}_{i,t} - \theta_i h_t)^2$ , where the minimization is w.r.t. the vectors  $H \in \mathbb{R}^T$  of factor values and  $\Theta = (\theta_1, \dots, \theta_n)' \in \mathbb{R}^n$  of factor loadings in a one-factor model, subject to the normalization constraint  $\frac{H'H}{T} = 1$ . Indeed, the largest

eigenvalue  $\mu_1 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^X \bar{\varepsilon}_i \bar{\varepsilon}_i' \right)$  corresponds to the difference between  $SS_0$  and  $SS_1$ . Furthermore, the criterion  $\xi$  is equal to the difference of the penalized criteria for zero- and one-factor models defined in Bai and Ng (2002) applied on the residuals. Indeed,  $\xi = PC(0) - PC(1)$ , where  $PC(0) = SS_0$ , and  $PC(1) = SS_1 + g(n, T)$ .

The proof of the validity of the selection rule in GOS2 exploits an asymptotic upper bound on the largest eigenvalue of a symmetric matrix based on similar arguments as in Geman (1980), Yin et al. (1988), and Bai and Yin (1993) without exploiting distributional results from random matrix theory valid when  $n$  is comparable with  $T$ . This exemplifies a key difference with the proportional asymptotics used in Onatski (2010) or Ahn and Horenstein (2013) for balanced panel without observable factors. The asymptotic setting in GOS2 accommodates the condition  $T/n = o(1)$  by having  $\bar{\gamma} < 1$  in (6), which agrees with the “large  $n$ , small  $T$ ” case that we face in empirical applications (for example, ten thousand individual stocks monitored over forty-five years of either monthly, or quarterly, returns). Another key difference of GOS2 w.r.t. the rest of the literature is the handling of unbalanced panels. We need to address explicitly the presence of the observability indicators  $I_{i,t}$  and the trimming devices  $\mathbf{1}_i^X$  in the proofs of the asymptotic results.

The recent literature on the properties of the two-pass regressions for fixed  $n$  and large  $T$  shows that the presence of useless factors (Kan and Zhang (1999a,b), Gospodinov et al. (2014)) or weak factor loadings (Kleibergen (2009)) does not affect the asymptotic distributional properties of factor loading estimates, but alters the ones of the risk premia estimates. Useless factors have zero loadings, and weak loadings drift to zero at rate  $1/\sqrt{T}$ . The vanishing rate of the largest eigenvalue of the empirical cross-sectional covariance matrix of the residuals does not change if we face useless factors or weak factor loadings in the observable factors under  $\mathcal{M}_1$ . The same remark applies under  $\mathcal{M}_2$ . Hence the selection rule remains the same since the probability of taking the right decision still approaches 1. If we have a number of useless factors or weak factor loadings strictly smaller than the number  $m$  of the omitted factors under  $\mathcal{M}_2$ , this does not impact the asymptotic rate of the diagnostic criterion. If we only have useless factors in the omitted factors under  $\mathcal{M}_2$ , we face an identification issue. We cannot distinguish such a specification from  $\mathcal{M}_1$  since it corresponds to a particular approximate factor structure. Again the selection rule remains the same since the probability of taking the right decision still approaches 1. In a “large  $n$ , large  $T$ ” setting, the estimates of the risk premia are unchanged since we keep an approximate factor structure and risk remuneration is only

attached to the strong factors in an APT framework. Here the presence of weak factors affects the pattern of the weak cross-sectional dependence and this only impacts variance estimator obtained by thresholding in the next section. On the contrary, if we have weak factors among the observable factors, Anatolyev and Mikusheva (2018) show that the conventional two-pass estimation procedure delivers inconsistent estimates of the risk premia. In the time-invariant case, they propose a modified procedure based on sample-splitting instrumental variables estimation at the second pass, and examine its asymptotic distribution.

Several papers in the empirical asset pricing literature focus on distinguishing between useful, useless and redundant factors starting from different points of view. Bryzgalova (2016) develops a shrinkage-based estimator that identify the weak factors (i.e., factors that do not correlate with the assets) and ensure consistency and normality to the estimates of the risk premia. Feng et al. (Forthcoming, 2019) propose a model-selection method to evaluate the risk prices of observable factors. Freyberger et al. (Forthcoming, 2019) propose a nonparametric method to determine which firm characteristics provide incremental information for the cross section of expected returns. Kozak et al. (2018) use model selection techniques to identify characteristics portfolios with a good explanatory power for returns. These papers do not deal with the identification of systematic factors for which the errors are weakly cross-sectionally correlated. The model selection procedure is not able to answer at our key question on the presence of omitted factors in the chosen specification.

In the previous lines, we have studied a diagnostic criterion to check whether the error terms are weakly cross-sectionally correlated or share at least one unobservable common factor. Hereafter we aim at answering: do we have one, two, or more omitted factors? The design of the diagnostic criterion to check whether the error terms share exactly  $k$  unobservable common factors or share at least  $k + 1$  unobservable common factors follows the same mechanics. We consider the following rival models:

$\mathcal{M}_1(k)$  : the linear regression model (4), where the errors  $(\varepsilon_{i,t})$  satisfy a factor structure with exactly  $k$  unobservable factors,

and

$\mathcal{M}_2(k)$  : the linear regression model (4), where the errors  $(\varepsilon_{i,t})$  satisfy a factor structure with at least  $k + 1$  unobservable factors.

The above definitions yield  $\mathcal{M}_1 = \mathcal{M}_1(0)$  and  $\mathcal{M}_2 = \mathcal{M}_2(0)$ . The diagnostic criterion exploits the  $(k + 1)$ th largest eigenvalue of the empirical cross-sectional covariance matrix of the residuals:

$$\xi(k) = \mu_{k+1} \left( \frac{1}{nT} \sum_i \mathbf{1}_i^X \bar{\varepsilon}_i \bar{\varepsilon}_i' \right) - g(n, T). \quad (11)$$

As discussed in Ahn and Horenstein (2013) (see also Onatski (2013)) for balanced panels, we can rewrite (11) as  $\xi(k) = SS_k - SS_{k+1} - g(n, T)$  where  $SS_k = \min \frac{1}{nT} \sum_i \sum_t \mathbf{1}_i^X (\bar{\varepsilon}_{i,t} - \theta_i' h_t)^2$  and the minimization is w.r.t.  $H \in \mathbb{R}^{T \times k}$  and  $\Theta = (\theta_1, \dots, \theta_n)' \in \mathbb{R}^{n \times k}$ . The criterion  $\xi(k)$  is equal to the difference of the penalized criteria for  $k$  and  $(k + 1)$ -factor models defined in Bai and Ng (2002) applied on the residuals. Indeed,  $\xi(k) = PC(k) - PC(k + 1)$ , where  $PC(k) = SS_k + kg(n, T)$  and  $PC(k + 1) = SS_{k+1} + (k + 1)g(n, T)$ .

The following model selection rule extends the previous one. We select  $\mathcal{M}_1(k)$  if  $\xi(k) < 0$ , and we select  $\mathcal{M}_2(k)$  if  $\xi(k) > 0$ , since (a)  $Pr[\xi(k) < 0 | \mathcal{M}_1(k)] \rightarrow 1$  and (b)  $Pr[\xi(k) > 0 | \mathcal{M}_2(k)] \rightarrow 1$ , when  $n, T \rightarrow \infty$ .

The proof of the validity of that second selection rule in GOS2 is more complicated than the proof of the first one. We need additional arguments to derive an asymptotic upper bound when we look at the  $(k + 1)$ th eigenvalue of a symmetric matrix, and this further complexity explains why we have developed the first selection rule as a special case. We rely on the Courant-Fischer min-max theorem and Courant-Fischer formula which represent eigenvalues as solutions of constrained quadratic optimization problems. We cannot directly exploit standard inequalities or bounds associated to a norm when we investigate the asymptotic behavior of the spectrum beyond its largest element. We know that the largest eigenvalue  $\mu_1(A)$  of a symmetric positive semi-definite matrix  $A$  is equal to its operator norm. There is no such useful norm interpretation for the smaller eigenvalues  $\mu_k(A)$ ,  $k \geq 2$ . We cannot directly exploit standard inequalities or bounds associated to a norm when we investigate the asymptotic behavior of the spectrum beyond its largest element. We cannot either exploit distributional results from random matrix theory since we also allow for  $T/n = o(1)$ . The slow convergence rate  $\sqrt{T}$  for the individual estimates  $\hat{\beta}_i$  also complicates the proof. In the presence of homogeneous regression coefficients  $\beta_i = \beta$  for all  $i$ , the estimate  $\hat{\beta}$  in Bai (2009) and Moon and Weidner (2015) has a fast convergence rate  $\sqrt{nT}$ . In that case, controlling for the estimation error in  $\hat{\varepsilon}_{i,t} = \varepsilon_{i,t} + x'_{i,t}(\beta - \hat{\beta})$  is straightforward due to the small asymptotic contribution of  $(\beta - \hat{\beta})$ . Hence

our results also apply to diagnose the absence of omitted interactive effects before applying a difference-in-differences procedure to avoid bias. The approach of Onatski (2010) requires the convergence of the upper edge of the spectrum (i.e., the first  $k$  largest eigenvalues of the covariance matrix, with  $k/T = o(1)$ ) to a constant, while the approach of Ahn and Horenstein (2013) requires an asymptotic lower bound on the eigenvalues. Extending these approaches for residuals of an unbalanced panel when  $T/n = o(1)$  looks challenging.

We can use the results of the selection rule in order to estimate the number of unobservable factors. It suffices to choose the minimum  $k$  such that  $\xi(k) < 0$ . GOS2 state the consistency of that estimate even in the presence of a degenerate distribution of the eigenvalues, and without needing to give conditions on the growth rate of the maximum possible number  $kmax$  of factors as in Onatski (2010) and Ahn and Horenstein (2013). We believe that this is a strong advantage since there are many possible choices for  $kmax$  and the estimated number of factors is sometimes sensitive to the choice of  $kmax$  (see the simulation results in those papers).

### 3.2 Estimation of conditional risk premia

In the linear regression (4), the coefficients associated to  $x_{1,i,t}$  and  $x_{2,i,t}$  are  $\beta_i = (\beta'_{1,i}, \beta'_{2,i})'$  such that

$$\begin{aligned}\beta_{1,i} &= \left( (N_p [(\Lambda - F)' \otimes I_p] \text{vec} [B'_i])', ((\Lambda - F)' \otimes I_q) \text{vec} [C'_i] \right)', & N_p &= \frac{1}{2} D_p^+ (W_p + I_{p^2}), \\ \beta_{2,i} &= \left( \text{vec} [B'_i]', \text{vec} [C'_i]' \right)',\end{aligned}\tag{12}$$

where parameter matrices  $B_i = B(\gamma_i)$ ,  $C_i = C(\gamma_i)$ ,  $\Lambda$  and  $F$  are defined in (3). The vector operator  $\text{vec}[\cdot]$  stacks the elements of a  $m \times n$  matrix as a  $mn \times 1$  vector. The matrix  $D_p^+$  is the  $p(p+1)/2 \times p^2$  Moore-Penrose inverse of the duplication matrix  $D_p$ , such that  $\text{vech}[A] = D_p^+ \text{vec}[A]$  for any matrix  $A \in \mathbb{R}^{p \times p}$  (see Chapter 3 in Magnus and Neudecker (2007)). The commutation matrix  $W_{p,q}$  is such that  $\text{vec}[A'] = W_{p,q} \text{vec}[A]$ , for any matrix  $A \in \mathbb{R}^{p \times q}$ , and  $W_p := W_{p,p}$ . When  $Z_t = 1$  and  $Z_{i,t} = 0$ , we have  $p = 1$  and  $q = 0$ , and the model in (4) reduces to a factor model with time-invariant coefficients and regressor  $x_t$  common across assets (scaled factors).

In Equations (12), the  $d_1 \times 1$  vector  $\beta_{1,i}$  is a linear transformation of the  $d_2 \times 1$  vector  $\beta_{2,i}$ . This clarifies that the asset pricing restriction (2) implies a constraint on the distribution of the random vector  $\beta_i$  via its

support. The coefficients of the linear transformation depend on matrix  $\Lambda - F$ . For the purpose of estimating the loading coefficients of the risk premia in matrix  $\Lambda$ , we rewrite the parameter restrictions as:

$$\beta_{1,i} = \beta_{3,i}\nu, \quad \nu = \text{vec} [\Lambda' - F'], \quad \beta_{3,i} = \left( [N_p (B'_i \otimes I_p)]', [W_{p,q} (C'_i \otimes I_p)]' \right)'. \quad (13)$$

Furthermore, we can relate the  $d_1 \times Kp$  matrix  $\beta_{3,i}$  to the vector  $\beta_{2,i}$  (see GOS):

$$\text{vec} [\beta'_{3,i}] = J_a \beta_{2,i}, \quad (14)$$

where the  $d_1 p K \times d_2$  block-diagonal matrix of constants  $J_a$  is given by  $J_a = \begin{pmatrix} J_1 & 0 \\ 0 & J_2 \end{pmatrix}$  with diagonal blocks  $J_1 = W_{p(p+1)/2, pK} (I_K \otimes [(I_p \otimes N_p) (W_p \otimes I_p) (I_p \otimes \text{vec} [I_p])])$  and  $J_2 = W_{pq, pK} (I_K \otimes [(I_p \otimes W_{p,q}) (W_{p,q} \otimes I_p) (I_q \otimes \text{vec} [I_p])])$ . The link (14) is instrumental in deriving the asymptotic results. In the time-invariant setting,  $\beta_{1,i} = a_i$ ,  $\beta_{2,i} = \beta_{3,i} = b_i$ , and the matrix  $J$  is equal to  $I_K$ . Hence, Equations (13) and (14) in the time-varying case are the counterparts of restriction  $a_i = b'_i \nu$  in the time-invariant case.

Let us now describe the two-pass approach to estimate the factor risk premia. The first pass consists in computing time-series OLS estimators  $\hat{\beta}_i$ , and was described in the previous subsection (see Equation (9)). The second pass consists in computing a cross-sectional estimator of  $\nu$  by regressing the  $\hat{\beta}_{1,i}$  on the  $\hat{\beta}_{3,i}$  keeping non-trimmed assets only. We use a multivariate WLS approach. The weights are estimates of  $w_i = (\text{diag} [v_i])^{-1}$ , where the matrices  $v_i$  are the asymptotic variances of the standardized errors  $\sqrt{T} (\hat{\beta}_{1,i} - \hat{\beta}_{3,i}\nu)$  in the cross-sectional regression for large  $T$ . We have  $v_i = \tau_i C'_{\nu} Q_{x,i}^{-1} S_{ii} Q_{x,i}^{-1} C_{\nu}$ , where  $Q_{x,i} = E [x_{i,t} x'_{i,t} | \gamma_i]$ ,  $S_{ii} = \text{plim}_{T \rightarrow \infty} \frac{1}{T} \sum_t \sigma_{ii,t} x_{i,t} x'_{i,t} = E [\varepsilon_{i,t}^2 x_{i,t} x'_{i,t} | \gamma_i]$ ,  $\tau_i = \text{plim}_{T \rightarrow \infty} \tau_{i,T} = E [I_{i,t} | \gamma_i]^{-1}$ ,  $C_{\nu} = (E'_1 - (I_{d_1} \otimes \nu') J_a E'_2)'$ , with  $E_1 = (I_{d_1} : 0_{d_1 \times d_2})'$ ,  $E_2 = (0_{d_2 \times d_1} : I_{d_2})'$ . We use the estimates  $\hat{v}_i = \tau_{i,T} C'_{\hat{\nu}_1} \hat{Q}_{x,i}^{-1} \hat{S}_{ii} \hat{Q}_{x,i}^{-1} C_{\hat{\nu}_1}$ , where  $\hat{S}_{ii} = \frac{1}{T_i} \sum_t I_{i,t} \hat{\varepsilon}_{i,t}^2 x_{i,t} x'_{i,t}$ ,  $\hat{\varepsilon}_{i,t} = R_{i,t} - \hat{\beta}'_i x_{i,t}$  and  $C_{\hat{\nu}_1} = (E'_1 - (I_{d_1} \otimes \hat{\nu}'_1) J_a E'_2)'$ . To estimate  $C_{\nu}$ , we use the multivariate OLS estimator  $\hat{\nu}_1 = \left( \sum_i \mathbf{1}_i^X \hat{\beta}'_{3,i} \hat{\beta}_{3,i} \right)^{-1} \sum_i \mathbf{1}_i^X \hat{\beta}'_{3,i} \hat{\beta}_{1,i}$ , i.e., a first-step estimator with unit weights. The WLS estimator is:

$$\hat{\nu} = \hat{Q}_{\beta_3}^{-1} \frac{1}{n} \sum_i \hat{\beta}'_{3,i} \hat{w}_i \hat{\beta}_{1,i}, \quad (15)$$

where  $\hat{Q}_{\beta_3} = \frac{1}{n} \sum_i \hat{\beta}'_{3,i} \hat{w}_i \hat{\beta}_{3,i}$  and  $\hat{w}_i = \mathbf{1}_i^X (\text{diag}[\hat{v}_i])^{-1}$ . Weighting accounts for the statistical precision of the first-pass estimates and includes trimming. The final estimator of the risk premia is  $\hat{\lambda}_t = \hat{\Lambda} Z_{t-1}$ , where we deduce  $\hat{\Lambda}$  from the relationship  $\text{vec}[\hat{\Lambda}'] = \hat{v} + \text{vec}[\hat{F}']$  with the estimator  $\hat{F}$  obtained by a SUR regression of factors  $f_t$  on lagged instruments  $Z_{t-1}$ :  $\hat{F} = \sum_t f_t Z'_{t-1} \left( \sum_t Z_{t-1} Z'_{t-1} \right)^{-1}$ .

