## SUMMARY

Automatic test data generation is a very popular domain in the field of search-based software engineering. Traditionally, the main goal has been to maximize coverage. However, other objectives can be defined, such as the oracle cost, which is the cost of executing the entire test suite and the cost of checking the system behavior. Indeed, in very large software systems, the cost spent to test the system can be an issue, and then it makes sense by considering two conflicting objectives: maximizing the coverage and minimizing the oracle cost. This is what we did in this paper. We mainly compared two approaches to deal with the multi-objective test data generation problem: a direct multi-objective approach and a combination of a mono-objective algorithm together with multi-objective test case selection optimization. Concretely, in this work, we used four state-of-the-art multi-objective algorithms and two mono-objective evolutionary algorithms followed by a multi-objective test case selection based on Pareto efficiency. The experimental analysis compares these techniques on two different benchmarks. The first one is composed of 800 Java programs created through a program generator. The second benchmark is composed of 13 real programs extracted from the literature. In the direct multi-objective approach, the results indicate that the oracle cost can be properly optimized; however, the full branch coverage of the system poses a great challenge. Regarding the mono-objective algorithms, although they need a second phase of test case selection for reducing the oracle cost, they are very effective in maximizing the branch coverage. ## 1. INTRODUCTION

Automatic software testing is one of the most studied topics in the field of search-based software engineering [1–4]. From the very first work [5, 6] to nowadays, many approaches have been proposed for solving the automatic test data generation problem (TDGP). This great effort in building computer-aided software testing tools is motivated by the cost and importance of the testing phase in the software development cycle. It is estimated that half the time spent on software project development, and more than half its cost, is devoted to testing the product [7]. This explains why software industry and academia are interested in automatic tools for testing.

Evolutionary algorithms (EAs) have been the most popular search-based algorithms for generating test cases [3]. In fact, the term *evolutionary testing* is used to refer to this approach. In the paradigm of *structural testing*, many researches have been performed using EAs and, in particular, different elements of the structure of a program have been studied in detail. Some examples are the presence of flags in conditions [8], the coverage of loops [9], the existence of internal states [10], and the presence of possible exceptions [11]. In addition, several EAs have been used as the search

<sup>†</sup>E-mail: ferrer@lcc.uma.es

engine such as scatter search [12], genetic algorithms (GAs) [13, 14], simulated annealing [15], and tabu search [16].

Traditionally, the solution of the TDGP is a set of test cases whose execution is able to cover all the software elements. Branch coverage is usually the most popular goal. Despite the most previous work only considering branch coverage, real-world engineers deal with the tedious and costly task of checking the system behavior for all the generated test cases. This significant and usually neglected cost is called the oracle cost [17]. Thus, a reformulation of the TDGP to deal with real-world problems is a need, taking into account the oracle cost as another important objective to minimize. The oracle cost can be reduced by minimizing the test suite size. The ideal scenario is to reduce the test suite size without any loss of coverage. However, in certain situations, the two objectives are in conflict: minimizing the oracle cost implies minimizing the coverage. When there are multiple conflicting objectives, the optimization literature recommends the consideration of a Pareto optimal optimization approach that is able to take into account the need to balance the conflicting objectives. Thus, the TDGP has been reformulated into a multi-objective problem (MOTDGP) in the work by Lakhotia *et al.* [18] and more recently, in 2010, in a work by Harman *et al.* [17].

Our main goal in this work is the comparison between two approaches to deal with the MOTDGP: a direct multi-objective approach (MM) and a combination of a mono-objective algorithm followed by a multi-objective test case selection optimization (mM). The general scheme of the proposed approaches can be seen in Figure 1.

On one hand, the MM approach considers the conflicting objectives during all the test data generation process, thus a priori, it focuses both on the test suite size minimization and the coverage maximization. On the other hand, the mM approach only considers the branch coverage during the test data generation process, thus a priori, it focuses only on the branch coverage maximization. For us to deal with the optimization of the test suite size, in this second approach, an additional second phase of multi-objective test case selection is performed. As nobody has previously compared these approaches yet, we can raise the following research questions and try to answer them in an extensive experimental study.

- How does MM approach deal with MOTDGP?
- Is the MM approach good enough in maximizing the coverage?
- How good is the mM approach performance in optimizing the coverage and the test suite size?
- Which approach is the best?

