Scientific and Technical<br>Information Branch

The purpose of this study was to evaluate the use of a computer-generated perspective tunnel display for following a strongly curved flight path. The display was evaluated by monitoring pilot performance in a fixed-base simulator with the vehicle dynamics of a $\mathrm{CH}-47$ tandem-rotor helicopter, linearized about a $33.5-\mathrm{m} / \mathrm{sec}(110 \mathrm{ft} / \mathrm{sec}$ ) forward velocity and a level flight trim condition. Superposition of the predicted future vehicle position on the tunnel image was also investigated to determine whether, and to what extent, it contributes to better system performance (the best predicted future vehicle position was sought).

Three types of simulator experiments were conducted: following a desired trajectory in the presence of disturbances; entering the trajectory from a random position, outside the trajectory; and detecting and correcting failures in automatic flight. Two other display configurations were considered for comparison: a tracking display which incorporates future trajectory information by displaying the predicted future error, and combined vertical and horizontal situation displays containing aircraft attitude information and trajectory map information, respectively.

The tunnel display with superimposed predictor/director symbols was shown to be a very successful combination, which outperformed the other two displays in all three experiments. A prediction time of 4 to 7 sec was found to optimize trajectory tracking for the given vehicle dynamics and flight condition. Pilot acceptance of the tunnel plus predictor/director display was found to be favorable, and the time the pilot needed for familiarization with the display was found to be relatively short.

The simulator study was conducted on the Langley Real-Time Simulation System using a fixed-base simulator cabin with helicopter controls. An Adage Graphics Terminal, the AGT/130, was programmed to generate the various display configurations. The Control Data CYBER 175 computer system at the Langley Research Center was used in the real-time mode for simulating the vehicle dynamics and for the on-line and off-line data processing.

The feasibility of the tunnel display for operation in actual flight was demonstrated at NASA Wallops Flight Center, Wallops Island, Va. A modified CH-47 helicopter served as the flight vehicle. The tunnel image provided sufficient control information for following the trajectory smoothly, and the deviations from the desired trajectory remained within reasonable limits.

## INTRODUCTION

In a conventional helicopter approach under instrument flight rules (IFR), control information (such as position, rate, and attitude information) is presented to the pilot by a set of electromechanical flight instruments. On most instruments, the control variable is explicitly displayed as the deviation of a pointer from an indicated reference line. However, this information is rather symbolic and shows little resemblance with the visual world the pilot is used to. Furthermore, several instruments are used, and the pilot must derive the control information by scanning them. Thus, the conventional IFR approach requires a high level of pilot proficiency and imposes a high workload. In order to minimize the probability of human errors, the approach path generally is kept simple, with a limited number of straight and curved sections.

In the advanced display concept under investigation, control information is presented to the pilot in a format similar to the "through-the-windshield" visual field. A simplified computer-generated perspective image of the visual field is presented to the pilot as if it were a "tunnel in the sky," in which the three-dimensional (3-D) approach path is to be followed. In contrast with conventional instrument displays, the control information is integrated into one format, natural to the pilot. This characteristic makes the display very suitable for following, with great accuracy, approaches which are complicated, strongly curved, and steep. This type of approach might become a necessity in heavily congested fixed-wing and helicopter traffic areas.

Use of trade names or names of manufacturers in this report does not constitute an official endorsement of such products or manufacturers, either expressed or implied, by the National Aeronautics and Space Administration.

## SYMBOLS AND ABBREVIATIONS

$\mathrm{A}_{\ell}, \mathrm{A}_{\mathrm{v}} \quad$ lateral or vertical not-augmented system matrix
$\hat{A}_{\ell}, \hat{A}_{\mathrm{V}} \quad$ lateral or vertical augmented system matrix, SAS engaged
$a_{\ell}, a_{v} \quad$ inertial accelerations of vehicle along $y_{b}$-axis and $z_{b}$-axis, respectively, $\mathrm{m} / \mathrm{sec}^{2}$
$a_{t} \quad$ centripetal trajectory acceleration, $m / \sec ^{2}$
$B_{\ell}, B_{v} \quad$ lateral or vertical input matrix
$\operatorname{cov}()$ autocovariance

D predictor distance, $m$
$d_{\ell}, d_{v} \quad$ lateral or vertical deviation from trajectory, $m$
$d_{p} \quad$ preview term, m, see equation (A34)
$d_{\gamma} \quad$ lateral intercept angle of velocity vector and trajectory direction, rad
$\mathrm{d}_{\theta} \quad$ vertical intercept angle of vehicle axis and trajectory direction, rad
$\mathrm{d}_{\psi} \quad$ lateral intercept angle of vehicle axis and trajectory direction, rad
$\mathrm{F}_{\ell}, \mathrm{F}_{\mathrm{V}} \quad$ lateral or vertical feedback matrix
$\mathrm{f}(\mathrm{t}) \quad$ lateral trajectory curvature, $\mathrm{m}^{-1}$
$f_{p}, g_{p} \quad$ roll rate on cyclic SAS gain and feedback, respectively
$\mathrm{f}_{\mathrm{pr}}, \mathrm{g}_{\mathrm{pr}} \quad$ roll rate on differential, cyclic SAS gain and feedback, respectively
$f_{q}, g_{q} \quad$ pitch rate on SAS gain and feedback, respectively
$f_{r}, g_{r} \quad$ yaw rate on SAS gain and feedback, respectively
$\mathrm{f}_{\mathrm{u}}, \mathrm{g}_{\mathrm{u}} \quad$ perturbed forward-velocity SAS gain and feedback, respectively
$\mathrm{f}_{\mathrm{v}}, \mathrm{g}_{\mathrm{v}} \quad$ sideslip SAS gain and feedback, respectively
$\mathrm{f}_{\theta}, \mathrm{g}_{\theta} \quad$ pitch SAS gain and feedback, respectively
$\mathrm{g} \quad$ acceleration due to gravity, $\mathrm{m} / \mathrm{sec}^{2}$
${ }_{H_{\delta}}^{d}{ }_{s}^{d}(s), H_{\delta}^{d} v_{c}(s) \quad$ transfer function relating deviation to control input
$\mathrm{I}_{\mathrm{xx}}, \mathrm{I}_{\mathrm{yy}}, \mathrm{I}_{\mathrm{zz}} \quad$ vehicle moments of inertia about $\mathrm{x}_{\mathrm{b}}$-axis, $\mathrm{y}_{\mathrm{b}}$-axis, and $\mathrm{z}_{\mathrm{b}}$-axis, respectively, $\mathrm{kg}-\mathrm{m}^{2}$

| $\mathrm{I}_{\mathrm{xz}}$ | vehicle product of inertia in $\mathrm{x}_{\mathrm{b}} \mathrm{z}_{\mathrm{b}}$-plane, $\mathrm{kg}-\mathrm{m}^{2}$ |
| :---: | :---: |
| $\mathrm{K}_{\mathrm{d}_{\ell}}$ | lateral gain, stability augmentation system |
| $\mathrm{K}_{\mathrm{d}_{\mathrm{v}}}$ | vertical gain, stability augmentation system |
| $k_{b \ell}, k_{b v}$ | gain of biases on estimates of $v$ and $w$, respectively, see equations (7) and (8) |
| $\mathrm{k}_{\mathrm{br}}$ | undesired rudder input gain, see equation (9) |
| $\mathrm{k}_{\ell}, \mathrm{k}_{\mathrm{v}}$ | lateral or vertical automatic control system gain, see equations (3) and (4) |
| $\mathrm{k}_{\ell p}$ | simulated roll-rate feedback failure gain, see equation (10) |
| $\mathrm{k}_{\mathrm{pv}}$ | gain for reduction of vertical acceleration in computing vertical prediction, see equation (B5) |
| L, M, N | total rolling, pitching, and yawing moments about center of gravity of vehicle, $\mathrm{N} \cdot \mathrm{m}$ |
| m | vehicle mass, kg |
| $\mathrm{p}, \mathrm{q}, \mathrm{r}$ | vehicle angular velocity about $\mathrm{x}_{\mathrm{b}}$-axis, $\mathrm{y}_{\mathrm{b}}$-axis, and $\mathrm{z}_{\mathrm{b}}$-axis, respectively, $\mathrm{rad} / \mathrm{sec}$ |
| $\mathrm{R}_{\ell}, \mathrm{R}_{\mathrm{v}}$ | radius of curvature of lateral or vertical vehicle path, m |
| $\mathrm{R}_{\mathrm{t}}$ | radius of curvature of lateral trajectory, m |
| s | Laplace operator |
| sc( ) | deviation score for entry maneuvers, m |
| $\mathrm{T}_{\mathrm{c}}$ | time elapsed between moment of manual takeover and moment of reengagement of automatic control system (correction time), sec |
| $\mathrm{T}_{\mathrm{f}}$ | time of occurrence of automatic control failure, sec |
| $\mathrm{T}_{\mathrm{p}}$ | prediction time, sec |