In the time-invariant case, the estimator of the risk premia vector simplifies to

$$\hat{\lambda} = \hat{v} + \frac{1}{T} \sum_t f_t, \quad \hat{v} = \hat{Q}_b^{-1} \frac{1}{n} \sum_i \hat{w}_i \hat{b}_i \hat{a}_i, \quad (16)$$

where  $\hat{Q}_b = \frac{1}{n} \sum_i \hat{w}_i \hat{b}_i \hat{b}'_i$  and  $(\hat{a}_i, \hat{b}'_i)' = \hat{Q}_{x,i}^{-1} \frac{1}{T_i} \sum_t I_{i,t} x_t R_{i,t}$ . Hence, we estimate the model coefficients  $a_i$  and  $b_i$  by time series OLS regression, and the risk premium by cross-sectional WLS regression of the  $\hat{a}_i$ s on the  $\hat{b}_i$ s augmented by the factor mean. Moreover, under conditional homoskedasticity  $\sigma_{ii,t} = \sigma_{ii}$  and a balanced panel  $\tau_{i,T} = 1$ , we have  $v_i = c'_\nu Q_x^{-1} c_\nu \sigma_{ii}$ , where  $c_\nu = (1, -\nu)'$  and  $Q_x = E[x_t x'_t]$ . Then,  $v_i$  is directly proportional to  $\sigma_{ii}$ , and we can simply pick the weights as  $\hat{w}_i = \hat{\sigma}_{ii}^{-1}$ , where  $\hat{\sigma}_{ii} = \frac{1}{T} \sum_t \hat{\varepsilon}_{i,t}^2$  (Shanken (1992)). In the time-invariant case, we can avoid the trimming on the condition number if we substitute  $\hat{Q}_x = \frac{1}{T} \sum_t x_t x_t$  for  $\hat{Q}_{x,i}$  in the first-pass estimator definition. However, this increases the asymptotic variance of the bias corrected estimator of  $\nu$ , and does not extend to the time-varying case. Starting from the asset pricing restriction  $E[R_{i,t}] = b'_i \lambda$  in the time-invariant case, another estimator of  $\lambda$  is  $\bar{\lambda} = \hat{Q}_b^{-1} \frac{1}{n} \sum_i \hat{w}_i \hat{b}_i \bar{R}_i$ , where  $\bar{R}_i = \frac{1}{T_i} \sum_t I_{i,t} R_{i,t}$ . This estimator is numerically equivalent to  $\hat{\lambda}$  in the balanced case, where  $I_{i,t} = 1$  for all  $i$  and  $t$ . In the unbalanced case, it is equal to  $\bar{\lambda} = \hat{v} + \hat{Q}_b^{-1} \frac{1}{n} \sum_i \hat{w}_i \hat{b}_i \hat{b}'_i \bar{f}_i$ , where  $\bar{f}_i = \frac{1}{T_i} \sum_t I_{i,t} f_t$ . Estimator  $\bar{\lambda}$  is often studied by the literature (see, e.g., Shanken (1992), Kandel and Stambaugh (1995), Jagannathan and Wang (1998)), and is also consistent. Estimating  $E[f_t]$  with a simple average of the observed factor instead of a weighted average based on estimated betas simplifies the form of the asymptotic distribution in the unbalanced case. This explains our preference for  $\hat{\lambda}$  over  $\bar{\lambda}$ .

GOS show consistency and asymptotic normality of  $\hat{v}$  and  $\hat{\Lambda}$  under the asymptotics in (6) with  $1/\underline{\gamma} < 3$ . The estimator  $\hat{v}$  has a fast convergence rate  $\sqrt{nT}$  and features an asymptotic bias term:  $\sqrt{nT} \left( \hat{v} - \nu - \hat{B}_\nu/T \right) \Rightarrow N(0, \Sigma_\nu)$ . Both  $\hat{\beta}_{1,i}$  and  $\hat{\beta}_{3,i}$  in the definition of  $\hat{v}$  contain an estimation error; for  $\hat{\beta}_{3,i}$ , this is the well-known Error-In-Variable (EIV) problem. The EIV problem does not impede

consistency since we let  $T$  grow to infinity. However, it induces a bias term  $\hat{B}_\nu/T$  which centers the asymptotic distribution of  $\hat{\nu}$  (see GOS for details). Ang, Liu, and Schwarz (2010) look at a maximum likelihood analysis with a single asymptotic treatment (large  $T$ ,  $n$  fixed) and balanced panel under a particular approximate Gaussian factor structure (block diagonal covariance matrix of residuals) and time-invariant coefficients. Their setting further assumes that the factors have zero mean. Such an assumption gives  $\hat{\lambda} = \hat{\nu}$  in a time-invariant setting. Under a zero mean (or a known mean, i.e., not to be estimated), the asymptotic variance of  $\hat{\lambda}$  corresponds to the asymptotic variance  $\Sigma_\nu$  of  $\hat{\nu}$  and the rate of convergence is  $\sqrt{nT}$ . On the contrary, if we do not know the mean of the factor and need to estimate it, we have  $\hat{\lambda} = \hat{\nu} + \frac{1}{T} \sum f_t$ . The asymptotic variance of  $\hat{\lambda}$  corresponds to the asymptotic variance  $\Sigma_f$  of the sample average of the factors, and the rate of convergence is  $\sqrt{T}$ . Jagannathan and Wang (2002) is an early reference on the impact of knowing or not the mean of the factors for asymptotic analysis. With an unknown mean, only the variability of the factor drives the asymptotic distribution of  $\hat{\lambda}$ , since the estimation error  $O_p\left(1/\sqrt{T}\right)$  of the sample average  $\frac{1}{T} \sum_t f_t$  dominates the estimation error  $O_p\left(1/\sqrt{nT} + 1/T\right)$  of  $\hat{\nu}$ . This result is an oracle property for  $\hat{\lambda}$ , namely that its asymptotic distribution is the same irrespective of the knowledge of  $\nu$ . This property is in sharp difference with the single asymptotics with a fixed  $n$  and  $T \rightarrow \infty$ . In the balanced case and with homoskedastic errors for the time-invariant case, Theorem 1 of Shanken (1992) shows that the rate of convergence of  $\hat{\lambda}$  is  $\sqrt{T}$  and that its asymptotic variance is  $\Sigma_{\lambda,n} = \Sigma_f + \frac{1}{n}\Sigma_{\nu,n}$ , for fixed  $n$  and  $T \rightarrow \infty$ . The two components in  $\Sigma_{\lambda,n}$  come from estimation of  $E[f_t]$  and  $\nu$ , respectively (see also Theorem 1 in Jagannathan and Wang (1998), or Theorem 3.2 in Jagannathan, Skoulakis, and Wang (2009)). Letting  $n \rightarrow \infty$  gives  $\Sigma_f$  under weak cross-sectional dependence. Thus, exploiting the full cross-section of assets improves efficiency asymptotically, and the positive definite matrix  $\Sigma_{\lambda,n} - \Sigma_f$  corresponds to the efficiency gain. Using a large number of assets instead of a small number of portfolios does help to eliminate the contribution coming from estimation of  $\nu$ .

GOS suggest exploiting the analytical bias correction  $\hat{B}_\nu/T$  and using estimator  $\hat{\nu}_B = \hat{\nu} - \frac{1}{T}\hat{B}_\nu$  instead of  $\hat{\nu}$ . In the time-invariant setting,  $\hat{\lambda}_B = \hat{\nu}_B + \frac{1}{T} \sum_t f_t$  delivers a bias-free estimator of  $\lambda$  at order  $1/T$ , which shares the same root- $T$  asymptotic distribution as  $\hat{\lambda}$ . We can relate that suggestion to bias-corrected estimation accounting for the well-known incidental parameter problem (Neyman and Scott (1948)) in the panel literature (see Lancaster (2000) for a review). To highlight the main idea, let us focus

on the model with time-invariant coefficients. We can write the factor model under restriction  $a_i = b_i' \nu$  as  $R_{i,t} = b_i'(f_t + \nu) + \varepsilon_{i,t}$ . In the likelihood setting of Hahn and Newey (2004) (see also Hahn and Kuersteiner (2002)), the  $b_i$ s correspond to the individual fixed effects and  $\nu$  to the common parameter of interest. Available results on the fixed-effect approach tell us: (i) the ML estimator of  $\nu$  is inconsistent if  $n$  goes to infinity while  $T$  is held fixed, (ii) the ML estimator of  $\nu$  is asymptotically biased even if  $T$  grows at the same rate as  $n$ , (iii) an analytical bias correction may yield an estimator of  $\nu$  that is root- $(nT)$  asymptotically normal and centered at the truth if  $T$  grows faster than  $n^{1/3}$ . The two-pass estimators  $\hat{\nu}$  and  $\hat{\nu}_B$  exhibit the properties (i)-(iii) as expected by analogy with unbiased estimation in large panels. This clear link with the incidental parameter literature highlights another advantage of working with  $\nu$  in the second-pass regression. Chamberlain (1992) considers a general random coefficient model nesting the factor model with time-invariant coefficients. He establishes asymptotic normality of an estimator of  $\nu$  for fixed  $T$  and balanced panel data. His estimator does not admit a closed-form and requires a numerical optimization. This leads to computational difficulties in the conditional setting. This also makes the study of his estimator under double asymptotics and cross-sectional dependence challenging. Recent advances on the incidental parameter problem in random coefficient models for fixed  $T$  are Arellano and Bonhomme (2012) and Bonhomme (2012).

Finally, let us discuss confidence intervals. Their construction for components of  $\hat{\Lambda}$  to achieve valid asymptotic coverage is straightforward through the use of standard HAC estimators such as in Newey and West (1994) or Andrews and Monahan (1992). The construction of confidence intervals for the components of  $\hat{\nu}$  is more difficult. Indeed, the asymptotic variance involves a limiting double cross-sectional sum scaled by  $n$  and not  $n^2$ . A naive approach consists in replacing unknown quantities by any consistent estimator, but this does not work here. To handle this, GOS rely on recent proposals in the statistical literature on consistent estimation of large-dimensional sparse covariance matrices by hard thresholding (Bickel and Levina (2008), El Karoui (2008)). Fan, Liao, and Mincheva (2011) focus on the estimation of the variance-covariance matrix of the errors in large balanced panel with nonrandom time-invariant coefficients and i.i.d. disturbances.

### 3.3 Testing asset pricing restrictions

From (13), the null hypothesis underlying the asset pricing restriction (2) is

$$\mathcal{H}_0 : \text{there exists } \nu \in \mathbb{R}^{pK} \text{ such that } \beta_1(\gamma) = \beta_3(\gamma)\nu, \text{ for almost all } \gamma \in [0, 1],$$

where  $\beta_1(\gamma)$  and  $\beta_3(\gamma)$  are defined as  $\beta_{1,i}$  and  $\beta_{3,i}$  in Equations (12) and (13) replacing  $B(\gamma)$  and  $C(\gamma)$  for  $B_i$  and  $C_i$ . This null hypothesis is written on the continuum of assets. Under  $\mathcal{H}_0$ , we have  $E[(\beta_{1,i} - \beta_{3,i}\nu)'(\beta_{1,i} - \beta_{3,i}\nu)] = 0$ . Since we estimate  $\nu$  via the WLS cross-sectional regression of the estimates  $\hat{\beta}_{1,i}$  on the estimates  $\hat{\beta}_{3,i}$ , GOS suggest a test based on the weighted sum of squared residuals SSR of the cross-sectional regression. The weighted SSR is  $\hat{Q}_e = \frac{1}{n} \sum_i \hat{e}'_i \hat{w}_i \hat{e}_i$ , with  $\hat{e}_i = \hat{\beta}_{1,i} - \hat{\beta}_{3,i} \hat{\nu} = C'_{\hat{\nu}} \hat{\beta}_i$ , which is an empirical counterpart of  $E[(\beta_{1,i} - \beta_{3,i}\nu)' w_i (\beta_{1,i} - \beta_{3,i}\nu)]$ . Let us now introduce the following statistic  $\hat{\xi}_{nT} = T\sqrt{n} \left( \hat{Q}_e - \frac{1}{T} \hat{B}_\xi \right)$ , where the recentering term simplifies to  $\hat{B}_\xi = d_1$  thanks to the weighting scheme. Under the null hypothesis  $\mathcal{H}_0$  and asymptotics (6) with  $1/\underline{\gamma} < 2$ , GOS prove  $\hat{\xi}_{nT} \Rightarrow N(0, \Sigma_\xi)$ , and show how to get a feasible testing procedure by exploiting a consistent estimate of the asymptotic variance  $\Sigma_\xi$ .

Finally, GOS derive a test for the null hypothesis when the factors come from tradable assets, i.e., are portfolio excess returns:

$$\mathcal{H}_0 : \beta_1(\gamma) = 0 \text{ for almost all } \gamma \in [0, 1],$$

against the alternative hypothesis

$$\mathcal{H}_1 : E[\beta'_{1,i} \beta_{1,i}] > 0.$$

We only have to substitute  $\hat{Q}_a = \frac{1}{n} \sum_i \hat{\beta}'_{1,i} \hat{w}_i \hat{\beta}_{1,i}$  for  $\hat{Q}_e$ . Since the constrained form of  $\beta_{1,i}$  in (13) comes from (2), we take directly into account the no-arbitrage restrictions imposed by the model specification. This gives an extension of Gibbons, Ross and Shanken (1989) to the conditional case with double asymptotics. Implementing the original GRS test, which uses a weighting matrix corresponding to an inverted estimated large variance-covariance matrix, becomes quickly problematic. We face a large number  $nd_1$  of restrictions; each  $\beta_{1,i}$  is of dimension  $d_1 \times 1$ , and the estimated covariance matrix to invert is of dimension  $nd_1 \times nd_1$ . We expect to compensate the potential loss of power induced by a diagonal weighting via the larger number of restrictions since we use a large number  $n$  of assets. Monte Carlo simulations in GOS show that the

test exhibits good power properties against both risk-based and non risk-based alternatives (e.g. MacKinlay (1995)) already for a thousand assets with a time series dimension similar to the one in the empirical analysis. Fan et al. (2015) discuss power enhancement in high dimensional cross-sectional tests.

Finally, let us mention that Ma et al. (forthcoming, 2019) has recently developed a test of the nullity of the alphas when the alphas and betas are taken as smooth functions of time in a “large  $n$ , large  $T$ ” setting (see Li and Yang (2011) and Ang and Kristensen (2012) for the “small  $n$ , large  $T$ ” case).