In order to completely answer the questions, we should use all the possible automatic test data generators in both multi-objective and mono-objective or, at least, a large number of them. We can also focus on some test data generators and answer the previous questions on them, taking into account that, in this case, the results will be valid for the test data generators considered. This is what we do in this paper. In particular, we study the MOTDGP with two objectives, maximizing the branch coverage and minimizing the oracle cost. Among our contributions, we generate the test data, and we also minimize the number of tests needed to achieve different values of coverage of the program. The solutions are provided as Pareto fronts. For the MM approach, we use five test

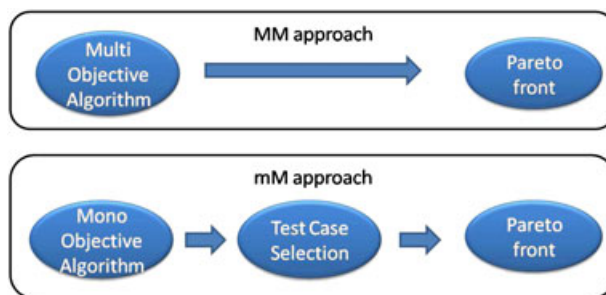

Figure 1. The general scheme of the two proposed approaches.

data generators: four of them based on evolutionary testing and an additional one based on random search. In the mM approach, we use three mono-objective test data generators with a second phase of multi-objective test data selection.

The rest of the paper is organized as follows. In Section 2, we define the multi-objective TDGP. Then, in Section 3, we present some background on multi-objective optimization. Next, in Section 4, we describe the MM approach and the multi-objective algorithms. After that, in Section 5, we describe the mM approach and provide details regarding the general structure of the test data generator for single-objective algorithms and the algorithms used in the experiments. Section 6 is devoted to the experimental methodology where we explain the quality indicators and the benchmark of programs that we used in the experiments. In Section 7, we show the results of the experiments and answer the proposed research questions. Finally, in Section 8, some conclusions and future work are outlined.

## 2. MULTI-OBJECTIVE TEST DATA GENERATION PROBLEM

The most popular technique to test software programs consists in executing the program with a set of test data (*software testing*). The engineer selects an initial set of configurations for the program under test (PUT), called test data suite and checks the PUT behavior with them. Because the size of the test data suite is an engineer's decision, she or he can control the effort devoted to this task, which is the oracle cost. In order to ensure the correctness of a program with this technique, it would be necessary to execute the PUT with all the possible configurations, but in practice, this is unfeasible. The alternative consists in testing the program with a representative set of test data.

Automatic test data generation (*automatic software testing*) consists in proposing an adequate set of test data in an automatic way to test a program, thus preventing the engineer from the task of selecting an adequate set of test data to test the PUT. This automation of the process requires a precise definition of what is an 'adequate set' of test data, definition that we will defer until some terms are defined. As we said before, this is a costly and hard task of the software development. Thus, another objective for a software engineer is the minimization of the oracle cost, which can be reduced to the minimization of the test suite size. In the following, we formally define the MOTDGP, but we first need to introduce several terms and notation.

Let  $P$  be a program, and we denote with  $B_P$  the set of branches of the program and with  $BranchExec_P(C)$  the set of branches covered in  $P$  because of the execution of a given set of test data,  $C$ . We define the branch coverage of the test suite  $C$ ,  $BrCov_P(C)$ , as the ratio between the traversed branches in the executions of the program  $P$  with the set of test data  $C$  and the number of branches of the program, that is,

$$BrCov_P(C) = \frac{|BranchExec_P(C)|}{|B_P|}. \quad (1)$$

The adequacy criterion of branch coverage states that a test suite  $C$  for a program  $P$  is 'adequate' when  $BrCov_P(C) = 1$ . Nevertheless, it is not always possible to reach such a value of coverage, and in case of reaching it, the cost to test the entire program can be unaffordable. Consequently, a balance between a coverage and the cost to achieve such coverage is mandatory. Because the cost of the testing phase depends on the test suite size, minimizing the test suite size, denoted with  $|C|$ , must be another goal.

Finally we deal with the MOTDGP with two conflicting objectives:

- $\max BrCov_P(C)$ , and
- $\min |C|$ ,

that is, maximizing the branch coverage and minimizing the test suite size.

## 3. MULTI-OBJECTIVE BACKGROUND

In this section, we provide background on multi-objective optimization. In particular, we define the concept of multi-objective optimization problem (MOP), Pareto dominance, and Pareto front. In these definitions, we are assuming, without loss of generality, that minimization is the goal for all the objectives.