| $\mathrm{T}_{\mathrm{r}}$ | time elapsed between occurrence of automatic control failure and moment of manual takeover (reaction time), sec |
| :---: | :---: |
| $\mathrm{T}_{\mathrm{s} \ell}, \mathrm{~T}_{\mathrm{sv}}$ | lateral or vertical settling time, sec |
| $\mathrm{T}_{1}, \mathrm{~T}_{2}$ | starting point and end point, respectively, of run-time range (used for computation of deviation scores) |
| t | time |
| $\mathbf{u}, \mathrm{v}, \mathrm{w}$ | velocity of vehicle along $\mathrm{x}_{\mathrm{b}}$-axis, $\mathrm{y}_{\mathrm{b}}$-axis, and $\mathrm{z}_{\mathrm{b}}$-axis, respectively, $\mathrm{m} / \mathrm{sec}$ |
| $\mathrm{u}_{\mathrm{N}},{ }^{\text {w }} \mathrm{N}$ | nominal trim values of $u$ and $w, m / s e c$ |
| V | ground speed, m/sec |
| $\overrightarrow{\mathrm{V}}$ | vehicle velocity vector |
| $\mathrm{v}_{\mathrm{g}}, \mathrm{w}_{\mathrm{g}}$ | lateral or vertical gust component, $\mathrm{m} / \mathrm{sec}$ |
| $W_{\ell}, W_{v}$ | lateral or vertical disturbance matrix |
| X, Y, Z | total aerodynamic, thrust, and gravitational forces along $\mathrm{x}_{\mathrm{b}}$-axis, $\mathrm{y}_{\mathrm{b}}$-axis, and $\mathrm{z}_{\mathrm{b}}$-axis, respectively, N |
| $\mathrm{x}_{\mathrm{b}}, \mathrm{y}_{\mathrm{b}}, \mathrm{z}_{\mathrm{b}}$ | orthogonal body-axis coordinate system, with $x_{b}$-axis pointing toward front of vehicle, $\mathrm{y}_{\mathrm{b}}$-axis pointing to right, and $\mathrm{z}_{\mathrm{b}}$-axis pointing downward |
| $\mathrm{x}_{\mathrm{i}}, \mathrm{y}_{\mathrm{i}}, \mathrm{z}_{\mathrm{i}}$ | orthogonal inertial coordinate system, with $\mathrm{x}_{\mathrm{i}}$-axis pointing to north, $\mathrm{y}_{\mathrm{b}}$-axis to east, and $\mathrm{z}_{\mathrm{b}}$-axis downward |
| $\vec{x}_{\ell}, \vec{x}_{V}$ | lateral or vertical state vector |
| $\delta_{b}, \delta_{c}, \delta_{s}, \delta_{r}$ | differential-collective, collective, cyclic, and differential-cyclic control inputs, cm |
| $\delta_{b, a}{ }^{, \delta_{c, a}}{ }^{\prime} \delta_{s}$ | $\begin{aligned} & \mathrm{a}^{, \delta_{r, a}} \quad \text { differential-collective, collective, cyclic, and differential-cyclic } \\ & \text { actuator inputs, } \mathrm{cm} \end{aligned}$ |

| $\vec{\delta}_{\ell}, \vec{\delta}_{\mathbf{V}}$ | lateral or vertical control input vector |
| :---: | :---: |
| $\vec{\delta}_{\mathrm{s}, \mathrm{a}}, \vec{\delta}_{\mathrm{v}, \mathrm{a}}$ | lateral or vertical actuator input vector |
| $\epsilon_{\ell}, \epsilon_{\mathrm{v}}$ | lateral or vertical predicted deviation from trajectory, m |
| $\zeta$ | damping factor |
| $\theta, \phi, \psi$ | pitch, roll, and yaw attitude angles, rad |
| ${ }^{\theta} \mathrm{N}$ | nominal trim value of pitch attitude, rad |
| $\theta_{\mathrm{t}}$ | downslope of trajectory, rad |
| $\lambda_{\ell}, \lambda$ | lateral or vertical displacement of predictor on screen, in screen coordinates |
| $\sigma$ | standard deviation (root-mean-square deviation from mean) |
| $\omega_{\mathrm{n}}$ | natural frequency, rad/sec |

Abbreviations:

EADI electronic attitude director indicator

HSI horizontal situation indicator

IFR instrument flight rules

SAS stability augmentation system

VAC vehicle axis cross

VALT VTOL approach and landing technology

An arrow over a symbol denotes a vector quantity. A dot over a symbol denotes the first derivative with respect to time. A prime denotes values generated by the automatic control system.

## DISPLAY CONFIGURATION

The conceptual tunnel display is shown in figure 1. The trajectory to be followed is presented as a perspective image of a tunnel with a square cross section. The perspective appearance of the tunnel changes with the vehicle position. Positional cues are derived from this perspective appearance, while rate cues are derived from the rate of change in the appearance.

The tunnel cross section is constant and square with a scale width of 45.7 m ( 150 ft ), which corresponds to the width of a typical runway. The Adage Graphics Terminal is programmed to draw (see fig. 2(a)) tunnel squares (1) and cornerlines (2) . An experimental configuration was chosen in which the tunnel squares are drawn a scale distance of 91.4 m ( 300 ft ) apart. In order to augment the impression of forward velocity, the cornerlines are dashed. Only the five squares nearest to the vehicle are drawn. Thus, the number of lines drawn is substantially reduced, which prevents cluttering of the display. The tunnel is shown in the viewing range from 0 to 762 m ( 2500 ft ). The maximum horizontal and vertical field of view is from $+45^{\circ}$ to $-45^{\circ}$. The tunnel image generated is square and is shown on the $33-\mathrm{cm}$ ( $13-\mathrm{in}$.) display monitor, with aspect ratio $4: 3$ (horizontal:vertical). The tunnel image magnification is 0.165 for an average viewing distance of 76.2 cm ( 30 in .) from the monitor. Pitch scales (3) and pitch poiniers (5) are located at the left and right sides of the image, and a roll scale (4) is located at the top. Pitch motion is also visualized by an equivalent rotation of the optical axis. For small angles, this is equivalent to a vertical displacement of 0.22 cm per degree pitch angle of the tunnel image. The pitch pointer and the tunnel image are displaced, while the pitch scales remain vertically fixed.

Digital readouts of magnetic heading (MAG) 10 and airspeed (TAS) (11) are displayed in boxes on the vertical centerline at the top and bottom of the image, respectively. (See fig. 2(a).) These boxes also provide a reference for estimating the center of the image. Note that a large area in the center of the display is kept clear of symbology to prevent cluttering the tunnel image.

In addition to the basic tunnel display, several other displays were used in the evaluation, either as additions to the tunnel display to improve pilot performance or as primary displays for purposes of comparison. The following display configurations were investigated.

## Roll-Stabilized Tunnel (Configuration A)

In visualizing the roll motion, two versions were considered. In the first version (fig. 2(a)), the tunnel image, pitch scales, horizon, and roll scales are roll-stabilized, and the bank angle $\phi$ is visualized by rotating the wing bars (7) and the roll pointer (9), in fixed-wing aircraft. This image does not conform to the through-the-windshield visual field and can only be used in head-down type displays.

## Rolling Tunnel (Configuration B)

In the second version (see fig. 2(b)), the tunnel image is rotated with the pitch and roll scales, and the aircraft reference symbology remains stationary. Note that, in this configuration, the pitch motion results in an image displacement perpendicular to the rotated horizon represented by the pitch pointers.

## Predictor/Director Display (Configuration C)

In order to obtain the rate information required, it is necessary to estimate the predicted vehicle path. As discussed in references 1 and 2, peripheral vision is utilized in estimating the vehicle path from the apparent motion in the visual field. Since peripheral vision is partially missing due to the limited size of the monitor, this estimation process is expected to be limited. A possible solution for this problem is to display the predicted vehicle position explicitly on the tunnel image. A display was designed in which a flight-path predictor and a flight-path director are displayed. (See fig. 2(c).) The predictor is displayed as a cross located on the predicted flight path at a distance D ahead of the vehicle. The director is displayed as a square with its center located on the desired flight path a distance D ahead of the vehicle. The outer dimensions of the cross and the square are equal (i.e., width: $45.7 \mathrm{~m}(150 \mathrm{ft})$ ). The distance D can be varied, and the apparent size of the cross and square on the image varies accordingly. The predictor cross remains parallel to the vehicle wing line at all times, and thus, will remain upright in the roll version and rotate in the roll-stabilized version. With this display, the control task reduces to a simple tracking task.

In a well-defined trajectory-following task, in the presence of random disturbances, and for a well chosen prediction time $T_{p}$, this predictor/director (i.e., predictor cross plus director square) display is expected to perform equally well as a more complex tunnel plus predictor/director (i.e., tunnel plus predictor cross plus director square) display. However, the predictor/director display yields the following shortcomings:
(1) Without the tunnel image, the pilot has no knowledge of the position or attitude of the vehicle with respect to the tunnel. Thus, the pilot has no way of judging how well the predictor/director performs in following the trajectory.
(2) With the predictor/director display, the pilot is forced to use the control error between the cross and the square. With the tunnel plus predictor/director display, the pilot has the option of partially or fully rejecting the information provided by the predictor/director and relying more on the tunnel image.
(3) It is clear from shortcoming (2) that the predictor/director display will perform adequately only in the well-defined stationary control task for which $T_{p}$ is adjusted correctly. However, the control task generally is not stationary and is subject to large variations in velocity, disturbance spectrum, stability derivatives, etc.

Tunnel Plus Predictor/Director (Configuration D)
This configuration (see fig. 2(d)) is a combination of the roll-stabilized tunnel (configuration A) and a superimposed predictor/director (configuration B). The predictor cross (12) shows the predicted vehicle position at a distance $D$ ahead of the vehicle. The bright director square (13) represents the desired future vehicle position at distance $D$. In contrast with the squares of the tunnel, this square moves along with the vehicle at a fixed distance $D$ ahead.

## Vehicle Axis Cross (VAC)/Director (Configuration E)

In this display (see fig. $2(e)$ ), the cross represents the vehicle axis at a distance $D$ ahead. The cross is locked in the center of the image and rolls with the vehicle. The director square is identical to the director square of configuration $C$.

Tunnel Plus Vehicle Axis Cross/Director (Configuration F)
This configuration (see fig. 2(f)) is a superposition of the tunnel (configuration A) and the VAC/director (configuration E).

Combination Vertical and Horizontal Situation (CVHS) Displays
(Configuration G)
In this configuration (see figs. $2(\mathrm{~g})$ and $2(\mathrm{~h})$ ), the information of conventional electromechanical instruments is presented on two monitors. The configuration is not intended as a new development, but serves rather as a baseline for comparing conventional with more advanced display concepts. The upper monitor (fig. 2(g)) shows the horizon bar (1), pitch scales (2), roll scale (3), fixed vehicle axis reference cross (4), wing line (5), vertical speed indicator (6), actual altitude (7), commanded altitude (8), and digital read outs of magnetic heading (9) and airspeed (10). In addition to this, the actual lateral and vertical deviation is visualized by the square (11), which is of the same size as the vehicle reference cross (4) and which corresponds to the apparent size of the tunnel cross section $137 \mathrm{~m}(450 \mathrm{ft})$ ahead of the vehicle. A displacement of the square, equal to the width of the square, corresponds to a deviation of 45.7 m ( 150 ft ).