## 4 Inference in models with unobservable factors

In this section, we review methodologies for inference in large-dimensional conditional factor models when the factor values are unobserved by the econometrician. In this setting, we cannot use standard Principal Component Analysis (PCA) to extract the factor space since PCA assumes either constant factor loadings (Stock and Watson (2002a,b), Bai (2003, 2009), Bai and Ng (2002, 2006)) or at most small instabilities in the factors loadings (Bates et al. (2013)). Intuitively, invalidity of standard PCA in a conditional framework comes from a factor with time-varying loading being potentially confused with multiple static factors.

The model specification is:

$$R_{i,t} = a_{i,t} + b'_{i,t}f_t + \varepsilon_{i,t}, \quad (17)$$

where  $f_t$  is the  $K$ -dimensional vector of the unobservable factor values. Several estimation approaches are based on assuming that the intercepts  $a_{i,t}$  and the factor loadings  $b_{i,t}$  are either parametric or nonparametric functions of lagged time-varying observable variables, with or without imposing the no arbitrage restrictions. Among the parametric approaches, Kelly et al. (2017, 2019) model the coefficients as linear functions of characteristics plus some noise term:

$$a_{i,t} = A'Z_{i,t-1} + \nu_{i,t}, \quad (18)$$

$$b_{i,t} = B'Z_{i,t-1} + \eta_{i,t}, \quad (19)$$

where  $Z_{i,t}$  is a vector of observed characteristics,  $A$  and  $B$  are a vector and a matrix of unknown parameters, and  $\nu_{i,t}$  and  $\eta_{i,t}$  are unobservable noise terms. By plugging (18) and (19) into (17), we get  $R_{i,t} = Z'_{i,t-1}A + Z'_{i,t-1}Bf_t + \varepsilon^*_{i,t}$ , where the composite error term is  $\varepsilon^*_{i,t} = \varepsilon_{i,t} + \nu_{i,t} + \eta'_{i,t}f_t$ . The Instrumented Principal

Component Analysis (IPCA) estimator of Kelly et al. (2017, 2019) is obtained by minimizing a LS criterion w.r.t. parameter matrices  $A$ ,  $B$  and the factor values  $f_t$ ,  $t = 1, \dots, T$ , i.e.,  $\min_{\alpha, B, f_t, t=1, \dots, T} \sum_{i=1}^n \sum_{t=1}^T (R_{i,t} - Z'_{i,t-1}A - Z'_{i,t-1}Bf_t)^2$  subject to the static normalization restrictions that the matrix  $BB'$  is diagonal, and  $\frac{1}{T} \sum_{t=1}^T f_t = 0$ ,  $\frac{1}{T} \sum_{t=1}^T f_t f_t' = I_K$ . They propose an iterative numerical procedure to perform the optimization.

In the nonparametric setting, an early contribution is provided by an extension of the model considered by Connor and Linton (2007) and Connor et al. (2012), in which the factor loadings are functions of observed covariates:

$$R_{i,t} = \sum_{k=1}^K b_k(Z_{k,i,t-1})f_{k,t} + \varepsilon_{i,t}, \quad (20)$$

where  $b_k(\cdot)$  is an unknown smooth function of observable variable  $Z_{k,i,t-1}$ , for  $k = 1, \dots, K$  (see Connor et al. (2012) p. 728 for a short discussion of this extension; their base model assumes that the covariates are time-invariant). The identification scheme requires that the characteristics differ across factors. Indeed, Connor et al. (2012) estimate model (20) by deploying the property that it corresponds to an additive non-parametric regression at each date  $t$ . They propose an iterative procedure that alternates at each step the cross-sectional estimation of (i) the loadings functions via the backfitting projection algorithm, and (ii) the factor values by least-square regression, subject to normalization restrictions. They obtain the final estimates of the loadings functions  $b_k(\cdot)$  by averaging across time the cross-sectional estimates. Fan et al. (2016b) extend the characteristic-based modeling in Connor and Linton (2007) and Connor et al. (2012) by allowing the betas  $b_k(Z_i) + \gamma_{i,k}$  to include unknown asset-specific additive constants (see Liao and Yang (2018) for the continuous-time case under infill asymptotics for high frequency data). They propose a so-called Projected PCA method to estimate this specification with time-invariant loadings. It is an open question whether we can extend this estimation approach to accommodate time-variation in the characteristics. Pelger and Xiong (2019) instead let the factor loadings be functions of an observable state variable. They consider the model:

$$R_{i,t} = \sum_{k=1}^K b_{i,k}(Z_{t-1})f_{k,t} + \varepsilon_{i,t}, \quad (21)$$

where the  $b_{i,k}(\cdot)$  are smooth functions and  $Z_t$  is a vector of observed variables, common across assets. Pelger and Xiong (2019) estimate model (21) by minimizing a local version of the Least-Squares criterion underlying PCA, where localization is implemented by kernel smoothing. In practice, the number of conditioning

variables, which we can accommodate, is small.

Among the nonparametric approaches, some recent work takes advantage of machine learning methods to achieve greater flexibility in the modeling of time-varying betas and accommodate the large dimensionality of the set of potential characteristics and state variables. Gu et al. (2019) consider the setting where the loadings are a nonparametric function of a large-dimensional vector of characteristics:  $b_{i,t} = b(Z_{i,t-1})$ , and use an autoencoder to estimate this relationship. Autoencoder is a class of universal approximators in the realm of Artificial Neural Networks (see Gu et al. (2019) and references therein). Using  $L_b$  hidden layers and an activator function  $g$ , each component of the loadings vector is approximated as:

$$\begin{aligned} b_{i,t,k}(\theta_b) &= G_k(Z_{i,t-1}, L_b, g, \theta_b) := A_k + B'_k Z_{i,t-1}^{(L)}, \\ Z_{i,t-1,j}^{(\ell)} &= g\left(A_j^{(\ell-1)} + B_j^{(\ell-1)'} Z_{i,t-1}^{(\ell-1)}\right), \ell = 1, \dots, L, \\ Z_{i,t-1}^{(0)} &= Z_{i,t-1}, \end{aligned}$$

where the parameter vector  $\theta_b$  includes the  $A_k, B_k, A_j^{(\ell-1)}, B_j^{(\ell-1)}$  for all  $k, j, \ell$ . Gu et al. (2019) approximate the factor values also with an autoencoder as  $f_{t,k}(\theta_f) = G_k(\hat{x}_t, L_f, g, \theta_f)$  using as input the standardized cross-sectional averages  $\hat{x}_t = \left(\frac{1}{n} \sum_i Z_{i,t-1} Z_{i,t-1}'\right)^{-1} \frac{1}{n} \sum_i Z_{i,t-1} R_{i,t}$ , i.e., characteristics-based portfolio returns. They minimize the penalized criterion  $\min_{\theta} \sum_i \sum_t (R_{i,t} - b_{i,t}(\theta_b)' f_t(\theta_f))^2 + \lambda \|\theta\|_1$ , where  $\|\theta\|_1$  is the  $L^1$  norm of the parameter vector  $\theta = (\theta_b', \theta_f)'$ . The inferential theory for this estimator is unknown.

In the rest of this section, we review a recent proposal for inference in time-varying statistical factor models developed by Gagliardini and Ma (2019). As the focus of these authors is on the problem of conducting inference on the conditional factor space, including its dimension, the adopted nonparametric framework is general regarding the beta dynamics and encompasses the linear and nonlinear beta specifications of e.g. Kelly et al. (2017, 2019), and Gu et al. (2019). The framework allows for time-variation in the number of conditional factors as an effect of the changing macroeconomic environment. The main idea is to see the estimation of factor values as a cross-sectional Instrumental Variable (IV) problem and deploy a well-chosen (conditional) normalization of the factor vector to accommodate an essentially unspecified beta dynamics. Here we review the main results in the simpler framework with constant number of conditional factors, and refer the reader to Gagliardini and Ma (2019) for the more general setting, the regularity conditions, and the

derivation of the results.

After imposing the no arbitrage restrictions  $a_{i,t} = b'_{i,t}\nu_t$  (see Equation (2)), model (17) becomes:  $R_{i,t} = b'_{i,t}g_t + \varepsilon_{i,t}$ , where  $g_t = f_t + \nu_t$ . Gagliardini and Ma (2019) assume that the  $m$ -dimensional lagged instruments  $Z_{i,t-1}$  are cross-sectionally uncorrelated with errors and correlated with betas under a full rank condition:

$$\begin{aligned} \text{plim}_{n \rightarrow \infty} \frac{1}{n} \sum_i Z_{i,t-1} \varepsilon_{i,t} &= 0, \\ \text{plim}_{n \rightarrow \infty} \frac{1}{n} \sum_i Z_{i,t-1} b'_{i,t} &=: \Gamma_t \text{ is a full column-rank matrix,} \end{aligned} \quad (22)$$

for all  $t$ , which implies the order condition  $m \geq K$ . Being the limit of a cross-sectional average of pre-determined variables, the matrix  $\Gamma_t$  is measurable w.r.t. the information set  $\mathcal{G}_{t-1}$  of aggregate shocks at time  $t-1$ , i.e., the non-diversifiable shocks (see Gagliardini and Ma (2019) for more details). It is assumed that  $\mathcal{G}_t$  is generated by the vector process  $Z_t$ , and that the econometrician observes  $Z_t$ . Under (22), it holds:

$$\xi_t := \text{plim}_{n \rightarrow \infty} \frac{1}{n} \sum_i Z_{i,t-1} R_{i,t} = \Gamma_t g_t. \quad (23)$$

Process  $\xi_t$  is identifiable from population moments. Its conditional variance given  $\mathcal{G}_{t-1}$  is  $V[\xi_t | \mathcal{G}_{t-1}] = \Gamma_t V[g_t | \mathcal{G}_{t-1}] \Gamma'_t$ . Thus, the number of non-zero eigenvalues of  $V[\xi_t | \mathcal{G}_{t-1}]$  equals the number of factors  $K$ , and the associated eigenvectors span the column space of matrix  $\Gamma_t$ . This allows to identify  $g_t$  from (23) up to a non-singular transformation matrix which is  $\mathcal{G}_{t-1}$ -measurable. In fact, the conditional factor space in model (17) is identifiable up to transformations  $f_t \rightarrow c_{t-1} + A_{t-1}f_t$ , where  $c_{t-1}$  and  $A_{t-1}$  are  $\mathcal{G}_{t-1}$ -measurable. Gagliardini and Ma (2019) show how to choose a convenient normalization of the factor space in order to get a closed form expression for  $g_t$ . Specifically, Gagliardini and Ma (2019) normalize the latent factors such that  $E[f_t | \mathcal{G}_{t-1}] = 0$ , and  $\Gamma_t = J_t$ , where  $J_t$  is the matrix whose columns are the  $K$  normalized eigenvectors of  $V[\xi_t | \mathcal{G}_{t-1}]$  associated with the non-zero eigenvalues. Under this normalization, it follows  $g_t = (J'_t \Omega_t J_t)^{-1} J'_t \Omega_t \xi_t$ , where  $\Omega_t$  is any  $m \times m$  positive definite matrix measurable w.r.t.  $\mathcal{G}_{t-1}$ , and  $f_t = g_t - E[g_t | \mathcal{G}_{t-1}]$ .

In a setting with  $n, T \rightarrow \infty$ , Gagliardini and Ma (2019) define consistent estimators for the conditional factor space and for its dimension by replacing population (cross-sectional, or conditional) expectations with sample analogues. They get  $\hat{g}_t = (\hat{J}'_t \Omega_t \hat{J}_t)^{-1} \hat{J}'_t \Omega_t \hat{\xi}_t$ , and  $\hat{f}_t = \hat{g}_t - \hat{E}[\hat{g}_t | \mathcal{G}_{t-1}]$ , where

$\hat{\xi}_t = \frac{1}{n} \sum_i Z_{i,t-1} R_{i,t}$ . Here,  $\hat{J}_t$  is the matrix of the standardized eigenvectors to the  $K$  largest eigenvalues of  $\hat{V}[\hat{\xi}_t|\mathcal{G}_{t-1}]$ , and  $\hat{E}[\cdot|\mathcal{G}_{t-1}]$  and  $\hat{V}[\cdot|\mathcal{G}_{t-1}]$  are nonparametric estimators for the conditional expectation given  $Z_{t-1}$ . Given the potentially large dimension of vector  $Z_t$ , Gagliardini and Ma (2019) consider estimators based on post-Lasso and Artificial Neural Networks (ANN). The estimator of the conditional factor space is in closed form up to the nonparametric regression given  $Z_{t-1}$ . The estimator of the number of factors is  $\hat{K} = \text{mode} \left\{ \hat{k}_t, t \geq 1 \right\}$ , and  $\hat{k}_t = \arg \max_{1 \leq k \leq k_{max}} \frac{\mu_{k+1}(\hat{V}[\hat{\xi}_t|\mathcal{G}_{t-1}])}{\mu_k(\hat{V}[\hat{\xi}_t|\mathcal{G}_{t-1}])}$ , where  $\mu_k(\cdot)$  denotes the  $k$  largest eigenvalue of a symmetric matrix. Estimator  $\hat{k}_t$  exploits the idea of the eigenvalue ratio test but in a different context than Ahn and Horenstein (2013), since  $\hat{V}[\hat{\xi}_t|\mathcal{G}_{t-1}]$  is not a large-dimensional sample variance-covariance matrix.

In the framework of Kelly et al. (2017, 2019), Equation (19) yields  $\Gamma_t = Q_{Z,t-1}B$ , where  $Q_{Z,t-1} = \text{plim}_{n \rightarrow \infty} \frac{1}{n} \sum_i Z_{i,t-1} Z'_{i,t-1}$ , which implies a constraint on the time variation of  $\Gamma_t$ . In Gu et al. (2019), we have  $x_t := \text{plim}_{n \rightarrow \infty} \hat{x}_t = Q_{Z,t-1}^{-1} \xi_t = Q_{Z,t-1}^{-1} \Gamma_t g_t$ . Hence, for large  $n$ , the autoencoder mapping for the latent factor essentially amounts to fixing a normalization of the latent factor such that some  $k \times k$  block of  $Q_{Z,t-1}^{-1} \Gamma_t$  is time-invariant, so that we can write  $g_t$  as a time-invariant function of  $x_t$ . This function is linear. The methodology of Gagliardini and Ma (2019) does not impose constraints on the dynamics of  $\Gamma_t$  and deploys the structural linear link between  $\xi_t$  and  $g_t$  conditional on  $\mathcal{G}_{t-1}$ .

Among the possible extensions of the model setting, we can further impose a group structure on the latent factor space in order to accommodate the presence of both common pervasive factors and group-specific pervasive factors. The former affect all series in the panel while the latter have an impact on subgroups of assets. The subgroups can correspond to e.g. economic sectors, asset classes, markets or countries. Andreou et al. (2019) develop inference procedures in a ‘‘large  $n$ , large  $T$ ’’ setting for estimating the common and group-specific numbers of factors and the corresponding spanned factor spaces.

Finally, let us mention that there is also work on inference for large-dimensional models with unobservable factors with high frequency data (Fan et al. (2016a), Ait-Sahalia and Xiu (2017), Pelger (2019a,b)), but extensions to the conditional case with instruments still need to be developed there. Fan and Kim (2018) discuss how to robustify such methods and Kim and Fan (2019) how to impose a dynamic parametric structure based on a factor GARCH-Itô process for prediction. Li et al. (2019) develop tests for deciding whether

a large cross-section of asset prices obey an exact factor structure at the times of factor jumps with infill asymptotics.

Besides, if we face a short time series panel (for example a 5-year window) without the availability of high-frequency data, asymptotics with fixed  $T$  and large  $n$  are better suited. Keeping  $T$  fixed impedes consistent estimation of the risk premia, and inference has to focus on ex-post risk premia (Shanken (1992)). Examples of work in that direction are Zaffaroni (2019) for inferential theory with unobservable factors and Kim and Skoulakis (2018), Raponi et al. (Forthcoming, 2019) with observable factors.

## 5 Empirical findings

In this section, we provide some empirical findings based on a large number of financial factor models. We provide contrast analysis based on monthly returns of individual stocks and standard sets of portfolios.