A general MOP can be formally defined as follows:

Find a vector  $\mathbf{x}^* = (x_1^*, x_2^*, \dots, x_n^*)$  that satisfies the  $m$  inequality constraints  $g_i(\mathbf{x}) \geq 0, i = 1, 2, \dots, m$ , and the  $p$  equality constraints  $h_i(\mathbf{x}) = 0, i = 1, 2, \dots, p$ , and minimizes the vector function  $\mathbf{f}(\mathbf{x}) = (f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_m(\mathbf{x}))^T$ , where  $\mathbf{x} = (x_1, x_2, \dots, x_n)^T$  is the vector of decision variables. The set of all the values satisfying the constraints defines the *feasible region*  $\Omega$ , and any point  $\mathbf{x} \in \Omega$  is a *feasible solution*.

Taking into account this definition of a MOP, a solution  $\mathbf{x}^1 = (x_1^1, x_2^1, \dots, x_n^1)$  is said to dominate a solution  $\mathbf{x}^2 = (x_1^2, x_2^2, \dots, x_n^2)$ , denoted with  $\mathbf{x}^1 > \mathbf{x}^2$ , if and only if  $f_i(\mathbf{x}^1) \leq f_i(\mathbf{x}^2)$  for  $i = 1, 2, \dots, m$ , and there exists at least one  $j$  ( $1 \leq j \leq m$ ) such that  $f_j(\mathbf{x}^1) < f_j(\mathbf{x}^2)$ . Conversely, two points are said to be nondominated whenever none of them dominates the other. Figure 2 depicts some examples of dominated and nondominated solutions. In this figure,  $A$  dominates  $C$  because  $f_1(A) < f_1(C)$  and  $f_2(A) < f_2(C)$ . Meanwhile,  $A$  and  $B$  are nondominated solutions because  $A$  is better than  $B$  in the first objective function ( $f_1(A) < f_1(B)$ ), but  $B$  is better than  $A$  in the other objective function ( $f_2(A) > f_2(B)$ ).

The solution of a given MOP is usually a set of solutions (referred to as the Pareto optimal set) satisfying the following:

- Every pair of two solutions in the set are nondominated.
- Any other solution,  $y$ , is dominated by at least one solution in the set.

The representation of this set in the objective space is referred to as the *Pareto front*. Generating the *Pareto front* of a problem is the main goal of multi-objective optimization techniques. In theory, a Pareto front could contain a large number of points. In practice, a usable approximate solution will only contain a limited number of them; thus, an important goal is that solutions should be as close as possible to the exact Pareto front and uniformly spread, otherwise, they would not be very useful to the decision maker. Besides, closeness to the Pareto front ensures that we are dealing with optimal solutions, whereas a uniform spread of the solutions means that we have made a good exploration of the objective space and no regions are left unexplored.

Figure 3 depicts these issues of convergence and diversity. The left front (Figure 3(a)) depicts an example of good convergence and bad diversity: the approximation set contains Pareto optimal solutions, but there are some unexplored regions of the objective space. The approximation set depicted on the right (Figure 3(b)) illustrates poor convergence but good diversity: it has a diverse

Figure 2. Examples of dominated and nondominated solutions.