On the lower monitor (fig. 2(h)), the horizontal situation is shown with vehicle reference symbol (12), which remains stationary, and a moving map (13), which shows a plan view of the desired trajectory.

## VEHICLE MODEL

A linear time-invariant vehicle model, derived from reference 3, was used in the calculation of vehicle motion. The longitudinal and lateral dynamics and kinematics were assumed to be fully decoupled and linearized. The stability derivatives used in this model are valid for relatively small perturbations about a trim condition in which the vehicle is in a level flight with a commanded null velocity of $\mathrm{V}=33.5 \mathrm{~m} / \mathrm{sec}$ ( $110 \mathrm{ft} / \mathrm{sec}$ ). A detailed description of the vehicle model and the state equations for the nonaugmented lateral and longitudinal dynamics are given in appendix A. The lateral and longitudinal stability derivatives are given in table 1.

## EXP ERIMENTAL EVALUATION

Objectives of the Experimental Program
The objectives of the experimental program are:
(1) To determine whether the three-dimensional tunnel image provides sufficient positional, rate, and attitude information for entering and following a steep and curved trajectory in a moderate to heavy gust environment
(2) To investigate the effect of predictive information
(3) To compare the performance of the tunnel display with the performance of displays based on conventional approach instrumentation
(4) To investigate the effect of roll cues
(5) To investigate the abilities of the tunnel display in monitoring automatic approaches

## Description of the Experimental System

The experimental program was carried out on the Langley Real-Time Simulation System. A functional diagram of the experimental system is shown in figure 3. A Control Data CYBER 175 computer system at the Langley Research Center was used on a time-sharing basis for the real-time digital simulation of the vehicle dynamics. The computed vehicle motions were imparted to an Adage Graphics Terminal, the AGT/130, which was programmed to generate images of the various display configurations. These images were displayed on two display monitors, mounted one above the other, in a fixedbase simulator cabin equipped with helicopter controls (fig. 4). Vehicle motions, thus presented on the cabin display monitors, were utilized by the pilot to generate the control commands, which were imparted to the CYBER computer system.

Prior to each experimental run, the experimental conditions, such as display parameters, run control parameters, initial conditions, and disturbances, were set at the CYBER 175 console. On-line data processing included the computation of actual and predicted deviations from the trajectory as well as the computation of running averages of these deviations, of the vehicle motions, and of the control commands.

Note that all display computations have been performed by the Adage Graphics Terminal on a stand-alone basis, without interfacing with the CYBER 175 computer. The only variables transferred from the AGT/ 130 to the CYBER 175 were the vehicle motions and the control parameters which defined the display to be generated.

The reasons for operating the AGT/130 on a stand-alone basis are twofold:
(1) It enabled direct implementation of the display in the Flight Display Research System (FDRS) at the NASA Wallops Flight Center (ref. 4), where a real flight vehicle was used and measurements of actual vehicle motions were fed to the AGT/130.
(2) Stand-alone graphics techniques, thus developed, prepared the way for the development of techniques for onboard generation of the display with special purpose microprocessors.

The real-time simulation program was written in Fortran and used $102_{8} \mathrm{~K}$ memory storage. A fourth-order Runge-Kutta integration scheme was used for solving the equations of motion. Integration, sampling, and averaging was at a rate of 32 Hz . Data could be recorded at 32 Hz as well. Overall computation time of one iteration amounted to 40 percent of the time interval. Data were transferred from the CYBER 175 to the AGT/ 130 at a rate of 32 Hz in 15 -bit fixed-point format. The images generated by the AGT/ 130 were refreshed at 30 Hz , but the tunnel image was updated at 12 Hz .

The simulator cabin was equipped with a two-axis electrohydraulic control stick, spring loaded rudder pedals, and an unloaded, balanced, collective control lever. The range of the two-axis control stick was from +12.7 to -12.7 cm ( +5 to -5 in .), and the spring torque was $0.0848 \mathrm{~N} \cdot \mathrm{~m}(0.75 \mathrm{lbf} \cdot \mathrm{in}$.) for both axes. The range of the collective level was from +12.7 to -12.7 cm ( +5 to -5 in .). As discussed previously, the zero-stickforce velocity of the vehicle was kept constant at $33.5 \mathrm{~m} / \mathrm{sec}(110 \mathrm{ft} / \mathrm{sec}$ ), and the forward and aft control stick motion generated a command to increase or decrease the velocity about $0.75 \mathrm{~m} / \mathrm{sec}$ per cm stick deflection ( $6 \mathrm{ft} / \mathrm{sec}$ per in. stick deflection). The lateral control stick motion generated a roll-rate command, resulting in an initial roll rate of about $0.058 \mathrm{rad} / \mathrm{sec}$ per cm stick deflection ( $8.5 \mathrm{deg} / \mathrm{sec}$ per in. stick deflection). Turn coordination was carried out automatically, and the rudder pedals were not used. The vertical speed was controlled by the collective lever, geared to a vertical speed at $2.04 \mathrm{~m} / \mathrm{sec}$ per cm lever deflection ( $17 \mathrm{ft} / \mathrm{sec}$ per in. lever deflection). Null position of the collective lever corresponded to zero vertical velocity.

The electromechanical instruments of figure 4 were not connected, and all control information was derived from the two display monitors. On the upper monitor (measuring 33 cm ( 13 in .) diagonally), a raster-scan image of the tunnel, or of an electronic attitude director indicator (EADI), was shown. On the lower monitor (measuring 22.9 cm ( 9 in .) diagonally), a horizontal situation indicator was shown in part of the experiments. The average distance from the subjects eye to the monitors was about 76.2 cm ( 30 in .).

## Description of the Experiments

All experiments were concerned with the approach phase of the flight in the range from 4570 to 152 m ( 15000 to 500 ft ) from the landing point. A plan view of the desired trajectory is shown in figure 5, and the desired vertical descent profile along the trajectory is shown in figure 6. In all experiments, the forward velocity was set at $33.5 \mathrm{~m} / \mathrm{sec}(110 \mathrm{ft} / \mathrm{sec}$ ) with vertical speed, bank angle, and pitch angle initially set to zero.

The experiments were designed to cover a broad range of frequently occurring control situations. Following are discussions of the three types of experiments that were chosen.

Trajectory following in the presence of random, lateral, and vertical gust disturbances. - The pilot was instructed to minimize the lateral and vertical deviations from the trajectory with minimum control effort. Each run started from initial location 7 (see fig. 5) with a lateral deviation of $30.5 \mathrm{~m}(100 \mathrm{ft})$ to the right of the trajectory, a vertical deviation of zero, and an intercept angle of zero. Thus, control action was required from the pilot immediately after starting the run, to bring the vehicle back on the trajectory. Gust disturbances were generated by passing band-limited white noise through a first order filter with a break frequency of $0.2 \mathrm{rad} / \mathrm{sec}$. The root-mean-square value of the lateral gusts was $5.33 \mathrm{~m} / \mathrm{sec}$ and of the vertical gusts $4.57 \mathrm{~m} / \mathrm{sec}$.

Each run lasted 120 sec , during which time the means and autocovariances of deviations, vehicle motions, and control commands were computed according to the equation

$$
\begin{equation*}
\operatorname{cov}(x)=\frac{1}{t} \int_{0}^{t} x^{2} d t \tag{1}
\end{equation*}
$$

where $\operatorname{cov}(x)$ is the autocovariance of variable $x$, and $x$ can be $p, d_{\psi}, d_{\ell}, d_{v}$, $\epsilon_{\ell}, \epsilon_{\mathrm{v}}, \dot{\epsilon}_{\ell}, \dot{\epsilon}_{\mathrm{v}}, \delta_{\mathrm{S}}$, or $\delta_{\mathrm{c}}$.

Entering the trajectory from a randomly chosen, unknown location outside the tunnel. - This experiment attempted to simulate the situation in which the pilot, after not viewing the display for some time, was at once confronted with the situation of being located outside the tunnel. The pilot was instructed to bring the vehicle back on the
desired trajectory as fast as possible, as smoothly as possible, and with minimum control effort. Gust disturbances were not present in this experiment. In order to prevent the pilot from knowing his initial position before the start of a simulation run, the tunnel image, the tunnel cross-sectional square, the map, and the altimeter scale were initially blanked and were only made visible immediately after starting the simulation run.

Each run started randomly from one of the six initial locations shown in figure 5. For all locations, the initial lateral deviation was 305 m ( 1000 ft ) to the left or to the right of the trajectory, and the initial vertical deviation was 45.7 m ( 150 ft ) above or below the trajectory. The initial intercept angle was set between $0^{\circ}$ and $72^{\circ}$.

Each entry run lasted 50 sec , during which the following performance scores were computed: the lateral settling time $\mathrm{T}_{\mathrm{s} \ell}$ - defined as the time from the start of the run to the moment the lateral deviation remains within a $\pm 15.2-\mathrm{m}$ ( $50-\mathrm{ft}$ ) settling tolerance about the desired trajectory - and the vertical settling time $\mathrm{T}_{\mathrm{Sv}}$ - for which the settling tolerance is $\pm 10.7 \mathrm{~m}(35 \mathrm{ft})$; the autocovariances of the roll rate p , of the intercept angle $\mathrm{d}_{\psi}$, of the predicted lateral and vertical deviations $\epsilon_{\ell}$ and $\epsilon_{\mathrm{v}}$ and their rates $\dot{\epsilon}_{\ell}$ and $\dot{\epsilon}_{\mathrm{V}}$, and of the control commands $\delta_{\mathrm{s}}$ and $\delta_{c}$; the lateral deviation score defined as the averaged absolute value of the lateral deviation computed between $t=T_{1}$ and $t=T_{2}$, where $T_{1}=10 \mathrm{sec}$ and $T_{2}=50 \mathrm{sec}$ according to

$$
\begin{equation*}
\operatorname{sc}\left(\mathrm{d}_{\ell}\right)=\frac{1}{\left(\mathrm{~T}_{2}-\mathrm{T}_{1}\right)} \int_{\mathrm{t}=\mathrm{T}_{1}}^{\mathrm{t}=\mathrm{T}_{2}}\left|\mathrm{~d}_{\ell}\right| \mathrm{dt} \tag{2}
\end{equation*}
$$

The vertical deviation score was computed in the same way, with $\mathrm{T}_{1}=6 \mathrm{sec}$ and $\mathrm{T}_{2}=50 \mathrm{sec}$. The lateral and vertical deviation scores were chosen to be averaged absolute values rather than averaged squared values, in order to prevent these scores from being dominated by the large initial deviation. For the same reason, the averaging process only starts at $t=T_{1}$ sec. Starting point $T_{1}$ was chosen to be 25 percent less than the best previously recorded settling time.