### 5.1 Data description and factor models

Our dataset includes monthly excess returns of stocks data from CRSP database. We proxy the risk free rate with the monthly 30-day T-bill beginning-of-month yield. We exclude financial firms (Standard Industrial Classification Codes between 6000 and 6999) as in Fama and French (2008). The dataset after matching CRSP and Compustat contents comprises  $n = 10,827$  stocks, and covers the period from July 1963 to December 2017 with  $T = 654$  months. Table 1 provides the distribution of asset returns of stocks w.r.t.  $T_i$  the number of observations available for each asset. About half of the stocks in the panel have more than 120 monthly return observations. We observe the complete time series of observations for only 2% of the stocks. Table 2 provides the distribution of stocks w.r.t. the classification of industry in Ferson and Harvey (1999). The two most frequent industry categories are Professional Services (2282) and Healthcare (1194), while the two less frequent ones are Aerospace (64) and Paper (129).

For comparison purposes with a standard methodology for small  $n$ , we consider i) the 25 Fama-French (FF) portfolios and ii) the 44 industry (Indu.) portfolios excluding four financial sectors (banking, insurance, real estate, and trading) as base assets.

We consider several linear factor models that involve financial variables (see GOS2 for models with

macroeconomic variables). Table 3 lists the financial models, the factors, the number of parameters to estimate, and the trimmed cross-sectional dimensions  $n^\chi$  considering time-invariant and time-varying specifications. The three factors of Fama and French (1993) are the monthly excess return  $r_{m,t}$  on CRSP NYSE/AMEX/Nasdaq value-weighted market portfolio over the risk free rate, and the monthly returns on zero-investment factor-mimicking portfolios for size and book-to-market, denoted by  $r_{smb,t}$  and  $r_{hml,t}$ . We denote the monthly returns on portfolio for momentum by  $r_{mom,t}$  (Carhart (1997)). The two operative profitability factors of Fama and French (2015) are the difference between monthly returns on diversified portfolios with robust and weak profitability and investments, and with low and high investment stocks, denoted by  $r_{rmw,t}$  and  $r_{cma,t}$ . We have downloaded the time series of these factors from the website of Kenneth French. We also consider a model with long-only factors, that should be more immune to market imperfections (e.g., transaction costs). We build the long-only factors from the six FF research portfolios available on the website of Ken French. The excess return of the "Small" factor (denoted by  $r_{s,t}$ ) is the average excess return of the three small portfolios, and the excess return of the "Value" factor (denoted by  $r_{h,t}$ ) is the average excess return of the two value portfolios. Furthermore, we include quality minus junk ( $qmj_t$ ) and bet against beta ( $bab_t$ ) factors as described in Asness et al. (2019) and Frazzini and Pedersen (2014). The factor return  $qmj_t$  is the average return on the two high quality portfolios minus the average return on the two low quality (junk) portfolios. The bet against beta factor is a portfolio that is long low-beta securities and short high-beta securities. We have downloaded these data from the website of AQR. As additional specifications, from the website of Kenneth French, we consider the two reversal factors which are monthly returns on portfolios for short-term and long-term reversals, denoted by  $r_{strev,t}$  and  $r_{ltrev,t}$ .

To account for time-varying alphas, betas and risk premia, we use a conditional specification based on one common variable and a firm-level variable. We take the instruments  $Z_{t-1} = (1, divY_{t-1})'$ , where  $divY_{t-1}$  is the lagged dividend yield and the asset specific instrument  $bm_{i,t-1}$  corresponds to the lagged book-to-market equity of firm  $i$ . We compute the book-to-market equity of firm  $i$  as defined in logarithmic terms by Fama and French (2008). We compute the firm characteristics from Compustat as in the appendix of Fama and French (2008). We consider all the assets for which the book-to-market equity is always positive over the sample period, as in Fama and French (2008). The number of assets reduces to  $n = 8,570$  for the estimation of the time-varying specifications. We refer to Avramov and Chordia (2006) for convincing

theoretical and empirical arguments in favor of the chosen conditional specification. In Table 3, the vector  $x_{i,t}$  has maximum dimension  $d = 23$  (CAR and REV model), and parsimony explains why we have not included e.g. the size of firm  $i$  as an additional stock specific instrument. We have downloaded time series of portfolio characteristics from the website of Kenneth French.

## 5.2 Time-invariant specifications

Let us first focus on the time-invariant specifications (i.e.  $Z_t = 1$  and  $Z_{i,t} = 0$ ) in order to benchmark the results of the next section for the time-varying specifications. We use  $\chi_{1,T} = 15$  as advocated by Greene (2008), together with  $\chi_{2,T} = 546/60$ . The number of assets whose condition number is below 15 is 7,754 for each model specification.

First, we compute the diagnostic criterion and the number  $k$  of omitted factors. Table 4 reports the contribution in percentage of the first eigenvalue  $\mu_1$  with respect to the variance of normalized residuals  $\frac{1}{n \times T} \sum_i \mathbf{1}_i^X \bar{\bar{\epsilon}}_i \bar{\bar{\epsilon}}_i'$ , that is equal to one by construction under our variance scaling for each time series of residuals. We also report the selected number of omitted factors  $k$ , the contribution of the first  $k$  eigenvalues, i.e.,  $\sum_{j=1}^k \mu_j$ , and the incremental contribution of the  $(k+1)$ -th eigenvalue  $\mu_{k+1}$ . For each model, we also specify the numerical value of the penalisation function  $g(n^\chi, T)$ , as defined in GOS2. The number  $k$  of omitted factors is larger than one for the most popular financial models, e.g., the CAPM (Sharpe (1964)) and the three-factor Fama-French model (FF). On the contrary, for the the four-factor Carhart (1997) model (CAR), the five-factor Fama-French model (5FF), quality minus junk (QMJ), and models involving the reversal factors, we find no omitted latent factor. We observe that adding observable factors helps to reduce the contribution of the first eigenvalue  $\mu_1$  to the variance of residuals. However, when we face latent factors, the omitted systematic contribution  $\sum_{j=1}^k \mu_j$  only accounts for a small proportion of the residual variance. For instance, we find  $k = 1$  omitted factors in the CAPM. That latent factor only contributes to  $\mu_1 = 2.39\%$  of the residual variance. Figures 1, 3, 5 summarize this information graphically by displaying the penalized scree plots and the plots of cumulated eigenvalues for the CAPM, the three Fama-French factors model and the four-factor CAR model. For instance,  $\mu_2 = 1.54\%$  lies below the horizontal line  $g(n^\chi, T) = 1.55\%$  in Panel A for the time-invariant CAPM, so that  $k = 1$ . In Panel B for the time-invariant CAPM, the

vertical bar  $\mu_1 + \mu_2 = 3.93\%$  is divided into the contribution of  $\mu_1 = 2.39\%$  (light grey area) and that of  $\mu_2 = 1.54\%$  (dark grey area). Figure 2 Panel A displays the scree plots of squared eigenvalues for the CAPM and the square  $g^2(n^x, T)$  of the penalisation function relative to the squared Frobenius norm  $\sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^x \bar{\varepsilon}_i \bar{\varepsilon}_i' \right)$ . By construction, the conclusion of the number of omitted factor is the same as for the scree plot shown in Figure 1. For example, we get that the sum of the square of the two first eigenvalues accounts for 21.45% of the square of the Frobenius norm for the time-invariant CAPM. Thus, the two latent factors are much more representative of the off-diagonal components. We conclude similarly for the time-invariant FF model (see Figure 4), even if the correlation explanation provided by the single omitted factor is lower.

Tables 5-8 gather the estimated annual risk premia and the estimates of the components of  $\nu$ , with the corresponding confidence intervals at 95% level, for the ten time-invariant models listed in Table 3. For individual stocks, we use bias-corrected estimates for  $\lambda$  and  $\nu$ . In order to build the confidence intervals, we use the HAC estimators  $\hat{\Sigma}_f$  defined as in Newey and West (1994) and  $\hat{\Sigma}_\nu$  defined in GOS. When we consider the 25 FF and 44 Indu. portfolios as base assets, we use asymptotics for fixed  $n$  and  $T \rightarrow \infty$ . In particular, we compute the estimates of the variance-covariance matrices  $\Sigma_{\lambda,n}$  and  $\Sigma_{\nu,n}$  defined in GOS. The estimated risk premia for the market factor are of the same magnitude and all positive across the three universes of assets and all financial models. In Table 7, for the four-factor CAR model and the individual stocks, the size factor is positively remunerated (3.5430%) and it is significantly different from zero. The value factor commands a significant negative reward (-4.9265%). The momentum factor is largely remunerated (8.0947%) and significantly different from zero. For the 25 FF portfolios, we observe that the size factor is not significantly positively remunerated while the value factor is significantly positively remunerated (2.5028% and 4.1996%). The momentum factor bears a significant positive reward (34.6689%). For  $\lambda_m$ ,  $\lambda_{smb}$ ,  $\lambda_{hml}$ , we obtain similar inferential results when we consider the Fama-French model in Table 8. Our point estimates of  $\lambda_m$ ,  $\lambda_{smb}$ , and  $\lambda_{hml}$  for large  $n$  agree with Ang et al. (2010). Our point estimates and confidence intervals for  $\lambda_m$ ,  $\lambda_{smb}$ , and  $\lambda_{hml}$  agree with the results reported by Shanken and Zhou (2007) for the 25 FF portfolios. The large, but imprecise, estimate for the momentum premium when  $n = 25$  comes from the estimate for  $\nu_{mom}$  (26.7559%) that is much larger and less accurate than the estimates for  $\nu_m$ ,  $\nu_{smb}$ , and  $\nu_{hml}$  (0.9447%, -0.0225%, -0.3662%). Moreover, while the estimates of  $\nu_m$ ,  $\nu_{smb}$ , and  $\nu_{hml}$

are statistically not significant for the 25 FF portfolios, the estimates of  $\nu_m$ ,  $\nu_{smb}$ , and  $\nu_{hml}$  are statistically different from zero for individual stocks. In particular, the estimate of  $\nu_{hml}$  is large and negative. This explains the negative estimate on the value premium for individual stocks displayed in Table 7, despite the positive time average of the value factor. Phalippou (2007) obtained a similar growth premium for portfolios built on stocks with a high institutional ownership. The results with the 44 Indu. portfolios sharply differ from those with the 25 FF portfolios. The former are more like the results for individual stocks; in particular, they yield negative estimates of coefficient  $\nu_{hml}$  and value premium  $\lambda_{hml}$  (albeit the latter not statistically significant). In Table 6, the 5FF model also exhibits large differences between estimated risk premia on individual stocks, FF and Indu. portfolios. For example, we get a significant  $\lambda_{rmw} = 5.3198\%$  for the FF portfolios and an insignificant  $\lambda_{rmw} = 0.8911\%$  for individual stocks. On the contrary, we get an insignificant  $\lambda_{cma} = 0.8787\%$  for the FF portfolios (with a large confidence interval) and a significant  $\lambda_{cma} = -3.2867\%$  for individual stocks. The estimated risk premia on the Indu. portfolios exhibit large confidence intervals. For example, we get insignificant  $\lambda_{rmw} = 2.3817\%$  and  $\lambda_{cma} = -0.3614\%$ .

The size, value, and momentum factors are tradable in theory. In practice, their implementation faces transaction costs due to rebalancing and short selling. A nonzero  $\nu$  might capture these market imperfections (Cremers et al. (2012)). In Table 8, we also get zero estimates with the FF portfolios except for value, and nonzero estimates with the Indu. portfolios and the individual stocks for market and value, when we use a time-invariant model with long-only factors derived from the FF methodology. Market imperfections are probably not the key drivers here (see Frazzini et al. (2012)) for empirical support based on live trading data from a large institutional money manager).

A potential explanation of the discrepancies revealed in Tables 5-8 between individual stocks and the FF portfolios is the much larger heterogeneity of the factor loadings for the former. As already discussed in Lewellen et al. (2010), the FF portfolio betas are all concentrated in the middle of the cross-sectional distribution obtained from the individual stocks. Creating portfolios with an ad hoc methodology distorts information by shrinking the dispersion of betas. The estimation results for the momentum factor on the FF portfolios exemplify the problems related to a small number of portfolios exhibiting a tight factor structure. Another potential explanation of the discrepancy revealed in Tables 5-8 is the effect of model misspecification on the risk premia because of omitted factors as observed in Table 4 for the three-factor FF model.

### 5.3 Time-varying specifications

We use  $\chi_{1,T} = 15$  and  $\chi_{2,T} = 546/60$ . The number of assets whose condition number is below 15 is often between 2,000 and 3,000, for instance 2,578 for the four-factor CAR model.

For the time-varying specifications of Table 3, we still find one omitted factor for the CAPM and the 4-factor MOM and REV model in Table 4. The other time-varying models passes the diagnostic criterion. As already discussed in the Introduction, this diagnostic step is crucial to decide whether we can feel comfortable with the chosen set of observable factors before proceeding further in an empirical analysis of a large cross sectional equity data set under the APT setting. The time-varying specification is more parsimonious for the factor space in the conditional sense, but less parsimonious for the parameter space. From an econometric point of view, it is not clear which parsimony we should favor to decide between the time-invariant specification (more factors, less parameters) and the time-varying specification (less factors, more parameters). For investment purposes, the first one is better suited for static (unconditional) decisions while the second one is better suited for dynamic (conditional) decisions. The choice between the two models should meet the investor needs or answer the empirical research question at hand.

Figure 7 plots the estimated time-varying paths of the four risk premia estimated assuming the four-factor CAR model and using the individual stocks (see GOS for a formal test of time-variation based on the estimated coefficients  $\hat{F}$  and  $\hat{\nu}$ ). For comparison purpose, we also plot the time-invariant estimates and the average lambdas over time. A well-known bias coming from market-timing and volatility-timing (Jagannathan and Wang (1996), Lewellen and Nagel (2006), Boguth et al. (2011)) explains the discrepancy between the time-invariant estimate and the average over time. After trimming, we compute the risk premia on  $n^\chi = 2,549$  individual assets in the four-factor CAR model. The observed discrepancy w.r.t. the average over time is only marginally explained by the larger size of the stock universe used for the time-invariant estimates. The risk premia for the factors feature a counter-cyclical pattern most of the time. Indeed, these risk premia increase during economic contractions and decrease during economic booms. Gomes et al. (2003) and Zhang (2005) constructed equilibrium models exhibiting a counter-cyclical behavior in size and book-to-market effects. Furthermore, time-varying estimates of the value premium are negative and might take positive values because of the large confidence intervals around recessions. Growth firms are riskier in boom times because of their in-the-money growth options; value firms are riskier in recession

times because of default risk. However, empirical evidence for such an interpretation is mixed. Some papers find that distress is related to size and book-to-market effects (Griffin and Lemmon (2002), Vassalou and Xing (2004)) while other papers find the opposite (Dichev (1998), Campbell et al. (2008)). Chava and Purnanandam (2010) find support for a positive relation and argued that conclusions regarding the risk return trade-off can change significantly depending on how the expected return is measured. Gomes and Schmid (2010) and Garlappi and Yan (2011) argue that financial leverage provides a rationale for a positive relation. The time-varying estimates of the size premium are most of the time slightly positive.

Figure 8 plots the estimated time-varying path of the four risk premia from the 25 FF portfolios. We also plot the time-invariant estimates and the average lambdas over time. The discrepancy between the time-invariant estimates and the averages over time is also observed for  $n = 25$ . The time-varying point estimates for  $\lambda_{mom,t}$  are typically smaller than the time-invariant estimate in Table 7, but both estimates are rather inaccurate. Finally, by comparing Figures 7 and 8, we observe that the patterns of risk premia look similar in terms of cyclicity except for the book-to-market factor. Indeed, the risk premium for the value effect estimated from the 25 portfolios is pro-cyclical, contradicting the counter-cyclical behavior predicted by finance theory. The paths of risk premia in the Fama-French model estimated from the 25 FF portfolios look similar to the corresponding estimates for the four-factor CAR model in Figure 8. The time-varying paths of risk premia for the 44 Indu. portfolios look similar to the corresponding estimates on individual stocks. This similarity, also observed in Section 5.2 with time-invariant models, is likely linked with the relative stability of the time-varying portfolio weights for the 44 Indu. portfolios compared to the weights of the 25 FF portfolios.