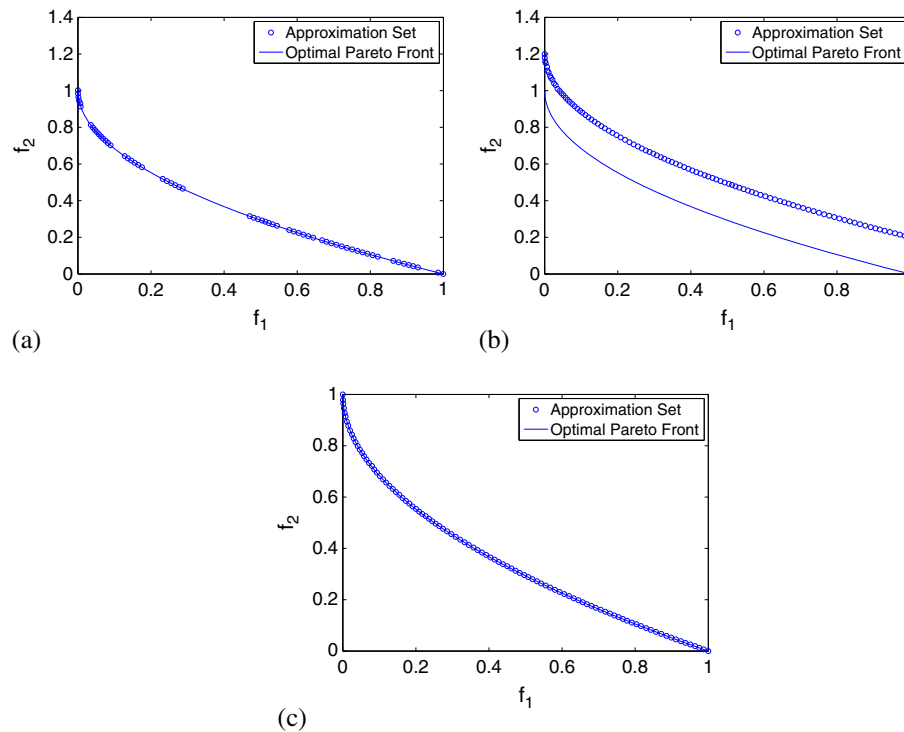

Figure 3. Examples of Pareto fronts with different behavior of convergence and diversity.

set of solutions, but they are not Pareto optimal. Finally, the lowermost front (Figure 3(c)) depicts an approximation front with both good convergence and good diversity.

#### 4. MM APPROACH

In this work, we are dealing with the MOTDGP from two points of view: a direct multi-objective approach (MM) and the application of a mono-objective algorithm followed by a multi-objective test case selection phase (mM). In this section, we explain the first approach: the MM approach. We describe how we deal with the MOTDGP and the algorithms used to solve the problem.

The MM approach considers the conflicting objectives during all the test data generation process, thus a priori, it focuses on both objectives during all the process. In this approach, a solution to the problem is a test suite, that is, a set of test data. These test suites are evaluated according to both objectives. The evaluation of the first objective (coverage) requires, in general, the execution of the test suite over the program under test. The evaluation of the second objective is a simple count of the number of test data in the set. In the following section, we present the multi-objective algorithms used in Section 7.

##### 4.1. Multi-objective algorithms

In this section, we describe the five multi-objective algorithms used in Section 7: Nondominated Sorting GA II (NSGA-II), Multi-Objective Cellular GA (MOCeLL), Strength Pareto EA 2 (SPEA2), Pareto Archived Evolution Strategy (PAES), and a random search algorithm (RNDMulti).

Nondominated Sorting GA II, proposed by K. Deb *et al.* [19], is a GA that is the reference algorithm in multi-objective optimization (with over 4,860 citations at the time of writing<sup>‡</sup>). Its pseudocode is presented in Algorithm 1. NSGA-II makes use of a population (P) of candidate

<sup>‡</sup>Data from Google Scholar: 4,860 citations on July 13, 2011.

**Algorithm 1** Pseudocode of NSGA-II.

```

1: proc Input:(nsga-II) //Algorithm parameters in 'nsga-II'
2: P ← Initialize_Population() // P = population
3: Q ← ∅ // Q = auxiliary population
4: while not Termination_Condition() do
5:   for i ← 1 to (nsga-II.popSize / 2) do
6:     parents ← Selection(P)
7:     offspring ← Recombination(nsga-II.Pc,parents)
8:     offspring ← Mutation(nsga-II.Pm,offspring)
9:     Evaluate_Fitness(offspring)
10:    Insert(offspring,Q)
11:   end for
12:   R ← P ∪ Q
13:   Ranking_And_Crowding(nsga-II, R)
14:   P ← Select_Best_Individuals(nsga-II, R)
15: end while
16: end_proc

```

---

solutions (known as individuals). In each generation, it works by creating new individuals after applying the genetic operators to P, in order to create a new population Q (lines 5–8). Then, both the current (P) and the new population (Q) are joined; the resulting population, R, is ordered according to a ranking procedure and a density estimator known as crowding distance (line 13) (for further details, please see [19]). Finally, the population P is updated with the best individuals in R (line 14). These steps are repeated until the termination condition is fulfilled.