Monitoring experiment. - The purpose of this experiment was to investigate the abilities of a pilot, using the various display configurations, to detect and correct control system failures in automatic approaches. Each run started as an automatic flight. At a random chosen time $t=T_{f}$ (between 5 and 20 sec ), a failure occurred in the automatic control system. After detecting the failure, the pilot responded by pressing one of two buttons on the control stick. This disengaged the automatic control system and engaged the manual control mode. The control mode, automatic or manual, was indicated on the display by AUTO or MAN, respectively. The pilot was instructed to bring the vehicle back on the desired trajectory as fast as possible and with minimum control activity. After returning the vehicle to the desired trajectory, the pilot had to reengage the
automatic control system by pressing the second button on the control stick. The control failure was assumed to be eliminated by the use of a backup automatic control system. The condition for the successful reengagement of the automatic control system was that the lateral and vertical deviations and the intercept angle must be within preset tolerances. These tolerances were $\pm 19.8 \mathrm{~m}(65 \mathrm{ft})$ for the lateral deviation, $\pm 15.2 \mathrm{~m}(50 \mathrm{ft})$ for the vertical deviation, and $\pm 0.15 \mathrm{rad}$ for the intercept angle.

Each run lasted 50 sec , during which the following performance scores were measured: the reaction time $\mathrm{T}_{\mathrm{r}}$ - defined as the time elapsed between the occurrence of the failure and the moment of manual takeover; the correction time $\mathbf{T}_{\mathbf{c}}$ - defined as the time elapsed between the moment of manual takeover and the moment of reengagement of the automatic control system; the autocovariances of $d_{\ell}, d_{v}, \epsilon_{\ell}, \epsilon_{v}, d_{\psi}, p, \delta_{s}$, and $\delta_{r}$ measured over the total $50-\mathrm{sec}$ interval of combined automatic and manual control.

Based on the predicted lateral and vertical deviations at 229 m ( 750 ft ) ahead of the vehicle, the lateral and vertical automatic control laws were

$$
\begin{align*}
& \delta_{s}^{\prime}=-k_{\ell} \epsilon_{\ell}  \tag{3}\\
& \delta_{c}^{\prime}=-k_{v} \epsilon_{v} \tag{4}
\end{align*}
$$

where automatic control inputs $\delta_{s}{ }^{\prime}$ and $\delta_{c}{ }^{\prime}$ replaced the manual control inputs $\delta_{s}$ and $\delta_{c}$ to the system with SAS engaged. The gains of the automatic control system were set to 0.018 for $k_{\ell}$ and 0.045 for $k_{v}$, and the vertical predictor gain $k_{p v}$ was 0.2 .

During each run, a control failure would occur, chosen at random from the four failures described hereafter:
(1) Lock of control inputs, where

$$
\begin{align*}
& \delta_{s}^{\prime}(t)=\delta_{s} \prime\left(T_{f}\right)  \tag{5}\\
& \delta_{c}{ }^{\prime}(t)=\delta_{c}{ }^{\prime}\left(T_{f}\right) \tag{6}
\end{align*}
$$

for $t \geqq T_{f}$.
(2) Error estimates for $v$ and $w$, which were used in computing the predicted vehicle position. In this study $v$ and $w$ were assumed to be perfect estimates. However, a control failure would occur when incorrect values of $v$ and $w$ were used in computing the predicted vehicle position. Additive errors, linearly increasing with time, were introduced. The error estimate values $\hat{\mathbf{v}}$ and $\hat{\mathbf{w}}$ are then given by

$$
\begin{align*}
& \hat{v}=v+k_{b \ell}\left(t-T_{f}\right)  \tag{7}\\
& \hat{w}=w+k_{b v}\left(t-T_{f}\right) \tag{8}
\end{align*}
$$

where $k_{b \ell}=k_{b v}=0$ for $t<T_{f}$ with $k_{b \ell}= \pm 5$ and $k_{b v}= \pm 2$ for $t \geqq T_{f}$.
(3) Undesired linearly increasing rudder input, according to

$$
\begin{equation*}
\delta_{r}^{\prime}=k_{b r}\left(t-T_{f}\right) \tag{9}
\end{equation*}
$$

where $k_{b r}=0$ for $t<T_{f}$ and $k_{b r}= \pm 0.1$ for $t \geqq T_{f}$.
(4) Roll-rate feedback failure, simulated by

$$
\begin{equation*}
\delta_{\mathrm{s}}^{\prime}=-\mathrm{k}_{\ell \ell} \epsilon_{\ell}+\mathrm{k}_{\ell \mathrm{p}^{\mathrm{p}}} \tag{10}
\end{equation*}
$$

where $k_{\ell p}=0$ for $t<T_{f}$ and $k_{\ell p}=7$ for $t \geqq T_{f}$.

## Results

Four subjects participated in the evaluation program. The background of the subjects is listed in table 2. Subject training consisted of two to four simulator sessions of 1 to 3 hours duration each, in which the subjects familiarized themselves with the various display configurations. In addition to this, 3 to 12 training runs were made, prior to the production runs, for each experimental condition. The four subjects completed a total of about 1640 production runs, totaling 28.6 hours of net simulation time. Each subject performed at least four repetitions for each experimental condition. The results for the four subjects were treated separately and are summarized in tables 3 to 12 . The result for each experimental condition represents the average and standard deviations of a set of four or more repetitions.

Significance tests on the difference between averages were performed with a Student-t test at a 5-percent level of significance. Although significant differences between the results of the four subjects were observed, the general trends were rather similar. Therefore, only the results of subject 1 were plotted.

A 40-min motion picture was made, in which the most characteristic results of the three experiments are recorded. Since the motion picture was made in real time directly from the display monitor and during actual simulation runs, it accurately reproduces the simulator experiments.

Results for the trajectory following experiment. - The results of the trajectory following experiment for the four subjects are summarized in tables 3 to 7. The results for subject 1 are shown in figures 7 to 22. From these results, the following can be concluded.

Comparison of the conventional EADI/map display with the basic tunnel display: For all four subjects, the tunnel display yielded a markedly better accuracy in following the trajectory than the EADI/map display, as can be seen from the significantly lower values for the autocovariances of $d_{\ell}$ and $d_{v}$ for the tunnel display. (See tables 3 to 5 and figs. 7 and 8.) The autocovariance of $d_{\psi}$ was also significantly lower for the tunnel display, indicating a less oscillatory lateral response. No significant difference in the roll activity, as indicated by $\operatorname{cov}(\mathrm{p})$, was found between the two displays. (See fig. 9.)

These results are confirmed by the time histories of the lateral and vertical responses, shown in figures 10 and 11. Note the stepwise character of the collective control input for the EADI/map display in figure 11. This might result from the fact that the pilot intermittently controls the lateral and vertical situations.

Comparison of the basic tunnel with the tunnel/vehicle axis cross (VAC): The effect of adding a VAC and a director to the tunnel image was investigated for subjects 1 and 2 with the cross and director at $D=305 \mathrm{~m}$ ( 1000 ft ).

No significant difference in the results was found between the basic tunnel and the tunnel plus VAC/director. (See tables 3 and 4 and figs. 7 to 9.) Thus, a VAC/director does not contribute to a better performance.

Comparison of the tunnel plus VAC/director with the VAC/director: The $\mathrm{VAC} /$ director at $\mathrm{D}=305 \mathrm{~m}(1000 \mathrm{ft})$ was investigated for subjects 1 and 2 . The autocovariances of the lateral and vertical deviations were significantly larger for the VAC/director than for the tunnel plus VAC/director. (See tables 3 and 4 and figs. 7 and 8.) This means that the error between the VAC and the director does not provide the correct control information for this task. Thus, with the tunnel plus VAC/director, all control cues are derived from the tunnel image and the VAC is ignored. This assumption is confirmed by the significantly larger value for the autocovariance of $\epsilon_{\ell}$ for the tunnel plus VAC/director.

Comparison of the basic tunnel with the tunnel plus predictor/director: For all four subjects, performance was found to improve significantly with the addition of predictor/director symbols to the basic tunnel display, as can be concluded from the markedly reduced roll activity and smaller lateral and vertical deviations. (See tables 3 to 5 and figs. 7 to 9 .)

In figures 10 and 11, the time histories for the tunnel plus predictor/director are compared with those for the basic tunnel. Note the lower roll and pitch activity and the smaller vertical deviations for the tunnel plus predictor/director.

The effect of the predictor distance D : The effect of the predictor distance D was investigated for subjects 1 and 2 for the predictor with $\mathrm{k}_{\mathrm{pv}}=1$ and $\mathrm{D}=91.4 \mathrm{~m}$ ( 300 ft ), 137 m ( 450 ft ), 229 m ( 750 ft ), and 305 m ( 1000 ft ). Lateral and vertical deviations were found to increase strongly with D. (See figs. 12 and 13 and tables 6 and 7.) On the other hand, the roll activity decreased with increasing D. (See fig. 14 and tables 6 and 7.) These results indicate that at $D=91.4 \mathrm{~m}(300 \mathrm{ft})$ the system is more oscillatory, indicating lower damping, and at $D=305 \mathrm{~m}(1000 \mathrm{ft})$ the system is too inaccurate. For this task and airspeed of $33.5 \mathrm{~m} / \mathrm{sec}$ ( $110 \mathrm{ft} / \mathrm{sec}$ ), the optimum predictor distance tends to be between $D=137 \mathrm{~m}(450 \mathrm{ft})$ and $\mathrm{D}=229 \mathrm{~m}(750 \mathrm{ft})$.