#### 5.4 Asset pricing restriction tests

As already discussed in Lewellen et al. (2010), the 25 FF portfolios have four-factor CAR market and momentum betas close to 1 and zero, respectively. As depicted in Figure 1 by Lewellen, Nagel, and Shanken (2010), this empirical concentration implies that it is easy to get artificially large estimates  $\hat{\rho}^2$  of the cross-sectional  $R^2$  for three-factor FF and four-factor CAR models. On the contrary, the observed heterogeneity in the betas coming from the individual stocks impedes this. This suggests that it is much less easy to find factors that explain the cross-sectional variation of expected excess returns on individual stocks than on

portfolios. Reporting large  $\hat{\rho}^2$ , or small SSR  $\hat{Q}_e$ , when  $n$  is large, is much more impressive than when  $n$  is small.

Tables 9 and 10 gather the results for the tests of the asset pricing restrictions in factor models with time-invariant coefficients. When  $n$  is large, we prefer working with test statistics based on the SSR  $\hat{Q}_e$  instead of  $\hat{\rho}^2$  since the population  $R^2$  is not well-defined with tradable factors under the null hypothesis (its denominator is zero). For the individual stocks, we compute the feasible test statistics based on  $\hat{Q}_e$  and  $\hat{Q}_a$  and hard thresholding to get consistent estimates  $\tilde{\Sigma}_\xi$  of covariance matrices, as well as their associated one-sided  $p$ -value. Our Monte Carlo simulations show that we need to set a stronger trimming level  $\chi_{2,T}$  to compute the test statistic than to estimate the risk premium. We use  $\chi_{2,T} = 546/240$ . For the 25 and 44 Indu. portfolios, we compute weighted test statistics (Gibbons et al. (1989)) as well as their associated  $p$ -values. For individual stocks, the test statistics reject both null hypotheses  $\mathcal{H}_0 : a(\gamma) = b(\gamma)' \nu$  and  $\mathcal{H}_0 : a(\gamma) = 0$  for all specifications at 1% level. Similar conclusions are obtained when using the 25 FF portfolios as base assets. For the 44 Indu. portfolios, we do not reject the null hypothesis  $\mathcal{H}_0 : a(\gamma) = b(\gamma)' \nu$ , but we reject  $\mathcal{H}_0 : a(\gamma) = 0$ .

Tables 11 and 12 gather the results for tests of the asset pricing restrictions in time-varying specifications. We do not report results for the FF long-only model since multicollinearity problems prevent us to estimate and test that model. Contrary to the time-invariant case, we do not report the values of the weighted test statistics (Gibbons et al. (1989)) computed for portfolios because of the numerical instability in the inversion of the covariance matrix. Instead, we report the values of the test statistics  $T\hat{Q}_e$  and  $T\hat{Q}_a$ . For individual stocks, the test statistics reject both null hypotheses  $\mathcal{H}_0 : a(\gamma) = b(\gamma)' \nu$  and  $\mathcal{H}_0 : a(\gamma) = 0$  for all specifications at 1% level.

In addition, we compare the cross-sectional distributions of  $\hat{\beta}'_{1,i} \hat{\beta}_{1,i}$ , the idiosyncratic risk (square root of residual variance), and the estimated time-series coefficient of determination  $\hat{\rho}_i^2$  (ratio of explained variance and total variance) for the time-varying specifications assuming the four-factor CAR model for the excess returns. We can view those estimates as measures of limits-to-arbitrage and missing factor impact (Pontiff (2006), Lam and Wei (2011), Ang et al. (2009)). For each asset (either stock, or portfolio)  $i$ , we compute four measures: (i) the estimated time-series coefficient of determination  $\hat{\rho}_i^2 = \frac{ESS_i}{TSS_i}$ , where  $ESS_i = \sum_t I_{i,t} (\hat{R}_{i,t} - \bar{\bar{R}}_i)^2$ , with  $\hat{R}_{i,t} = \hat{\beta}'_i x_{i,t}$  and  $\bar{\bar{R}}_i = \frac{1}{T_i} \sum_t I_{i,t} \hat{R}_{i,t}$ , and  $TSS_i = \sum_t I_{i,t} (R_{i,t} - \bar{R}_i)^2$ ,

with  $\bar{R}_i = \frac{1}{T_i} \sum_t I_{i,t} R_{i,t}$ ; (ii) the estimated adjusted  $R^2$  defined by  $\hat{\rho}_{ad,i}^2 = 1 - \frac{(T_i - 1)}{(T_i - d)} (1 - \hat{\rho}_i^2)$ ; (iii) the idiosyncratic risk  $IdiVol_i = \sqrt{\frac{RSS_i}{T_i}}$ , with  $RSS_i = \sum_t I_{i,t} \hat{\varepsilon}_{i,t}^2$ ; (iv) the systematic risk  $SysRisk_i = \sqrt{\frac{ESS_i}{T_i}}$ .

Figures 13 and 14 compare the cross-sectional distributions of the four measures (i)-(iv) computed on the time-invariant and time-varying four-factor CAR models using the individual stocks, 25 FF and 44 Indu. portfolios as base assets. The boxplots provided by the statistical software do not take into account the presence of estimation noise, i.e., of the EIV issue coming from using estimates instead of true quantities. Barras et al. (2019) explain how to correct for the EIV bias and to modify standard deviations and confidence intervals of estimates of p.d.f., c.d.f., quantiles, and moments computed from estimated quantities such as estimated regression coefficients in a “large  $n$ , large  $T$ ” setting. For comparison purposes, the cross-sectional distributions for individual stocks in both figures refer to the  $n^x = 2,549$  stocks used in the estimation of the time-varying specification after trimming. The time-series (adjusted)  $\hat{\rho}_i^2$  of the 25 FF portfolios are all larger than 0.80. The estimates  $\hat{\rho}_i^2$  of the individual stocks are typically much smaller, with a median below 0.30. As expected, the excess returns of individual stocks also have larger idiosyncratic volatilities. The time-series adjusted  $\hat{\rho}_i^2$  of individual stocks tend to be a bit larger in the time-varying model than in the time-invariant one, as a result of the explanatory power that we gain by allowing for beta dynamics. Figures 13 and 14 show that the use of the FF portfolios also shrinks the dispersion of  $\hat{\rho}_i^2$ ,  $IdiVol_i$ , and  $SysRisk_i$ , by a large amount. The distributions for the individual stocks and the 44 Indu. portfolios are comparable and share a wide support. Figure 15 plots the cross-sectional distributions of  $\hat{\beta}'_{1,i} \hat{\beta}_{1,i}$  for the three universes of assets. We observe a huge heterogeneity in  $\hat{\beta}'_{1,i} \hat{\beta}_{1,i}$  for the individual stocks in Figure 15, similar to the one observed on  $IdiVol_i$  in Figure 14. We may face the presence of limits-to-arbitrage and missing factors in that case. On the contrary, the estimates  $\hat{\beta}'_{1,i} \hat{\beta}_{1,i}$  are concentrated close to zero for the 25 FF and 44 Indu. portfolios. The 25 FF portfolios exhibit small  $\hat{\beta}'_{1,i} \hat{\beta}_{1,i}$ , small idiosyncratic risks, and large estimates  $\hat{\rho}_i$  compared to individual stocks as expected from the previous empirical results. Unreported preliminary results based on linear quantile regressions reveal that stocks with small size tend to yield large  $\hat{\beta}'_{1,i} \hat{\beta}_{1,i}$ , large idiosyncratic risks, and small estimates  $\hat{\rho}_i$ . We also find that firms with short observation periods tend to be associated with large values of both idiosyncratic and systematic risks (with a larger proportion of systematic risk to total risk), as well as small market capitalization.

## 5.5 Time-varying cost of equity

We can use the results in Section 3.2 for estimation and inference on the cost of equity in conditional factor models. We can estimate the time-varying cost of equity  $CE_{i,t} = r_{f,t} + b'_{i,t}\lambda_t$  of firm  $i$  with  $\widehat{CE}_{i,t} = r_{f,t} + \hat{b}'_{i,t}\hat{\lambda}_t$ , where  $r_{f,t}$  is the risk-free rate. We have

$$\begin{aligned} \sqrt{T} \left( \widehat{CE}_{i,t} - CE_{i,t} \right) &= \psi'_{i,t} E'_2 \sqrt{T} \left( \hat{\beta}_i - \beta_i \right) \\ &\quad + (Z'_{t-1} \otimes b'_{i,t}) W_{p,K} \sqrt{T} \text{vec} \left[ \hat{\Lambda}' - \Lambda' \right] + o_p(1), \end{aligned} \quad (24)$$

where  $\psi_{i,t} = \left( \lambda'_t \otimes Z'_{t-1}, \lambda'_t \otimes Z'_{i,t-1} \right)'$ . Standard results on OLS imply that estimator  $\hat{\beta}_i$  is asymptotically normal,  $\sqrt{T} \left( \hat{\beta}_i - \beta_i \right) \Rightarrow N \left( 0, \tau_i Q_{x,i}^{-1} S_{ii} Q_{x,i}^{-1} \right)$ , and independent of estimator  $\hat{\Lambda}$ . Then, from the asymptotic normality results for the estimator  $\hat{\Lambda}$ , we deduce that  $\sqrt{T} \left( \widehat{CE}_{i,t} - CE_{i,t} \right) \Rightarrow N \left( 0, \Sigma_{CE_{i,t}} \right)$ , conditionally on  $Z_{t-1}$ , where

$$\Sigma_{CE_{i,t}} = \tau_i \psi'_{i,t} E'_2 Q_{x,i}^{-1} S_{ii} Q_{x,i}^{-1} E_2 \psi_{i,t} + (Z'_{t-1} \otimes b'_{i,t}) W_{p,K} \Sigma_{\Lambda} W_{K,p} (Z_{t-1} \otimes b_{i,t}).$$

Figure 16 plots the path of the estimated annualized costs of equity for Microsoft Corp, Apple, Disney Walt, and Sony. We use the time-varying four-factor CAR model estimated on individual stocks. For the last twenty years, the cost of equity rose substantially during the subprime crisis, but came back to much lower levels in the recent years.

## 5.6 International equity data sets

All of the empirical findings on factor structure, asset pricing restrictions tests, risk premia estimation and cost of equity discussed so far are based on evidence from a large cross-sectional equity data set for the U.S. market. It is interesting to examine these important issues in a global context. Market integration and currency risk are two main factors that distinguish international financing and investment decisions from domestic ones.

A recent paper by Chaieb, Langlois and Scaillet (2018, CLS hereafter) applies the GOS methodology to international equity returns. The sample includes more than 62,000 stocks from 22 Developed Markets (DMs) and 24 Emerging Markets (EMs). GOS methodology is particularly suitable to model USD-denominated international equity returns as it can handle the correlation implications of denominating all

returns in a common currency. CLS explicitly consider the impact of currency conversion on correlations across stocks since they do not impose a priori an exact factor structure. Using this framework, CLS document several new empirical results based on individual stocks.

First, a CAPM model with a world market factor and a country-excess market factor - defined as the spread between the country market and the world market - can capture the factor structure in several markets after allowing for time-varying exposures to the two global and local market risk factors. Specifically, GOS2 diagnostic criterion shows no omitted factors in the model errors in 33 of 46 countries. Further augmenting this model with non-market global factors such as size, value, momentum, profitability and investment fully captures the factor structure in all DMs and most EMs. CLS obtain a factor model specification close to a block diagonal structure for the error covariance matrix with blocks corresponding to countries. Such a sparse matrix is compatible with the notion of weak cross-sectional dependence. Therefore, the leading Fama and French (2012, 2017) four-factor and five-factor international models and Hou et al. (2015) q-factor model (when applied using global factors) should allow factor exposures to vary over time and should add a country excess market factor to capture the factor structure of international individual equity returns for both DMs and EMs.

Second, CLS do not reject the asset pricing restrictions implied by these conditional asset pricing models in a large proportion of countries. That finding is not coming from lack of power or misspecification.

Third, CLS estimate the dynamics of the various risk premia across time and countries. They find heterogeneity in the level and volatility of risk premia across countries and across time. Specifically, value and momentum have more volatile risk premia than profitability and investment. More importantly, the magnitude and dynamics of factor non-tradability differ substantially between DMs and EMs.

## **6 Concluding remarks**

This chapter has reviewed recent advances in econometrics for conditional factor models estimated on data sets with “large  $n$ , large  $T$ ” in finance. The tools studied above are simple to implement and often similar to the ones used in a “small  $n$ , large  $T$ ” setting. The asymptotic treatment however differs substantially. We believe that extracting information directly from disaggregated data in finance will become increasingly popular in the upcoming years. The current big data trend favours the development of new econometric

tools, the collection of data sets at the individual level, and the improvement of computation/storage powers.

Table 1: **Distribution of individual stocks w.r.t.  $T_i$**

$T_i$	Frequency
$1 \leq 12$	18
$13 \leq 24$	607
$25 \leq 60$	2514
$61 \leq 120$	2444
$121 \leq 240$	2861
$241 \leq 360$	1351
$361 \leq 480$	557
$481 \leq 600$	286
$601 \leq 654$	189

We report the frequency counts of the individual stocks w.r.t. their buckets of sample size  $T_i$ .

Table 2: **Distribution of individual stocks w.r.t. industry**

Industry	Frequency
Aerospace	64
Transportation	152
Building Materials	147
Chemicals/Plastics	276
Construction	177
Entertainment	375
Food/Beverage	314
Healthcare	1194
Industrial Machinery	322

Retailing	577
Semiconductors	861
Telecommunications	901
Textiles/Apparel	200
Utilities	437
Wholesaling	639

We report the frequency counts of the individual stocks w.r.t. their industry category.

**Table 3: Financial linear factor models.**

Model	Observable Factors	time-invariant		time-varying	
		$K$	$n^\chi$	$d$	$n^\chi$
CAPM	$r_{m,t}$	1	7,754	8	3,215
FF	$r_{m,t}, r_{smb,t}, r_{hml,t}$	3	7,754	14	2,877
FF long-only	$r_{m,t}, r_{s,t}, r_{h,t}$	3	7,754	14	825
CAR	$r_{m,t}, r_{smb,t}, r_{hml,t}, r_{mom,t}$	4	7,754	17	2,549
FF and QMJ	$r_{m,t}, r_{smb,t}, r_{hml,t}, r_{qmj,t}$	4	7,754	17	2,251
FF and BAB	$r_{m,t}, r_{smb,t}, r_{hml,t}, r_{bab,t}$	4	7,754	17	2,471
MOM and REV	$r_{m,t}, r_{mom,t}, r_{strev,t}, r_{ltrev,t}$	4	7,754	17	2,569
5FF	$r_{m,t}, r_{smb,t}, r_{hml,t}, r_{rmw,t}, r_{cma,t}$	5	7,754	20	1,928
FF and REV	$r_{m,t}, r_{smb,t}, r_{hml,t}, r_{strev,t}, r_{ltrev,t}$	5	7,754	20	2,460
CAR and REV	$r_{m,t}, r_{smb,t}, r_{hml,t}, r_{mom,t}, r_{strev,t}, r_{ltrev,t}$	6	7,754	23	2,019

For each financial model, we report the list of observable factors and the trimmed cross-sectional dimension  $n^\chi$  for estimation from monthly data. We use  $\chi_{1,T} = 15$  and  $\chi_{2,T} = 546/60$ . For the time-invariant specifications, we report the number of observable factors  $K$ . The number of parameters to estimate is  $d = K + 1$ . For the time-varying specifications, we give the dimension  $d$  of vector  $x_{i,t}$  using  $Z_{t-1} = (1, \text{div}Y_{t-1})'$  and  $Z_{i,t-1} = bm_{i,t-1}$ .