Multi-Objective Cellular GA, introduced by Nebro *et al.* [20], is a cellular GA (cGA) that outperforms NSGA-II in some studies [20, 21]. In cGAs, the concept of (small) *neighborhood* is paramount. This means that an individual may only cooperate with its nearby neighbors in the breeding loop. Overlapped small neighborhoods of cGAs help in exploring the search space because they induce a slow diffusion of solutions through the population, providing a kind of exploration (diversification). Exploitation (intensification) takes place inside each neighborhood by applying the typical genetic operations (crossover, mutation, and replacement).

Multi-Objective Cellular GA includes an external archive to store the nondominated solutions found as the algorithm progresses. This archive is limited in size and uses the crowding distance of NSGA-II to maintain diversity. The pseudocode of MOCcell is presented in Algorithm 2, which corresponds with the version called aMOCcell4, described in [21].

We can observe that, in this version, for each individual, we select one parent from its neighborhood and one from the archive, in order to guide the search towards the best solutions found (lines 5–8). Then a new solution is created by applying the genetic operators to these parents. The new solution is used to replace the current solution (line 11) and is considered for inclusion in the archive (line 12). This constitutes a single iteration of the algorithm. The overall algorithm iterates until a termination condition is fulfilled.

**Algorithm 2** Pseudocode of MOCcell.

```

1: proc Input:(MOCcell) //Algorithm parameters in 'MOCcell'
2: archive ← ∅ //Creates an empty archive
3: while not Termination_Condition() do
4:   for individual ← 1 to MOCcell.popSize do
5:     n_list ← Get_neighbourhood(MOCcell,position(individual))
6:     parent1 ← Selection(n_list)
7:     parent2 ← Selection(archive)
8:     offspring ← Recombination(MOCcell.Pc,parent1, parent2)
9:     offspring ← Mutation(MOCcell.Pm,offspring)
10:    Evaluate_Fitness(offspring)
11:    Replacement(position(individual),offspring,MOCcell)
12:    Insert_Pareto_Front(offspring, archive)
13:   end for
14: end while
15: end_proc

```

---

The SPEA2 is a multi-objective EA proposed by Zitler *et al.* in [22]. We show the algorithm's pseudocode in Algorithm 3. SPEA2 uses a population and an archive simultaneously in its operation. In it, each individual is assigned a fitness value that is the sum of its strength raw fitness and a density estimation. The strength value of a solution  $i$  represents the number of solutions (in either the population or the archive) that are dominated by that solution, that is,  $S(i) = |\{j | j \in P_t \cup \overline{P}_t \wedge i > j\}|$ . The strength raw fitness value of a given solution  $i$ , on the contrary, is the sum of strengths of all the solutions that dominate it and is subject to minimization, that is,  $R(i) = \sum_{j \in P_t \cup \overline{P}_t, j > i} S(j)$ . The algorithm applies the selection, crossover, and mutation operators to fill an archive of individuals; then, the nondominated individuals of both the original population and the archive are copied into a new population. If the number of nondominated individuals is greater than the population size, a truncation operator based on calculating the distances to the  $k$ th nearest neighbor is used (a typical value is  $k = 1$ ),  $D(i) = 1/(\sigma_i^k + 2)$ , where  $\sigma_i^k$  is the distance from solution  $i$  to its  $k$ th nearest neighbor. This way, the individuals having the minimum distance to any other individual are chosen.

Pareto Archived Evolution Strategy is a metaheuristic proposed by Knowles and Corne [23]. The algorithm is based on a simple (1 + 1) evolution strategy. To find diverse solutions in the Pareto optimal set, PAES uses an external archive of nondominated solutions, which is also used to make decisions about new candidate solutions. An adaptive grid is used as a density estimator in the archive. The most remarkable characteristic of PAES is that it does not make use of any recombination operators (crossover). New solutions are generated only by modifying the current solution. The pseudocode of PAES is presented in Algorithm 4. It starts with a random solution (line 3). In each iteration, a new solution is produced by modifying the current solution (line 5). This