Note that the autocovariance for the predicted vertical error rate $\dot{\epsilon}_{\mathrm{v}}$ strongly increases with D. (See tables 6 and 7.) This results from the fact that the vertical disturbances are less filtered by the vehicle dynamics than the horizontal ones, which results in rapid vertical predictor motions.

The time histories for the tunnel plus predictor/director at $D=91.4 \mathrm{~m}$ ( 300 ft ) and $D=229 \mathrm{~m}(750 \mathrm{ft})$ are shown in figures 15 and 16 and confirm the results mentioned previously.

Comparison of the tunnel plus predictor/director with the predictor/director: The predictor/director was investigated for subjects 1 and 2 and for $D=91.4 \mathrm{~m}$ ( 300 ft ), $229 \mathrm{~m}(750 \mathrm{ft})$, and $305 \mathrm{~m}(1000 \mathrm{ft})$. At $\mathrm{D}=229 \mathrm{~m}(750 \mathrm{ft})$ and 305 m ( 1000 ft ), the autocovariances of the lateral and vertical deviations for the tunnel plus predictor/director were found to be generally smaller than for the predictor/director. (See tables 6 and 7 and figs. 12 and 13.) At $D=305 \mathrm{~m}$ ( 1000 ft ), the differences were found to be significant. The autocovariance of the predicted lateral deviation $\epsilon_{\ell}$ was significantly larger with the tunnel plus predictor/director than with the predictor/director. (See tables 6 and 7.) This indicates that, for a wrongly adjusted predictor distance, the pilot relies on the tunnel image rather than on the error between predictor and director. Note also the significantly lower roll activity for the predictor/director at $D=305 \mathrm{~m}$ ( 1000 ft ).

The time histories for the tunnel plus predictor/director and for the predictor/ director, both at $D=305 \mathrm{~m}(1000 \mathrm{ft})$, are shown in figures 17 and 18 and confirm these findings.

The simplified predictor and the effect of a reduced predictor gain: The simplified predictor, based on the bank angle $\phi$, was investigated for subjects 1 and 2 with $\mathrm{D}=229 \mathrm{~m}(750 \mathrm{ft})$. The autocovariance of the lateral deviation was significantly larger with the simplified predictor than with the regular one, but it was still significantly smaller than with the tunnel without predictor/director. (See tables 3 and 4.) No significant difference in roll activity was found between the simplified predictor and the regular one. These results indicate that the simplified predictor yields a somewhat less accurate
but adequately damped system. Thus, the roll angle may very well be used for the lateral prediction, in those situations where the lateral acceleration is not available.

In the vertical control, the simplified predictor with $\mathrm{k}_{\mathrm{pv}}=0$ yielded vertical deviations similar to those of the predictor with $\mathrm{k}_{\mathrm{pv}}=0.2$ and with $\mathrm{k}_{\mathrm{pv}}=1$. However, because of the rapid vertical predictor motions, the rate of the vertical error between the predictor and the director $\dot{\epsilon}_{\mathrm{v}}$ was found to be very large for $\mathrm{k}_{\mathrm{pv}}=1$. The test subjects objected to these rapid predictor motions. On the other hand, the vertical accelerations were completely disregarded for $k_{p v}=0$, which resulted in overcontrolling because of the lack of quickening in the display. A compromise between sufficient quickening and acceptable vertical predictor motions was found for $\mathrm{k}_{\mathrm{pv}}=0.2$.

The effect of roll cues: The effect of roll cues was investigated for subjects 1 and 2 with the tunnel plus predictor/director at $D=229 \mathrm{~m}(750 \mathrm{ft})$ and $\mathrm{k}_{\mathrm{pv}}=0.2$. No significant difference was found in the results between the roll version and the rollstabilized version. (See tables 3 and 4.) This indicates that, for this control task, the roll version and the roll-stabilized version perform equally well in a fixed-base simulator.

Results for the trajectory entry experiments. - The entry experiments were conducted in a series of six runs. For each run, the initial location was chosen at random from one of the six positions given in figure 5 . No position was used more than once. Significant differences between the scores were observed for the various initial locations. In order to rate the general entry performance, the results of the six runs in each series were averaged in order to obtain the series scores. For each display configuration, two to six series of runs were performed. The experimental results for the four subjects are summarized in tables 8 to 11. Each result represents the average and standard deviation of a set of four to six series scores. From these results, the following can be concluded.

Comparison of the EADI/map display with the basic tunnel display (roll version): For all four subjects, the entry performance for the basic tunnel was found to be markedly better than for the conventional EADI/map display. With the basic tunnel, significantly smaller lateral and vertical deviation scores, as well as smaller lateral and vertical settling times, were found (see tables 8 to 11 and figs. 19 to 22), indicating a faster and more accurate entry. For the tunnel display, the roll activity was found to be significantly lower as well, indicating better system damping. (See fig. 23.)

Shown in figures 28 and 29 are the time histories for the entry from location 3, for the EADI/map, and for the basic tunnel. Both displays yielded considerable roll activity, as shown in figure 24. Hewever, the tunnel display yields a more gradual and accurate entry, as can be seen from the time history of the lateral deviation. Similar results in the vertical control are shown in figure 25. Note the stepwise character of the collective
control input, for the EADI/map. This phenomenon was discussed earlier for the trajectory following experiment.

Comparison of the basic tunnel with the tunnel plus predictor/director: The effect of the predictor is noticed mainly in the markedly lower roll activity, as seen in figure 23. For the tunnel plus predictor/director, lateral and vertical deviation scores, as well as lateral and vertical settling times, were found to be significantly lower also. (See figs. 19 to 22.) Thus, the tunnel plus predictor/director yields a more accurate and better damped entry.

The effect of the predictor distance D: Lateral and vertical deviation scores, as well as lateral and vertical settling times, were found to increase with increasing $D$. The increase of these scores was not significant in the range between $D=91.4 \mathrm{~m}$ ( 300 ft ) and $D=229 \mathrm{~m}$ ( 750 ft ). However, a significant increase in these scores was found between $D=229 \mathrm{~m}(750 \mathrm{ft})$ and $\mathrm{D}=305 \mathrm{~m}(1000 \mathrm{ft})$. This trend is shown in figures 26 to 29 . On the other hand, the roll activity was found to decrease with increasing D . (See fig. 30.) This decrease in roll activity was found to be significant between $\mathrm{D}=91.4 \mathrm{~m}$ $(300 \mathrm{ft})$ and $\mathrm{D}=137 \mathrm{~m}(450 \mathrm{ft})$. These results indicate that, at $\mathrm{D}=91.4 \mathrm{~m}(300 \mathrm{ft})$, the system lacks damping and, at $D=305 \mathrm{~m}$ ( 1000 ft ), the system is too inaccurate. It is clear that, for the given forward velocity of $V=33.6 \mathrm{~m} / \mathrm{sec}(110 \mathrm{ft} / \mathrm{sec})$, a predictor distance in the range from $D=137 \mathrm{~m}(450 \mathrm{ft})$ to $\mathrm{D}=229 \mathrm{~m}(750 \mathrm{ft})$ yields the best compromise.

In figures 31 and 32 , the time histories for the entry from location 2 are shown for the tunnel plus predictor at $D=91.4 \mathrm{~m}(300 \mathrm{ft}), 137 \mathrm{~m}(450 \mathrm{ft})$, and $229 \mathrm{~m}(750 \mathrm{ft})$. The time histories of the lateral deviation and intercept angle indicate a smoother entry for larger D. (See fig. 31.) The time histories of the roll rate for $D=91.4 \mathrm{~m}$ ( 300 ft ) indicate a considerable increase in roll activity at the point of intercept with the tunnel. The lack of damping at $D=91.4 \mathrm{~m}(300 \mathrm{ft})$ was less pronounced in the vertical control. It was noticed in a slightly increased pitch rate. (See fig. 32.)

Comparison of the tunnel plus predictor/director with the predictor/director: The predictor/director display was investigated for $D=229 \mathrm{~m}$ ( 750 ft ) and 305 m ( 1000 ft ). Predictor distances smaller than $D=229 \mathrm{~m}$ ( 750 ft ) were not attempted, since the tunnel square was not visible during the first part of the entry.

At $D=229 \mathrm{~m}(750 \mathrm{ft})$ and 305 m ( 1000 ft ), lateral and vertical deviation scores, as well as lateral and vertical settling times, were found to be significantly larger for the predictor/director than for the tunnel plus predictor/director. (See figs. 26 to 29.) This proves that the tunnel image contributes significantly to the entry accuracy, particularly for a badly adjusted predictor (e.g., $D=305 \mathrm{~m}(1000 \mathrm{ft})$ ). The roll activity for the tunnel plus predictor/director was somewhat larger than for the predictor/director. When the tunnel image was shown in addition to the predictor/director, the pilot relied on the tunnel
image rather than on the error between predictor and director square. This is seen in the fact that the autocovariance of the predicted lateral error $\epsilon_{\ell}$ was significantly larger for tunnel plus predictor/director than for predictor/director.

In figures 33 and 34 , the time histories for the entry from location 4 are shown for the tunnel plus predictor/director and for the predictor/director. It is shown in figure 33 that, for the tunnel plus predictor/director, the pilot allows a rather large predicted lateral error, while the time history of the actual lateral deviation shows a smooth and accurate response. On the other hand, the predicted lateral error was kept small for the predictor/director; whereas, the time histories of the actual lateral deviation show a large overshoot.

Similar results were obtained for the vertical control, as can be seen from the time histories in figure 34.

The effect of roll cues: The roll and roll stabilized versions of the tunnel plus predictor/director at $D=137 \mathrm{~m}(450 \mathrm{ft})$ were compared, and the results are shown in tables 8 and 9 . The differences between the scores were not significant, even at a 10 -percent confidence level. This indicates that, in the entry task, the roll and rollstabilized versions perform equally well for fixed-base simulation.