We compute the statistics  $\tilde{\Sigma}_\xi^{-1/2} \tilde{\xi}_{n,T}$  based on  $\hat{Q}_e$  and  $\hat{Q}_a$  for the individual stocks to test the null hypotheses  $\mathcal{H}_0 : a(\gamma) = b(\gamma)'\nu$  and  $\mathcal{H}_0 : a(\gamma) = 0$ , respectively. For  $n = 25$  and  $n = 44$ , we compute the weighted statistics  $T\hat{e}'\hat{V}^{-1}\hat{e}$  and  $T\hat{a}'\hat{V}_a^{-1}\hat{a}$  (Gibbons, Ross and Shanken (1989)), where  $\hat{e}$  and  $\hat{a}$  are  $n \times 1$  vectors with elements  $\hat{e}_i$  and  $\hat{a}_i$ , and  $\hat{V} = (\hat{v}_{i,j})$  and  $\hat{V}_a = (\hat{v}_{a,i,j})$  are  $n \times n$  matrices with elements  $\hat{v}_{ij} = \hat{c}'_i \hat{Q}_x^{-1} \hat{S}_{ij} \hat{Q}_x^{-1} \hat{c}_i$ , and  $\hat{v}_{a,i,j} = E_1' \hat{Q}_x^{-1} \hat{S}_{ij} \hat{Q}_x^{-1} E_1$ . The table reports the  $p$ -values of the statistics.

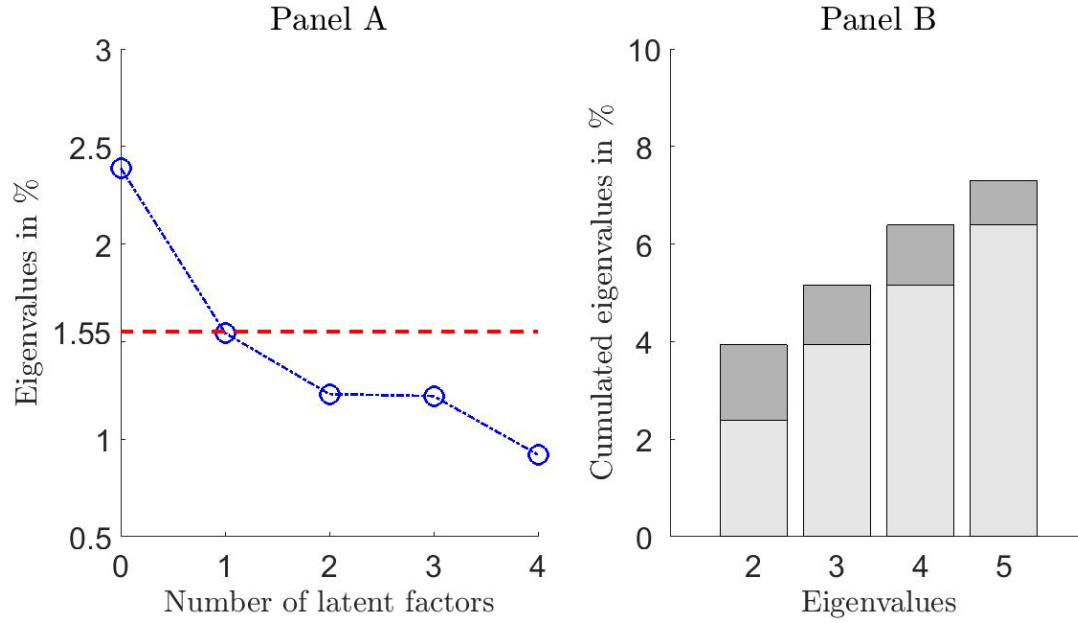

Figure 1: **Number of omitted factors and cumulated eigenvalues for the time-invariant CAPM model.** Panel A plots the scree-plot of the values of the first five eigenvalues in percentage, i.e.,  $\mu_j \left( \frac{1}{n \times T} \sum_i \mathbf{1}_i^X \bar{\varepsilon}_i \bar{\varepsilon}_i' \right)$  with  $j = 1, \dots, 5$ . The horizontal line corresponds to the penalty function  $g(n^X, T)$ . Panel B plots the cumulated eigenvalues in percentage. The light grey area corresponds to  $\sum_{l=1}^{j-1} \mu_l \left( \frac{1}{n \times T} \sum_i \mathbf{1}_i^X \bar{\varepsilon}_i \bar{\varepsilon}_i' \right)$ , the dark grey area is the contribution of the  $j$ -th eigenvalue in percentage.

Figure 2: **Number of omitted factors and cumulated squared eigenvalues for the time-invariant CAPM model.** Panel A plots the scree-plot of the values of the first five squared eigenvalues in percentage, i.e.,  $\mu_j^2 \left( \frac{1}{n^\chi T} \sum_i \mathbf{1}_i^\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i \right) / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i \right)$  with  $j = 1, \dots, 5$ . The horizontal line corresponds to the penalty function  $g(n^\chi, T)^2 / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i \right)$ . Panel B plots the cumulated squared eigenvalues in percentage. The light grey area corresponds to  $\sum_{l=1}^{j-1} \mu_l^2 \left( \frac{1}{n^\chi T} \sum_i \mathbf{1}_i^\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i \right) / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i \right)$ , the dark grey area is the contribution of the  $j$ -th squared eigenvalue in percentage.

Figure 3: **Number of omitted factors and cumulated eigenvalues for the time-invariant three-factor Fama-French model.** Panel A plots the scree-plot of the values of the first five eigenvalues in percentage, i.e.,  $\mu_j \left( \frac{1}{n^{\chi T}} \sum_i \mathbf{1}_i^{\chi} \bar{\varepsilon}_i \bar{\varepsilon}_i' \right)$  with  $j = 1, \dots, 5$ . The horizontal line corresponds to the penalty function  $g(n^{\chi}, T)$ . Panel B plots the cumulated eigenvalues in percentage. The light grey area corresponds to  $\sum_{l=1}^{j-1} \mu_l \left( \frac{1}{n^{\chi T}} \sum_i \mathbf{1}_i^{\chi} \bar{\varepsilon}_i \bar{\varepsilon}_i' \right)$ , the dark grey area is the contribution of the  $j$ -th eigenvalue in percentage.

Figure 4: **Number of omitted factors and cumulated squared eigenvalues for the time-invariant three-factor Fama-French model.** Panel A plots the scree-plot of the values of the first five squared eigenvalues in percentage, i.e.,  $\mu_j^2 \left( \frac{1}{n \times T} \sum_i \mathbf{1}_i^X \bar{\bar{\epsilon}}_i \bar{\bar{\epsilon}}_i' \right) / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^X \bar{\bar{\epsilon}}_i \bar{\bar{\epsilon}}_i' \right)$  with  $j = 1, \dots, 5$ . The horizontal line corresponds to the penalty function  $g(n^X, T)^2 / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^X \bar{\bar{\epsilon}}_i \bar{\bar{\epsilon}}_i' \right)$ . Panel B plots the cumulated squared eigenvalues in percentage. The light grey area corresponds to  $\sum_{l=1}^{j-1} \mu_l^2 \left( \frac{1}{n \times T} \sum_i \mathbf{1}_i^X \bar{\bar{\epsilon}}_i \bar{\bar{\epsilon}}_i' \right) / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^X \bar{\bar{\epsilon}}_i \bar{\bar{\epsilon}}_i' \right)$ , the dark grey area is the contribution of the  $j$ -th squared eigenvalue in percentage.

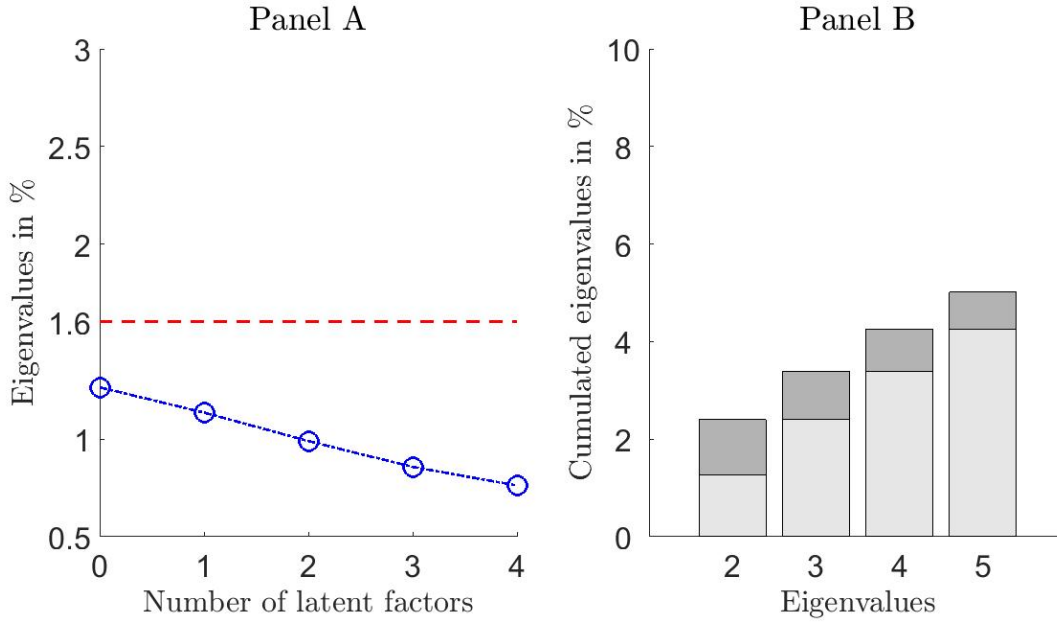

Figure 5: **Number of omitted factors and cumulated eigenvalues for the time-invariant four-factor CAR model.** Panel A plots the scree-plot of the values of the first five eigenvalues in percentage, i.e.,  $\mu_j \left( \frac{1}{n^{\lambda T}} \sum_i \mathbf{1}_i^{\lambda} \bar{\varepsilon}_i \bar{\varepsilon}_i' \right)$  with  $j = 1, \dots, 5$ . The horizontal line corresponds to the penalty function  $g(n^{\lambda}, T)$ . Panel B plots the cumulated eigenvalues in percentage. The light grey area corresponds to  $\sum_{l=1}^{j-1} \mu_l \left( \frac{1}{n^{\lambda T}} \sum_i \mathbf{1}_i^{\lambda} \bar{\varepsilon}_i \bar{\varepsilon}_i' \right)$ , the dark grey area is the contribution of the  $j$ -th eigenvalue in percentage.