Results for the monitoring experiment. - The monitoring experiments were conducted in a series of four runs of 50 sec each. In each run, one control failure appeared, chosen at random from the set of four failures discussed earlier. The polarity of the failure biases were chosen at random as well. The results of four runs in a series were averaged, in order to obtain averaged failure scores for the series (series scores). Sets of at least 12 series of four runs were conducted, for each experimental condition.

The monitoring experiment included the tunnel plus predictor/director at $\mathrm{D}=229 \mathrm{~m}$ ( 750 ft ), the predictor/director at $\mathrm{D}=229 \mathrm{~m}$, and the EADI/map. The results for subjects 1 and 2 are summarized in table 12. Each result represents the average and standard deviation of a set of 12 to 19 series scores. These results show that, for the lateral deviation, the vertical deviation, as well as the intercept angle, the tunnel plus predictor/ director yielded significantly smaller overall autocovariances than the other two displays. The EADI/map performed worst in this respect. The same trend is noticeable for the reaction time $T_{r}$ and the correction time $T_{c}$. The values of $T_{r}$ and $T_{c}$ were found to be significantly smaller for the tunnel plus predictor/director than for the EADI/map. Thus, the tunnel plus predictor/director enabled the best failure discovery and failure correction.

## Qualitative Flight Test Validation

The feasibility of the tunnel display for operation in actual flight was demonstrated at the NASA Wallops Flight Center. A CH-47C helicopter (fig. 35) served as the flight
vehicle. A special version of a tunnel/map display was developed for operation at Wallops. The displays were generated by a ground-based Adage Graphics Terminal, scan converted, transmitted by TV link to the vehicle, and displayed on two monitors mounted in the CH-47C cockpit. On the upper display, the roll version of the tunnel plus predictor/director was shown; on the lower display, an HSI combined with an altimeter and a vertical speed scale. This configuration, which was specially designed for the VTOL approach and landing technology (VALT) program, served primarily as a display for conducting and monitoring automatic control system experiments.

However, to validate the tunnel display, a limited number of manual approaches were conducted. Subject 3 was the research pilot, and he used the same approach trajectory as used in the simulator experiments. The CH-47C was flown with the SAS engaged, but the velocity hold system used in the simulator was not available. Although the approach trajectory was the same as in the simulator experiments, the control task was considerably more demanding, since the pilot also had to keep the forward velocity constant. Furthermore, the predictor/director was less effective than in the simulator experiments, since not all variables necessary to drive the predictor/director were available. The lateral prediction was based on the bank angle $\phi$ according to equation (B6). (See appendix B.) Since $v$ was not available, it was set to zero in equation (B3). (See appendix B.) In the vertical prediction, $\mathrm{k}_{\mathrm{pv}}$ was set to zero.

In spite of the task difficulty and the lack of training runs, the trajectory was followed smoothly, while the lateral and vertical deviations from the trajectory remained within $\pm 30.5 \mathrm{~m}(100 \mathrm{ft})$ and $15.2 \mathrm{~m}(50 \mathrm{ft})$, respectively.

The pilot commented that, due to the lack of a velocity hold system, the workload was rather high. However, the tunnel image provided sufficient information for following the trajectory. Since the predictor/director did not provide the correct control cues, the pilot chose to utilize the tunnel image rather than the predictor/director. However, the predictor/director did provide the damping cues to some extent. The pilot also commented that, in spite of the task difficulty, the display was acceptable and that solving the problems mentioned would reduce the workload considerably.

## CONCLUSIONS

The tunnel display with a superimposed predictor/director symbol was found to be a very successful combination. It outperformed the other two displays in all three experiments. A prediction time of 4 to 7 sec was found to optimize trajectory tracking for the given vehicle dynamics and flight conditions. Pilot acceptance of the tunnel plus predictor/ director display was favorable, and the time for familiarization was relatively short.

## Specifics:

1. The perspective tunnel image provides adequate positional and directional information and yields markedly better accuracy in trajectory following and trajectory entry than the conventional EADI/map display.
2. The basic tunnel display yields poor damping, due to the lack of rate information (caused by the narrow visual field).
3. Predictor/director symbols superimposed on the tunnel image provide the rate information which is vital for an adequately damped system. For the given vehicle dynamics and nominal forward velocity of $33.5 \mathrm{~m} / \mathrm{sec}$ ( $110 \mathrm{ft} / \mathrm{sec}$ ), a predictor symbol predicting the vehicle position 4 to 7 sec in advance yields the best compromise between positional accuracy and system damping.
4. The predictor/director display performs well in trajectory following. However, the use of this display is limited to the narrow range about the trajectory in which the director is visible.
5. The tunnel plus predictor/director display outperforms the predictor/director display when the predictor is badly adjusted, or in situations in which the director is out of the visible range.
6. A prediction time of 4 to 7 sec , which yields the best compromise for the lateral control, yields vertical predictor motions which are too rapid. A vertical prediction based on 20 percent of the actual vertical acceleration yields the best pilot acceptance.
7. A vehicle axis cross, superimposed on the tunnel image does not contribute to better tracking. The error between vehicle axis cross and director square does not provide the correct control cues in trajectory following in a fixed-base simulator.
8. The roll and roll-stabilized versions of the tunnel display perform equally well in trajectory following and entries. This leaves the option open, for applying the roll version to head-up displays, in which the image has to be conformal with the visual world.
9. The tunnel plus predictor/director display performs very satisfactorily in the detection and correction of failures in automatic flight.

## APPENDIX A

## VEHICLE MODEL

## Vehicle Model and Stability Augmentation System

All equations of motion comply with the north-east-down sign convention. The lateral equations of motion, for small deviations from the nominal trim condition are given by

## APPENDIX A

where

$$
\begin{equation*}
I_{1}=\frac{I_{x x} I_{z z}}{I_{x x} I_{z z}-I_{x z}{ }^{2}} \quad I_{2}=\frac{I_{x x} I_{x z}}{I_{x x} I_{z z}-I_{x z}^{2}} \quad I_{3}=\frac{I_{z z} I_{x z}}{I_{x x} I_{z z}-I_{x z}{ }^{2}} \tag{A2}
\end{equation*}
$$

For small angles of $\theta$, the horizontal coordinates of the vehicle location in the inertial reference system, $x_{i}$ and $y_{i}$, are obtained by integration of

$$
\begin{equation*}
\dot{x}_{i}=V \cos \left(\psi+\frac{v}{V}\right) \tag{A3}
\end{equation*}
$$

and

$$
\begin{equation*}
\dot{\mathrm{y}}_{\mathrm{i}}=\mathrm{V} \sin \left(\psi+\frac{\mathrm{v}}{\mathrm{~V}}\right) \tag{A4}
\end{equation*}
$$

The longitudinal equations of motion, for small deviations from the nominal trim condition, are given by

or written shortly as

$$
\begin{equation*}
\dot{\vec{x}}_{v}=A_{v} \vec{x}_{v}+B_{v} \vec{\delta}_{v, a}+W_{v} w_{g} \tag{A6}
\end{equation*}
$$

The altitude $z_{i}$ is obtained by integration of

## APPENDIX A

$$
\begin{equation*}
\dot{z}_{i}=V \sin \left(\frac{w}{V}-\theta\right) \tag{A7}
\end{equation*}
$$

A block diagram of the lateral SAS is shown in figure 36(a). The sideslip feedback is given by

$$
\begin{equation*}
g_{v}=f_{v} v \tag{A8}
\end{equation*}
$$

The yaw-rate feedback is given by

$$
\begin{align*}
& \mathrm{g}_{\mathrm{r}}=\mathrm{f}_{\mathrm{r}}\left(\mathrm{r}-\mathrm{g}_{1}\right)  \tag{A9}\\
& \dot{g}_{1}=-0.312 \mathrm{~g}_{1}+0.312 \mathrm{r} \tag{A10}
\end{align*}
$$

The roll rate on differential cyclic (rudder) feedback is given by

$$
\begin{align*}
& \mathrm{g}_{\mathrm{pr}}=\mathrm{g}_{2}  \tag{A11}\\
& \dot{\mathrm{~g}}_{2}=-0.243 \mathrm{~g}_{2}+0.243 f_{\mathrm{pr}} \mathrm{p} \tag{A12}
\end{align*}
$$

and the roll rate on cyclic feedback is given by

$$
\begin{equation*}
g_{p}=f_{p} p \tag{A13}
\end{equation*}
$$

With the SAS engaged, the cyclic and differential-cyclic actuator inputs $\delta_{s, a}$ and $\delta_{r, a}$ are given by

$$
\begin{align*}
& \delta_{s, a}=\delta_{s}-g_{p}  \tag{A14}\\
& \delta_{r, a}=\delta_{r}+g_{p r}-g_{r}+g_{v} \tag{A15}
\end{align*}
$$

where $\delta_{s}$ and $\delta_{r}$ are the lateral-control stick and rudder-pedal commands, respectively.

State equation (A1) can be augmented, in order to incorporate the SAS dynamics. The lateral, augmented open-loop (SAS disengaged) state equation becomes

## APPENDIX A

$$
+\left[\begin{array}{l}
\mathrm{B}_{\ell}-\text { Matrix }  \tag{A16}\\
\hdashline 0 \\
0
\end{array}\right]\left[\begin{array}{l}
\delta_{\mathrm{s}, \mathrm{a}} \\
0
\end{array}\right]+\left[\begin{array}{l}
\mathrm{w}_{\ell}-\text { Matrix } \\
\delta_{\mathrm{r}, \mathrm{a}}
\end{array}\right]\left[\begin{array}{l} 
\\
0 \\
0
\end{array}\right] \mathrm{v}_{\mathrm{g}}
$$

or written shortly as

$$
\begin{equation*}
\dot{\vec{x}}_{\ell}^{\prime}=\mathrm{A}_{\ell}^{\prime} \overrightarrow{\mathrm{x}}_{\ell}^{\prime}+\mathrm{B}_{\ell}^{\prime} \vec{\delta}_{\mathrm{s}, \mathrm{a}}+\mathrm{W}_{\ell}^{\prime} \mathrm{v}_{\mathrm{g}} \tag{A17}
\end{equation*}
$$

The lateral, augmented closed-loop (SAS engaged) system is given by

$$
\begin{equation*}
\dot{\vec{x}}_{l}^{\prime}=\hat{A}_{\ell} \overrightarrow{\mathrm{x}}_{l}^{\prime}+\mathrm{B}_{\ell}^{\prime} \vec{\delta}_{l}+\mathrm{W}_{\ell}^{\prime} \mathrm{v}_{g} \tag{A18}
\end{equation*}
$$

where $\hat{A}_{\ell}$ is the lateral closed-loop system matrix given by

$$
\begin{equation*}
\hat{A}_{\ell}=\left[A_{l}^{\prime}-B_{\ell}^{\prime} F_{\ell}\right] \tag{A19}
\end{equation*}
$$

and $F_{\ell}$ is the lateral feedback matrix given by

## APPENDIX A

$$
F_{\ell}=\left[\begin{array}{cccccc}
f_{p} & 0 & 0 & 0 & 0 & 0  \tag{A20}\\
0 & 0 & f_{r} & -f_{v} & -f_{r} & -1
\end{array}\right]
$$

and

$$
\vec{\delta}_{\ell}=\left[\begin{array}{l}
\delta_{\mathbf{s}}  \tag{A21}\\
\delta_{\mathbf{r}}
\end{array}\right]
$$

The lateral SAS can be easily altered or disengaged by altering or nullifying the matrix $F_{\ell}$.

A block diagram of the longitudinal SAS is shown in figure $36(\mathrm{~b})$. It consists of a pitch-rate feedback

$$
\begin{equation*}
\mathrm{g}_{\mathrm{q}}=\mathrm{f}_{\mathrm{q}} \mathrm{q} \tag{A22}
\end{equation*}
$$

a pitch-angle feedback

$$
\begin{equation*}
\mathrm{g}_{\theta}=\mathbf{f}_{\theta} \theta \tag{A23}
\end{equation*}
$$

and a perturbed forward-velocity feedback

$$
\begin{equation*}
g_{u}=f_{u} u \tag{A24}
\end{equation*}
$$

The vertical closed-loop system is given by

$$
\begin{equation*}
\dot{\vec{x}}_{v}=\hat{A}_{v} \vec{x}_{v}+B_{v} \vec{\delta}_{v}+W_{v} w_{g} \tag{A25}
\end{equation*}
$$

where $\hat{\mathrm{A}}_{\mathbf{v}}$ is the closed-loop system matrix given by

$$
\begin{equation*}
\hat{A}_{v}=\left[A_{v}-B_{v} F_{v}\right] \tag{A26}
\end{equation*}
$$

and $F_{v}$ is the vertical feedback matrix, given by

## APPENDIX A

$$
\mathrm{F}_{\mathrm{v}}=\left[\begin{array}{cccc}
-\mathrm{f}_{\mathrm{u}} & 0 & \mathrm{f}_{\mathrm{q}} & \mathrm{f}_{\theta}  \tag{A27}\\
0 & 0 & 0 & 0
\end{array}\right]
$$

It is clear from the lateral stability derivatives that the not-augmented vehicle had very poor directional stability and poor yaw and roll damping. The lateral stability augmentation system (SAS) was derived from reference 5 and is shown in figure 36(a). It consists of a sideslip feedback, which provides the directional stability; a yaw-rate feedback, which provides the necessary yaw damping; a roll rate on differential cyclic (rudder) feedback, which minimizes the effect of roll-induced yaw; and a roll rate (on cyclic) feedback, to provide the necessary roll damping. With the SAS engaged, lateral control is accomplished by a lateral stick command only, without using the rudders, while the turn coordination is accomplished automatically by the feedback on the sideslip.

The not-augmented longitudinal vehicle dynamics had an unstable pole at $\mathrm{s}=0.519 \mathrm{rad} / \mathrm{sec}$. The longitudinal SAS was specially designed for this study and is shown in figure $36(\mathrm{~b})$. The system had to provide longitudinal stability and had to keep the forward velocity constant. This was accomplished by a pitch-rate, pitch-attitude, and perturbed-forward-velocity feedback on the differential collective input (pitch). Thus, a forward stick command resulted in a proportional increase or decrease of the forward velocity. Vertical control was accomplished by a collective command. The rotor speed was assumed to remain constant, and the stability derivatives were assumed to be invariant with the engine torque.

The pole-zero location of the transfer function $H_{\delta}^{d_{S}}(s)$, relating the linearized lateral vehicle displacement with a cyclic control input, is shown in figure 37(a) for the SAS disengaged and in figure 37(b) for the SAS engaged. Shown in figures $38(\mathrm{a})$ and (b) are the locations for the ${ }_{H_{\delta}}^{d}{ }_{c}$ (s) transfer function, relating the linearized vertical displacement with a collective input. As shown in figure $37(\mathrm{~b})$, the lateral vehicle dynamics with SAS engaged were dominated by the three poles at the origin. The effect of the pair of complex poles with a natural frequency $\omega_{n}=0.32 \mathrm{rad} / \mathrm{sec}$ and a damping factor of $\zeta=0.43$ is less dominant, because of the closely located pair of complex zeros, with $\omega_{\mathrm{n}}=0.25 \mathrm{rad} / \mathrm{sec}$ and $\zeta=0.43$.

The longitudinal dynamics with SAS engaged, shown in figure $38(\mathrm{~b})$, were dominated by one pole at the origin and one at $s=-0.462 \mathrm{rad} / \mathrm{sec}$. The effect of the well damped pair of complex poles, with $\omega_{\mathrm{n}}=0.73 \mathrm{rad} / \mathrm{sec}$ and $\zeta=0.67$, was masked by the closely located pair of complex zeros, with $\omega_{\mathrm{n}}=0.63 \mathrm{rad} / \mathrm{sec}$ and $\zeta=0.76$.

## Control Task Definition and Candidate Loop Closures

The control task was to minimize the lateral and vertical deviations from a specified reference trajectory, with minimum control effort.

The horizontal situation for following an arbitrarily curved trajectory is shown in figure 39. The lateral deviation from the trajectory is denoted by $d_{\ell}$, the intercept angle of velocity vector and trajectory direction by $d_{\gamma}$, and the curvature of the trajectory at the approximate vehicle location by $f(t)=1 / R_{t}(t)$. The centripetal acceleration $a_{t}$ for following a curve with radius $R_{t}$ is given by

$$
\begin{equation*}
a_{t}(t)=\frac{v^{2}}{R_{t}(t)}=v^{2} f(t) \tag{A28}
\end{equation*}
$$

where $V$ is the ground speed. For small deviations, $d_{\gamma}$ and $d_{\ell}$ are given by

$$
\begin{align*}
& d_{\gamma}(t)=\frac{1}{V} \int\left[a_{\ell}(t)-a_{t}(t)\right] d t  \tag{A29}\\
& d_{\ell}(t)=V \int d_{\gamma}(t) d t \tag{A30}
\end{align*}
$$

where $a_{\ell}$ is the acceleration of the vehicle in lateral direction and with respect to an inertial reference system.

It has been shown in figure $37(b)$ that the transfer function ${ }_{H_{6}}^{\mathrm{H}_{\mathrm{S}}}(\mathrm{s})$ of the lateral augmented vehicle dynamics was dominated by three poles at the origin. It is clear that adequate rate information is required in order to stabilize the system. It is shown in references 1 and 2 that rate cues can originate from the visual field by deriving the control error a distance $D$ ahead of the vehicle. It is also shown that the pilot was able to obtain a rough estimate of the predicted vehicle path from the apparent motion of conspicuous objects in the visual field (texture points). In figure 39 this circular, predicted vehicle path is shown. Point $A$ is the predicted vehicle position at a distance $D$, or $T_{p}=D / V \sec$, ahead of the vehicle. The control error $\epsilon_{\ell}$ is defined as the deviation of point A from the reference trajectory. It follows from the geometry of figure 39 that, for small $d_{\ell} d_{\gamma}$ and $D / R_{t}$, the following linearized expression for $\epsilon_{\ell}$ can be derived:

$$
\begin{equation*}
\epsilon_{\ell}=d_{\ell}+D d_{\gamma}+\frac{1}{2}\left(a_{\ell}-a_{t}\right)+d_{p} \tag{A31}
\end{equation*}
$$

## APPENDIX A

or, with equations (2) and (3) and after Laplace transformation,

$$
\begin{equation*}
\epsilon_{\ell}(s)=\left(1+T_{p} s+\frac{1}{2} T_{p}^{2} s^{2}\right) d_{\ell}(s)+d_{p}(s) \tag{A32}
\end{equation*}
$$

The term $d_{p}$ constitutes a preview of the trajectory and accounts for changes in curvature $d_{p}(t)$ given by

$$
\begin{equation*}
d_{p}(t)=\int_{0}^{\sigma=T_{p}}\left[a_{t}(t)-a_{t}(\sigma)\right] d^{2} \sigma \tag{A33}
\end{equation*}
$$

It follows from equation (A33) that, for straight trajectories or trajectories with a constant curvature, $d_{p}$ will be zero.

A block diagram of this linearized system is shown in figure 40(a). The curvature $f(t)$ is the forcing function of the system.

A control error, based on the predicted vehicle position, yields the following advantages:
(1) A pair of complex zeros with a fixed damping factor of $\zeta=0.707$ and a natural frequency $\omega_{\mathrm{n}}$ which can be adjusted to the requirements of the system by varying the prediction time $\mathrm{T}_{\mathrm{p}}$.
(2) For straight trajectories or trajectories with a constant curvature, a zero value of $\epsilon_{\ell}$ will yield a zero steady-state value of $d_{\ell}$, as can be seen by setting $\epsilon_{\ell}$, $s$, and $d_{p}$ to zero in equation (A32).