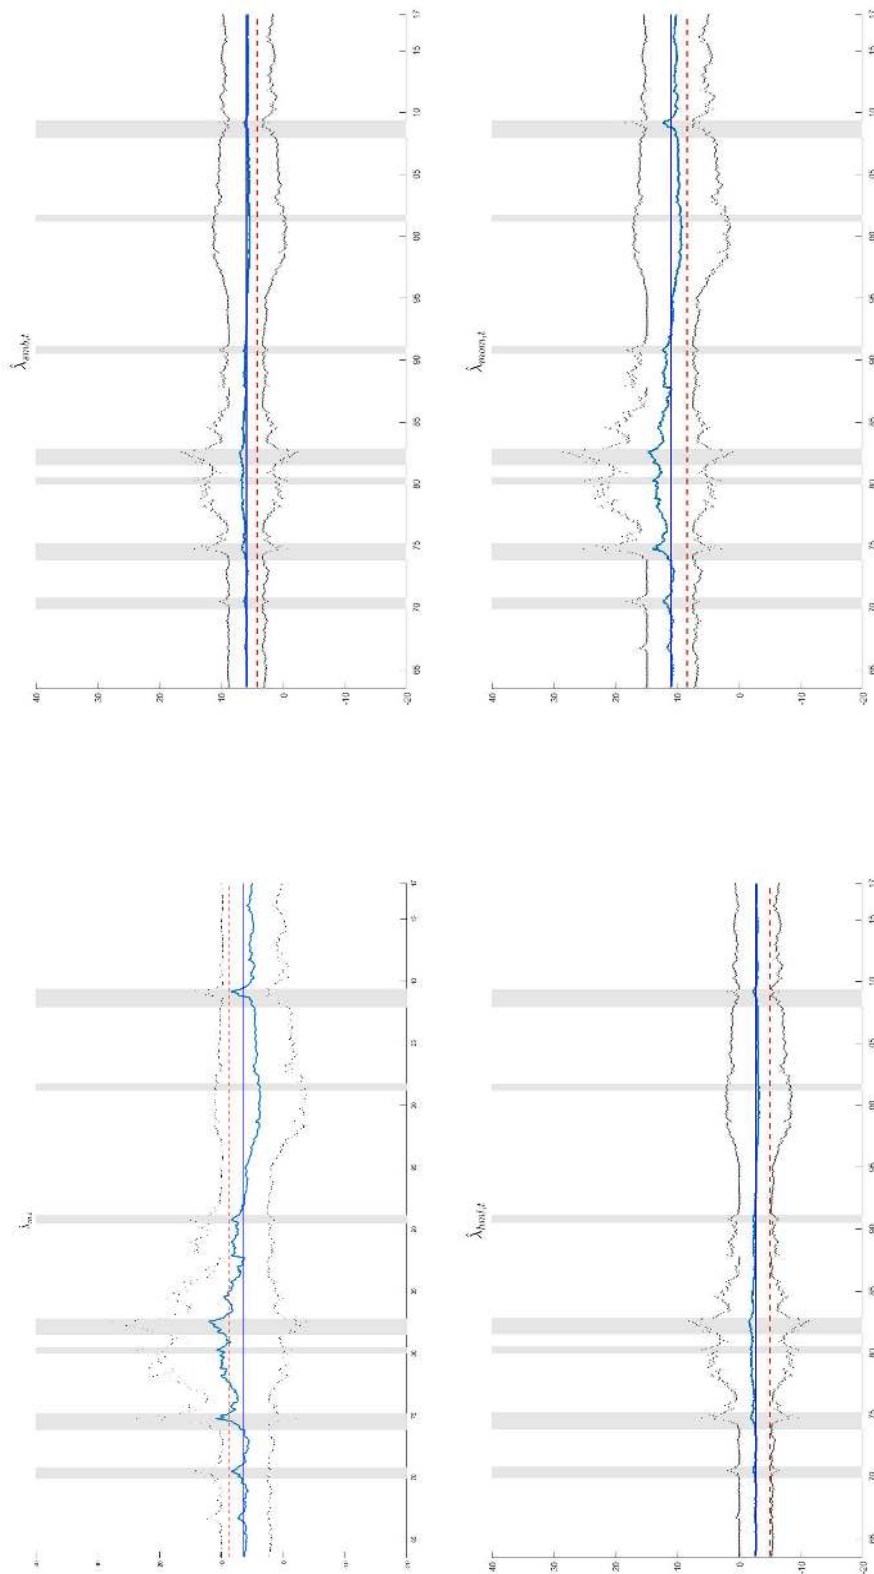

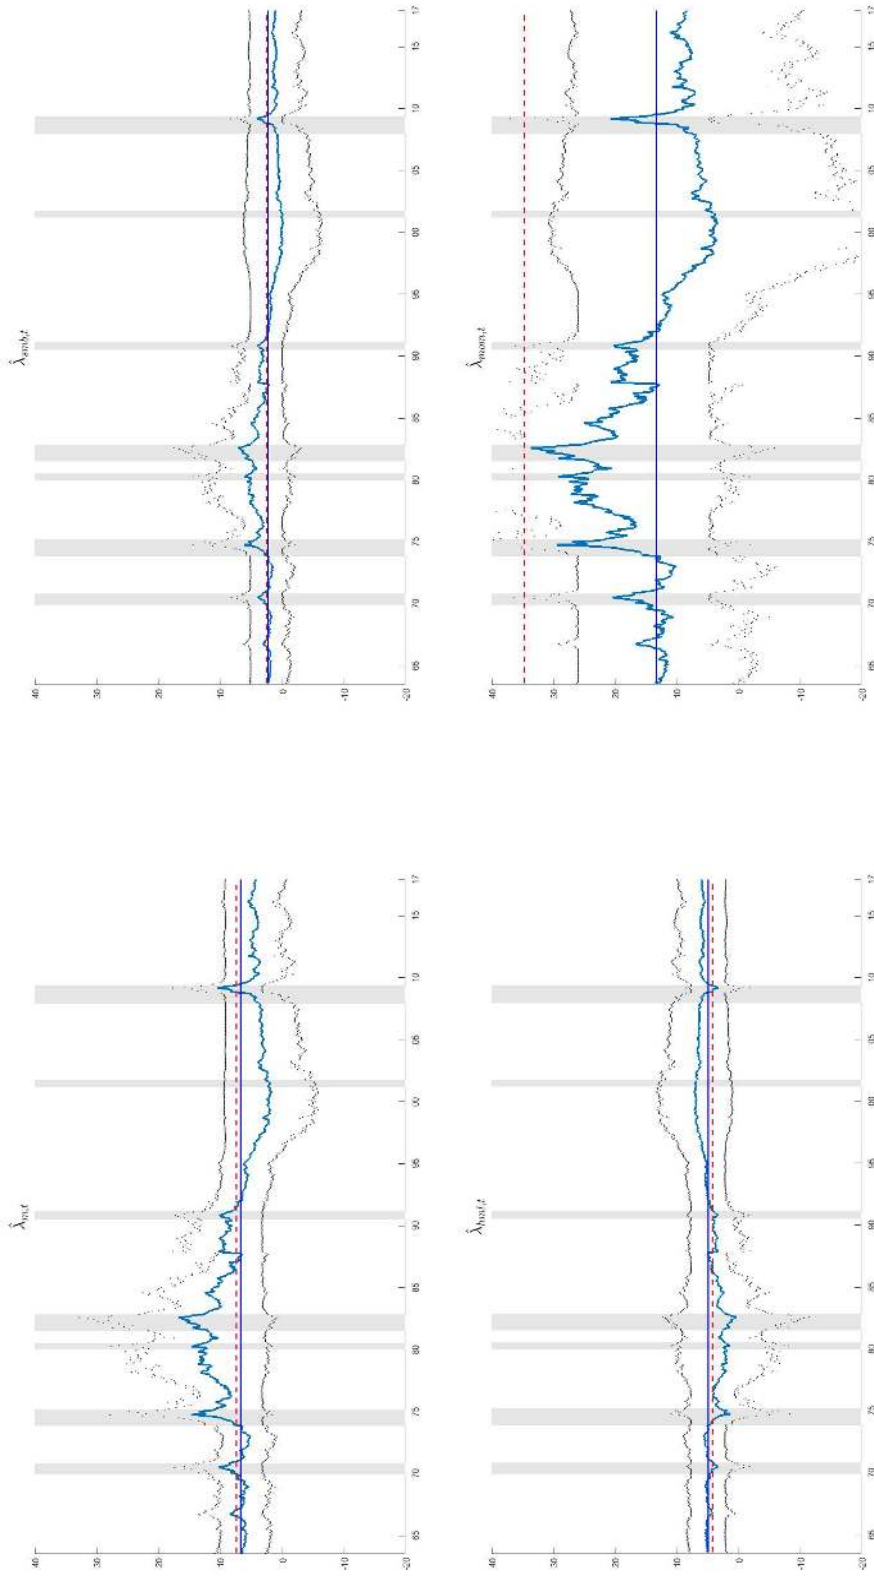

Figure 6: **Number of omitted factors and cumulated squared eigenvalues for the time-invariant four-factor CAR model.** Panel A plots the scree-plot of the values of the first five squared eigenvalues in percentage, i.e.,  $\mu_j^2 \left( \frac{1}{n^{\chi T}} \sum_i \mathbf{1}_i^{\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i} \right) / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^{\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i} \right)$  with  $j = 1, \dots, 5$ . The horizontal line corresponds to the penalty function  $g(n^{\chi}, T)^2 / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^{\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i} \right)$ . Panel B plots the cumulated squared eigenvalues in percentage. The light grey area corresponds to  $\sum_{l=1}^{j-1} \mu_l^2 \left( \frac{1}{n^{\chi T}} \sum_i \mathbf{1}_i^{\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i} \right) / \sum_{l=1}^T \mu_l^2 \left( \frac{1}{nT} \sum_i \mathbf{1}_i^{\chi \bar{\bar{\epsilon}}_i \bar{\epsilon}'_i} \right)$ , the dark grey area is the contribution of the  $j$ -th squared eigenvalue in percentage.

**Figure 7: Path of estimated annualized risk premia with  $n = 8, 570$  in the four-factor CAR model**

The figure plots the path of estimated annualized risk premia  $\hat{\lambda}_{m,t}$ ,  $\hat{\lambda}_{smb,t}$ ,  $\hat{\lambda}_{hml,t}$ , and  $\hat{\lambda}_{mom,t}$  and their pointwise confidence intervals at 95% probability level in the four-factor CAR model. We also report the time-invariant (dashed horizontal line) and the average conditional estimate (solid horizontal line). The vertical shaded areas denote recessions determined by the National Bureau of Economic Research (NBER). The recessions start at the peak of a business cycle and end at the trough.

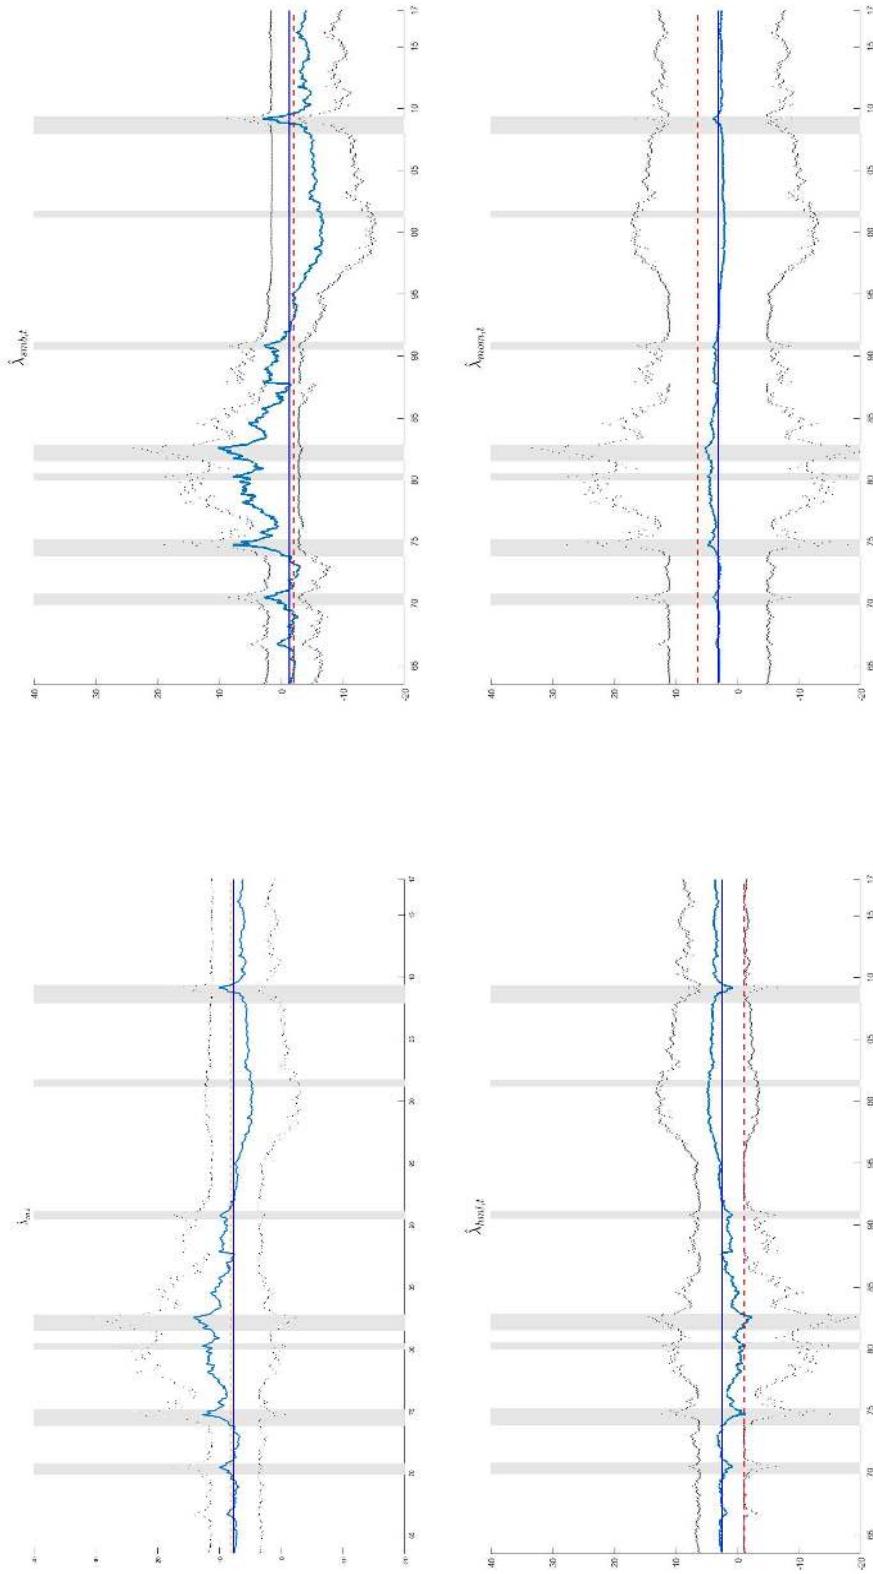

**Figure 8: Path of estimated annualized risk premia with  $n = 25$  in the four-factor CAR model**

The figure plots the path of estimated annualized risk premia  $\hat{\lambda}_{m,t}$ ,  $\hat{\lambda}_{smb,t}$ ,  $\hat{\lambda}_{hml,t}$ , and  $\hat{\lambda}_{mom,t}$  and their pointwise confidence intervals at 95% probability level in the four-factor CAR model. We use the returns of the 25 FF portfolios. We also report the time-invariant (dashed horizontal line) and the average conditional estimate (solid horizontal line). The vertical shaded areas denote recessions determined by the National Bureau of Economic Research (NBER).