An alternative loop closure can be formulated by considering a point $B$ on the vehicle direction of motion $T_{p}$ seconds ahead of the vehicle. (See fig. 39.) The control error is then defined as the deviation of point $B$ from the trajectory and, for small deviations, is given by

$$
\begin{equation*}
\epsilon_{\ell}(t)=d_{\ell}(t)+D d_{\gamma}(t)+\frac{1}{2} T_{p}^{2} a_{t}+d_{p}(t) \tag{A34}
\end{equation*}
$$

or

$$
\begin{equation*}
\epsilon_{\ell}(s)=\left(1+T_{p} s\right) d_{\ell}+\frac{1}{2} T_{p}{ }^{2} a_{t}(s) \tag{A35}
\end{equation*}
$$

A block diagram of this system is shown in figure $40(\mathrm{~b})$. Unlike the control error of equation (A32), equation (A35) provides only a single zero. It also follows from equation (A35) that, in following a constant curve, $d_{\ell}$ will maintain a steady-state error after bringing $\epsilon_{\ell}$ to zero.

## APPENDIX A

Vertical loop closures can be formulated in a way similar to that used for the lateral loop closures. The control error in this situation is based on either the vertical path or on the vertical direction of motion of the vehicle. The vertical path and vertical direction of motion are defined as the projection of the velocity vector on the $x_{b} z_{b}$ vertical plane of symmetry of the vehicle.

It has been shown in figure $38(\mathrm{~b})$ that the transfer function ${ }_{H_{\delta}}^{d_{c}}(\mathrm{~s})$ of the vertical, augmented vehicle dynamics is effectively of a lower order than the corresponding transfer function of the lateral dynamics. This softens the demand on the amount of rate information necessary to stabilize the system. Thus, a control error based on the vertical direction might yield a satisfactory vertical loop closure, since the single zero might be sufficient. Furthermore, the vertical trajectory profile does not have sections with constant curvature, so that the problem of a steady-state error in $d_{v}$ does not occur.

## APPENDIX B

## TUNNEL DISPLAY AND GENERATION

Tunnel Display

The basic principle, underlying the tunnel display, is shown in figure 41. The trajectory to be followed is presented as a perspective tunnel image with a constant square cross section. The perspective appearance of the tunnel changes with the vehicle position. Positional cues are derived from this perspective appearance, while rate cues are derived from the rate of change in the appearance. In figure 41, the line AA represents the horizon and point $C$ the center of the image, which represents the vehicle axis. Point C is not explicitly displayed, but the pilot can estimate its location by using the monitor frame as a reference. The trajectory is curved to the left, as shown in the corresponding plan view (fig. 42). The bank angle $\phi$ is determined from the inclination of the horizon with respect to the reference frame. Point $F$ indicates the tunnel direction and is not explicitly displayed. However, it is assumed that the location of point $F$ can be estimated by the pilot, by extending the four tunnel corner lines nearest to the vehicle, to a focal point at infinity. Point $S$ is the center of the nearest square and is to be estimated as well. The centerline FS constitutes the tunnel direction at the approximate position of the vehicle. When defining the $F_{y}$-axis to be parallel and the $F_{z}$-axis to be perpendicular to the horizon, the lateral and vertical deviations of the vehicle from the trajectory can be estimated from the distance between $F$ and $S$ in $F_{y}-$ and $F_{z}$-directions, respectively.

Attitude information can be estimated from the deviation of focal point $F$ from the center of the image C. Thus, the lateral intercept angle $d_{\psi}$ of the vehicle axis with the tunnel direction is estimated from the distance between $F$ and $C$ in $F_{y}$-direction, and the vertical intercept angle $d_{\theta}$ of the vehicle axis with the tunnel direction is estimated from the distance between $F$ and $C$ in $F_{z}$-direction. The downslope of the trajectory $\theta_{t}$ is determined by the distance point $F$ is under the horizon AA.

Rate cues originate from the rate of change of the above mentioned quantities. A relative impression of forward motion is derived from the "passing by" of tunnel segments. Note that this velocity impression can be augmented by presenting the corner lines of the tunnel as separate line segments, rather than solid lines.

A preview of the trajectory to be followed is obtained by considering a centerpoint T on the trajectory, a distance $D$ ahead of the vehicle. Point $R$ is a point on FS and is also a distance $D$ ahead. Unlike $R$ which is to be estimated, the tunnel section at $T$ is explicitly shown. The distance between $T$ and $R$ in $F_{y}$-direction provides an indication of the trajectory curvature, while the distance between $T$ and $R$ in $F_{z}$-direction indicates changes in the slope.

## APPENDIX B

## Predictor Display

The lateral as well as the vertical vehicle paths are assumed to be circular and tangential to the velocity vector $\overrightarrow{\mathrm{V}}$. The lateral and vertical curvatures are given by

$$
\begin{align*}
& \frac{1}{R_{l}}=\frac{a_{\ell}(t)}{v^{2}}  \tag{B1}\\
& \frac{1}{R_{v}}=\frac{a_{v}(t)}{v^{2}} \tag{B2}
\end{align*}
$$

where $a_{\ell}$ and $a_{v}$ are the lateral (in $y_{b}$ body-axis direction) and vertical (in $z_{b}$ body-axis direction) accelerations with respect to the inertial reference system. The predictor symbol $P$ indicates a point on the predicted vehicle path, a distance $D$ ahead of the vehicle. When defining $C_{y}$ and $C_{z}$ as the lateral and vertical screen axes (see fig. 41), the deviation of $P$ from the center of the monitor in the $C_{y}$-direction is given by

$$
\begin{equation*}
\lambda_{\ell}=\frac{v}{V}+\frac{D / R_{\ell}}{1+\sqrt{1-\left(D / R_{\ell}\right)^{2}}} \tag{B3}
\end{equation*}
$$

and in the $\mathrm{C}_{\mathrm{Z}}$ direction by

$$
\begin{equation*}
\lambda_{\mathrm{V}}=\frac{\mathrm{w}}{\mathrm{~V}}+\frac{\mathrm{D} / \mathrm{R}_{\mathrm{v}}}{1+\sqrt{1-\left(\mathrm{D} / \mathrm{R}_{\mathrm{v}}\right)^{2}}} \tag{B4}
\end{equation*}
$$

where $v$ and $w$ are the components of $\vec{V}$ in $y_{b}$ - and $z_{b}$-directions, respectively, and $V$ is the ground speed. The values of $\lambda_{\ell}$ and $\lambda_{v}$ are in fractional screen coordinates (screen limits are $\pm 1$ ), for $\mathrm{a} \pm 45^{\circ}$ horizontal-and-vertical field of view.

A valid control strategy for the tunnel plus predictor/director display is to minimize the error between the predictor $P$ and tunnel section $T$. The linearized control error is then given by equation (A32) of appendix A. A prediction time $\mathrm{T}_{\mathrm{p}}$ is chosen which yields the best compromise between positional accuracy and system damping for the given vehicle dynamics and airspeed.

Since the vertical dynamics are of a higher bandwidth than the lateral dynamics, a prediction time $\mathrm{T}_{\mathbf{p}}$ which yields the best results for the lateral control will probably be too large for the vertical control. An excessively large prediction time will result in a

## APPENDIX B

sluggish response in the vertical control. Furthermore, rapid vertical predictor motions will occur, since the vertical disturbances are less "filtered" by the vehicle dynamics. This problem is solved by choosing a value of $T_{p}$ which is the most appropriate for the lateral control on one hand and by reducing the vertical acceleration in computing the vertical curvature on the other hand. Thus, the vertical curvature is computed from

$$
\begin{equation*}
\frac{1}{R_{v}}=k_{p v} \frac{a_{v}}{v^{2}} \tag{B5}
\end{equation*}
$$

where $k_{p v}$ is a gain and $0 \leqq k_{p v} \leqq 1$. It is clear that for $k_{p v}=0$ the predictor symbol deteriorates into a velocity vector symbol.

Where the lateral acceleration $a_{\ell}$ is not measured or available, the curvature of the lateral path can be approximated from the bank angle $\phi$ according to

$$
\begin{equation*}
\frac{1}{\mathrm{R}_{\ell}}=\mathrm{g} \frac{\phi}{\mathrm{v}^{2}} \tag{B6}
\end{equation*}
$$

Since equation (B6) only yields the correct curvature in the steady state when following constant curves, system performance is expected to be less good than with the predictor based on the lateral acceleration. However, the steady-state error in $d_{\ell}$ in following constant curves with this simplified predictor will be zero as well.

## Variables Necessary To Drive the Display

The variables necessary to display the tunnel image are the coordinates of the vehicle position in the inertial reference system, $x_{i}, y_{i}$, and $z_{i}$, and the attitude angles of the vehicle, $\psi, \theta$, and $\phi$. The variables $x_{i}, y_{i}$, and $z_{i}$ can only be obtained by, or with the help of, ground-based equipment, such as a microwave landing system. The accuracy with which the desired trajectory can be followed directly depends on the accuracy with which the vehicle position can be estimated. The attitude angles $\psi, \theta$, and $\phi$ can be obtained with standard vertical and heading gyros.

The variables necessary to display the predictor symbol are the velocities $v, w$, and $V$, as well as the accelerations $a_{\ell}$ and $a_{v}$. The accelerations $a_{\ell}$ and $a_{v}$ can be measured directly with onboard accelerometers. The velocities $v$, $w$, and $V$ can be estimated from the sideslip, angle of attack, and airspeed, measured at the vehicle. However, these variables are calculated with respect to the air mass rather than to an inertial reference system so that the appropriate corrections for the steady-state wind components have to be made.

## APPENDIX B

An alternative method of obtaining $v, w$, and $V$ is by a rotational transformation of $\dot{x}_{i}, \dot{y}_{i}$, and $\dot{z}_{i}$ through $\psi, \theta$, and $\phi$. The velocities $\dot{x}_{i}$, $\dot{y}_{i}$, and $\dot{z}_{i}$ can be derived by differentiation of $x_{i}, y_{i}$, and $z_{i}$ or derived from estimates using position and accelerometer data. These computations can be carried out with onboard equipment.