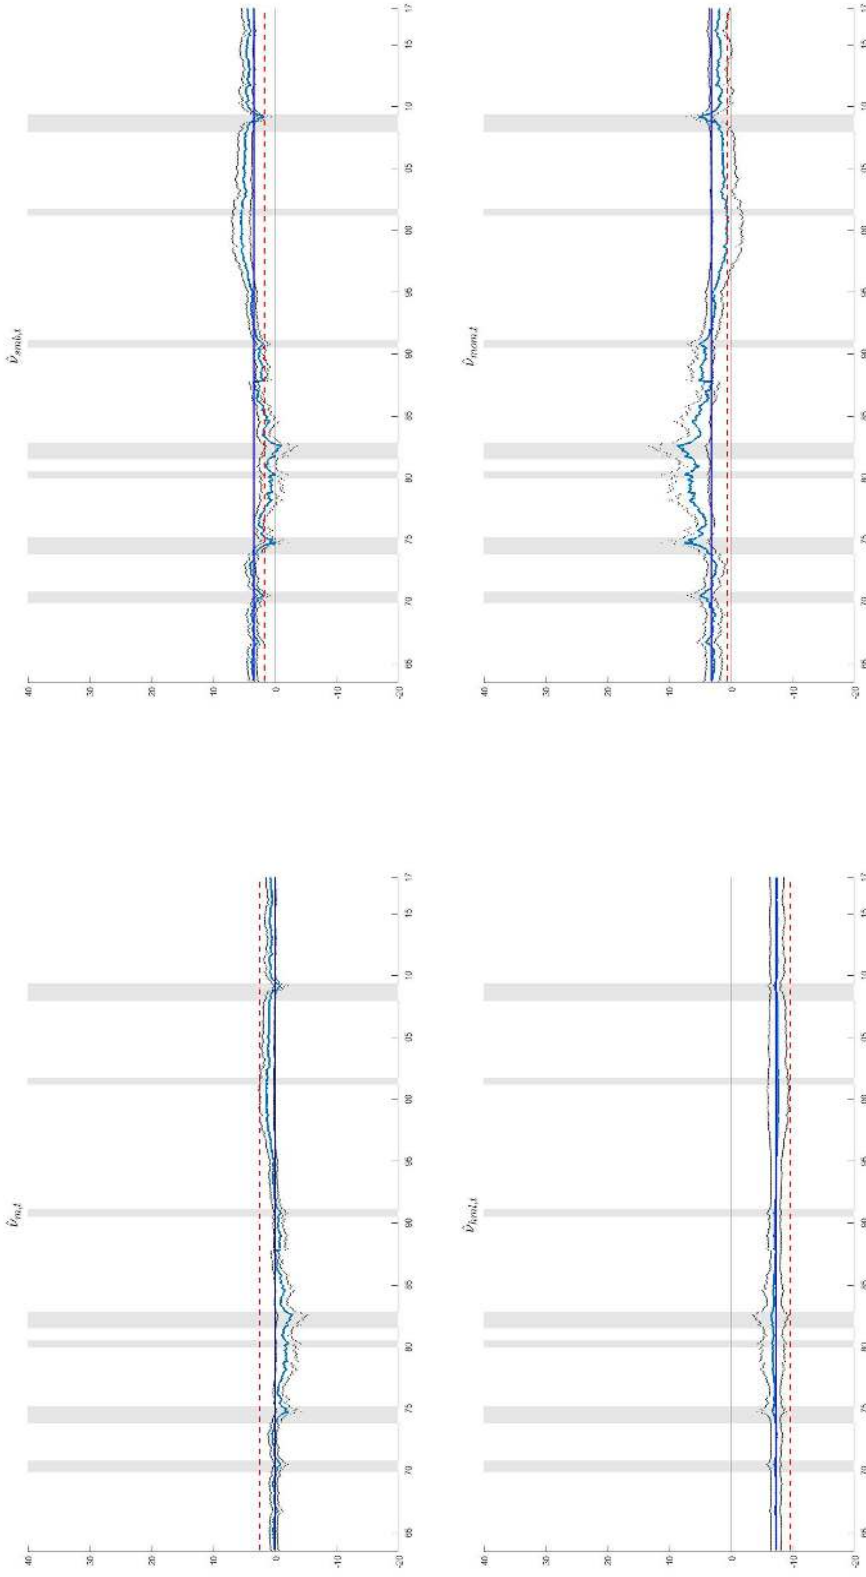

**Figure 9: Path of estimated annualized risk premia with  $n = 44$  in the four-factor CAR model**

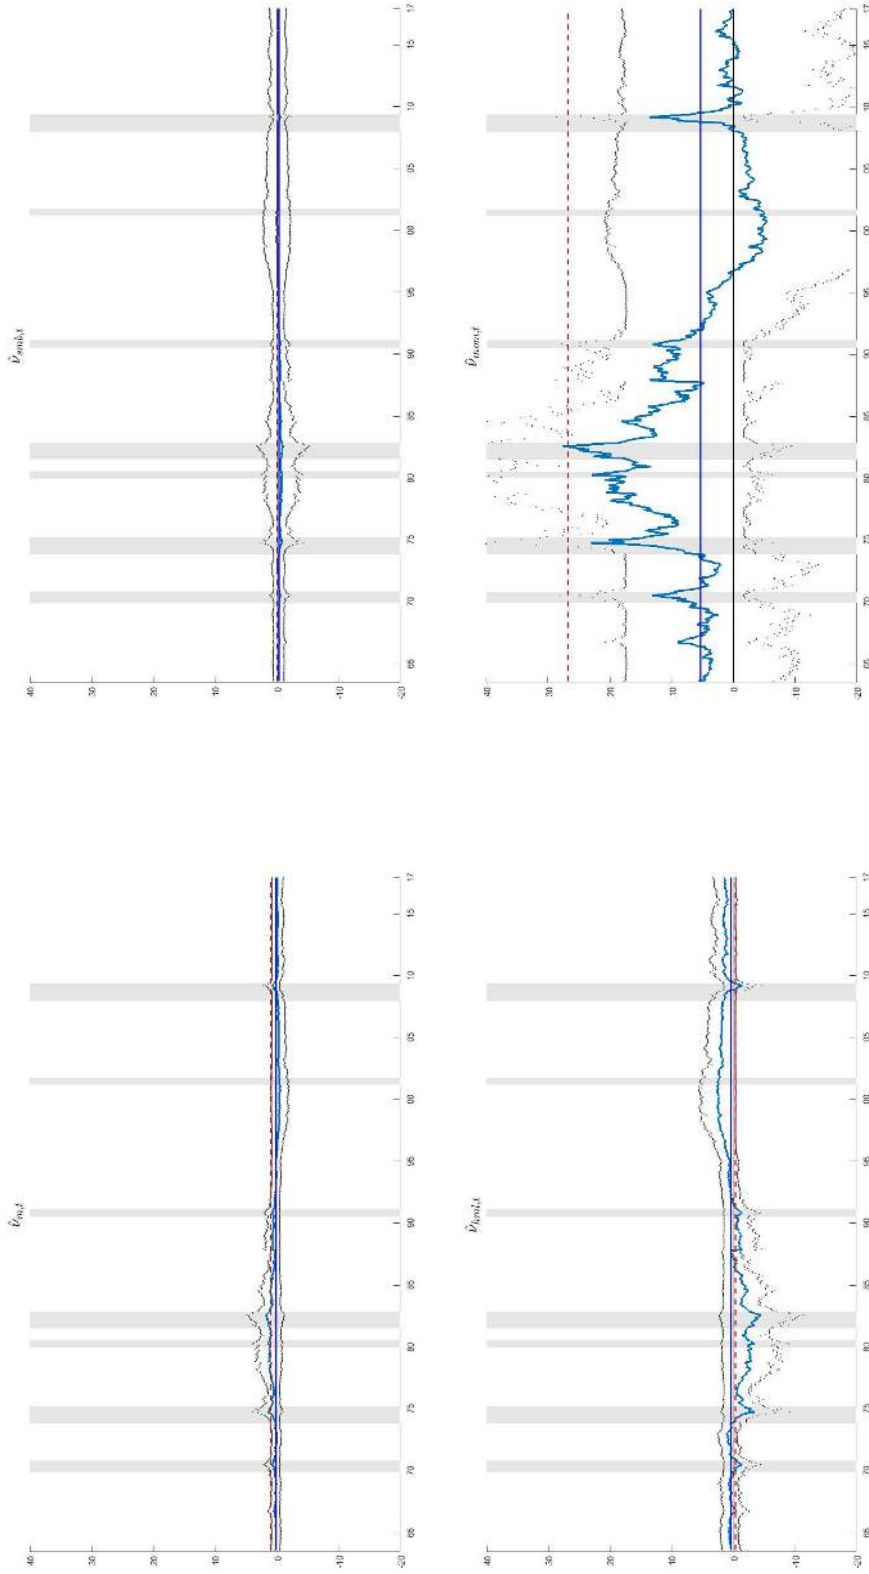

The figure plots the path of estimated annualized risk premia  $\hat{\lambda}_{m,t}$ ,  $\hat{\lambda}_{smb,t}$ ,  $\hat{\lambda}_{hml,t}$ , and  $\hat{\lambda}_{mom,t}$  and their pointwise confidence intervals at 95% probability level in the four-factor CAR model. We use the returns of the 44 industry portfolios. We also report the time-invariant (dashed horizontal line) and the average conditional estimate (solid horizontal line). The vertical shaded areas denote recessions determined by the National Bureau of Economic Research (NBER).

**Figure 10: Path of estimated annualized  $\nu_t$  with  $n = 8, 570$  in the four-factor CAR model**

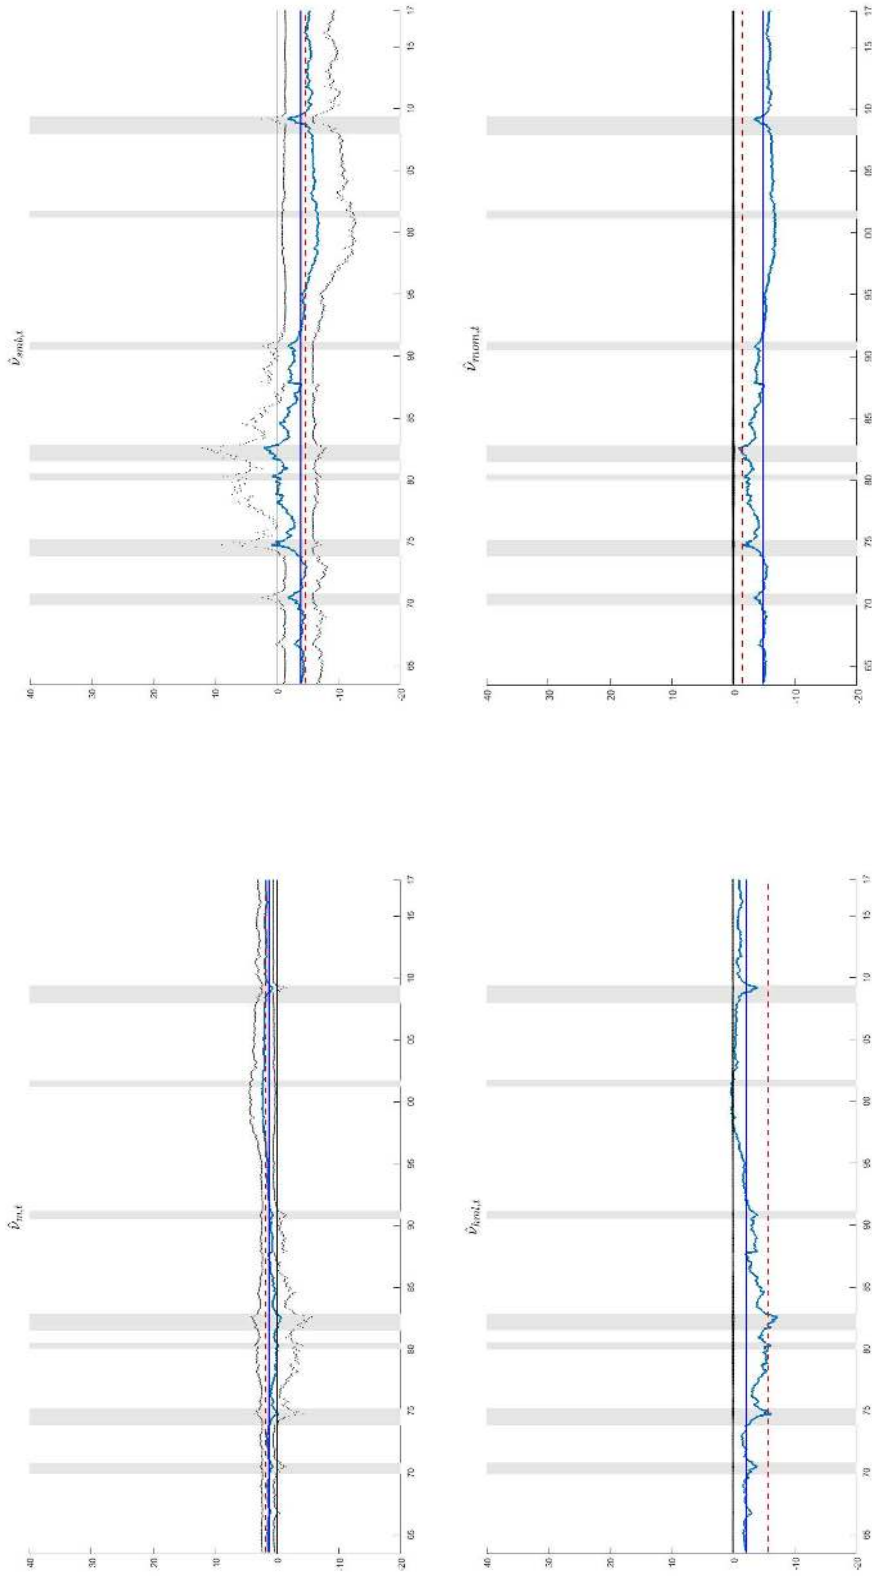

The figure plots the path of estimated annualized  $\hat{\nu}_{m,t}$ ,  $\hat{\nu}_{smb,t}$ ,  $\hat{\nu}_{hml,t}$ , and  $\hat{\nu}_{mom,t}$  and their pointwise confidence intervals at 95% probability level in the four-factor CAR model. We also report the time-invariant (dashed horizontal line) and the average conditional estimate (solid horizontal line). We consider all stocks as base assets ( $n = 8, 570$  and  $n^X = 2, 549$ ). The recessions start at the peak of a business cycle and end at the trough.

**Figure 11: Path of estimated annualized  $\nu_t$  with  $n = 25$  in the four-factor CAR model**

The figure plots the path of estimated annualized  $\hat{\nu}_{m,t}$ ,  $\hat{\nu}_{smb,t}$ ,  $\hat{\nu}_{hml,t}$ , and  $\hat{\nu}_{mom,t}$  and their pointwise confidence intervals at 95% probability level in the four-factor CAR model. We use the returns of the 25 FF portfolios. We also report the time-invariant (dashed horizontal line) and the average conditional estimate (solid horizontal line). The vertical shaded areas denote recessions determined by the National Bureau of Economic Research (NBER).

Figure 12: Path of estimated annualized  $\nu_t$  with  $n = 44$  in the four-factor CAR model

The figure plots the path of estimated annualized  $\hat{\nu}_{m,t}$ ,  $\hat{\nu}_{smb,t}$ ,  $\hat{\nu}_{hml,t}$ , and  $\hat{\nu}_{mom,t}$  and their pointwise confidence intervals at 95% probability level in the four-factor CAR model. We use the returns of the 44 industry portfolios. We also report the time-invariant (dashed horizontal line) and the average conditional estimate (solid horizontal line). The vertical shaded areas denote recessions determined by the National Bureau of Economic Research (NBER).

**Figure 13: Cross-sectional distributions of  $\hat{\rho}_i^2$ ,  $\hat{\rho}_{ad,i}^2$ ,  $IdiVol_i$ , and  $SysRisk_i$  for the time-invariant four-factor CAR model**

The figure displays the cross-sectional distributions of (i) the estimated coefficients of determination  $\hat{\rho}_i^2$ , (ii) the estimated adjusted coefficients of determination  $\hat{\rho}_{ad,i}^2$ , (iii) the idiosyncratic risks  $IdiVol_i$ , and (iv) the systematic risks  $SysRisk_i$  for the individual stocks (box-plots), the 25 FF portfolios (red triangles) and the 44 Indu. portfolios (blue stars). Estimates are for the time-invariant four-factor CAR model. For comparison purposes, the cross-sectional distribution for individual stocks refers to the  $n^x = 2,549$  stocks that are used in the estimation of the time-varying model after trimming.

**Figure 14: Cross-sectional distributions of  $\hat{\rho}_i^2$ ,  $\hat{\rho}_{ad,i}^2$ ,  $IdiVol_i$ , and  $SysRisk_i$  for the time-varying four-factor CAR model**

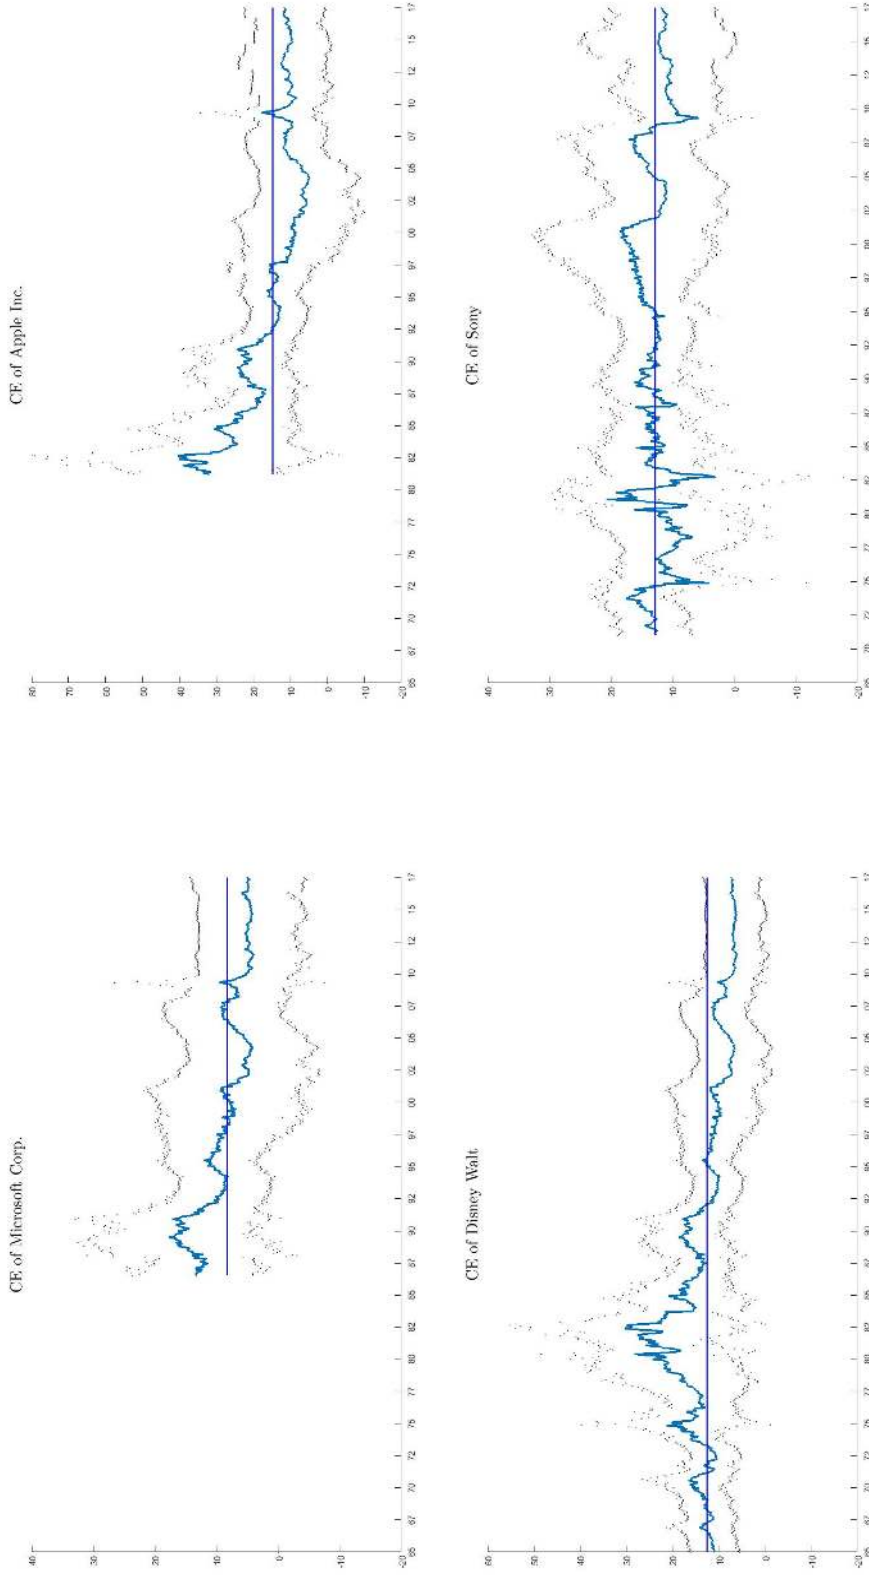

The figure displays the cross-sectional distributions of (i) the estimated coefficients of determination  $\hat{\rho}_i^2$ , (ii) the estimated adjusted coefficients of determination  $\hat{\rho}_{ad,i}^2$ , (iii) the idiosyncratic risks  $IdiVol_i$ , and (iv) the systematic risks  $SysRisk_i$  for the  $n^x = 2,549$  individual stocks (box-plots), the 25 FF portfolios (red triangles) and the 44 Indu. portfolios (blue stars). Estimates are for the time-varying four-factor CAR model.

**Figure 15: Cross-sectional distributions of  $\hat{\beta}'_{1,i}\hat{\beta}_{1,i}$  for the time-varying four-factor CAR model**

The figure plots the cross-sectional distributions of  $\hat{\beta}'_{1,i}\hat{\beta}_{1,i}$  for the  $n^x = 2,549$  individual stocks (box-plot), the 25 FF portfolios (red triangles) and the 44 Indu. portfolios (blue stars). Estimated  $\hat{\beta}_{1,i}$  are for the time-varying four-factor CAR model.

**Figure 16: Path of estimated annualized costs of equity**

The figure plots the path of estimated annualized costs of equity for Microsoft Inc., Apple Inc., Disney Walt, and Sony and their pointwise confidence intervals at 95% probability level. We use the time-varying four-factor CAR model estimated on individual stocks ( $n = 8, 570$ ,  $n^{\lambda} = 2, 549$ ). We also report the average conditional estimate (solid horizontal line).