6:   Insert(archive, newSolution)
7: end while
8: end_proc

```

---

new solution is included in the archive and is considered as a potential replacement for the current solution (lines 7–14). These steps are repeated until the maximum number of evaluations is reached.

We have included PAES in our study because of its simplicity. PAES does not use any recombination operator, and its only parameter is the number of partitions of the adaptive grid of the archive. Its relative simplicity makes it attractive because there are comparatively few parameters that require tuning in order to know that the algorithm is being applied properly (e.g., population size, crossover probability, and mutation probability).

We also apply a random search (RNDMulti). This is merely a ‘sanity check’; all metaheuristic algorithms should be capable of comfortably outperform random search for a well-formulated optimization problem. The pseudocode of the RNDMulti is presented in Algorithm 5. The final result of this random search is the set of all the nondominated solutions found.

## 5. mM APPROACH

In this section, we present the second approach. In this approach, we use a mono-objective test data generator to obtain a set of test data with the highest coverage. The mono-objective test data generator deals with only one branch of the program at the same time. This is an advantage to obtain high coverage because the search can focus on covering the most complex branches of the program.

However, the resulting test suite is usually large, redundant, and inefficient because these algorithms do not try to minimize the test suite size. One way to reduce the number of test cases in a test suite, and still test the same functionality, is by solving a multi-objective test case selection problem on the given test suite. This problem was recently formalized by Yoo and Harman in [24] as follows: Given a test suite  $T$  and several objective functions  $F_i$ , we must find a subset  $T' \subseteq T$  such that  $T'$  is a Pareto optimal set with respect to the objective functions. The resulting subset of the test suite,  $T'$ , is composed of the nondominated solutions considering the objectives as equally important.

In order to solve the multi-objective test case selection problem, we always use in Section 7 the multi-objective algorithm NSGA-II. Our implementation is able to generate a Pareto front from thousands of test cases previously generated by the mono-objective algorithms. But first, we delete repeated test cases from the obtained test suite in order to reduce from thousands of test cases to hundreds of them. Two test cases are repeated when both of them traverse the same branches. We have compared the results obtained with and without this reduction phase, and the results are better when this reduction is applied. Finally, for the mono-objective algorithm involved in the first phase of test data generation, we use three different algorithms: a GA, an evolutionary strategy (ES), and a random search. In the following, we describe in detail the test data generator and the algorithms used as its search engine.

### 5.1. Test data generator

Our test data generator breaks down the global objective (to cover all the branches) into several partial objectives consisting of dealing with only one branch of the program. Then, each partial objective can be treated as a separate optimization problem in which a solution to the problem is a test datum and the function to be minimized is a distance between the current test datum and one satisfying the partial objective. In order to solve such minimization problem, we use EAs. The main loop of the test data generator is shown in Figure 4.

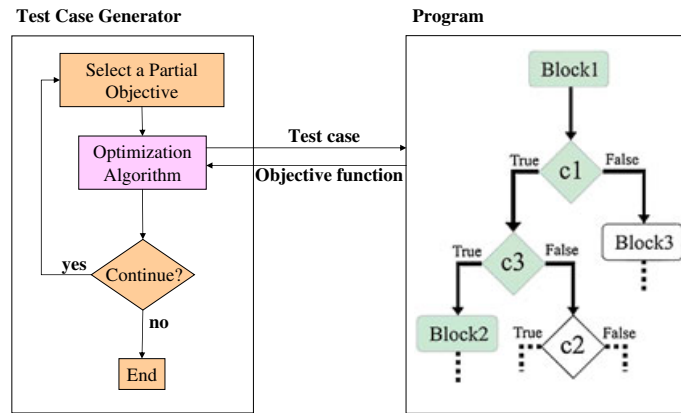

Figure 4. The test data generation process.

In a loop, the test data generator selects a partial objective (a branch) and uses the optimization algorithm to search for test data exercising that branch. When a test datum covers a branch, the test datum is stored in a set associated with that branch. The structure composed of the sets associated with all the branches is called *coverage table*. After the optimization algorithm stops, the main loop starts again, and the test data generator selects a different branch. This scheme is repeated until total branch coverage is obtained or a maximum number of consecutive failures of the optimization algorithm is reached. When this happens, the test data generator exits the main loop and returns the sets of test data associated with all the branches. In the following two sections, we describe two important issues related to the test data generator: the objective function to minimize and the optimization algorithms used.

### 5.2. Objective function

We have to solve several minimization problems: one for each branch. Now we need to define an objective function (for each branch) to be minimized. This function will be used for evaluating each test datum, and its definition depends on the desired branch and on whether the program flow reaches the branching condition associated with the target branch or not. If the condition is reached, we can define the objective function on the basis of the logical expression of the branching condition and of the values of the program variables when the condition is reached. The resulting expression is called *branch distance* and can be recursively defined on the structure of the logical expression. That is, for an expression composed of other expressions joined by logical operators, the branch distance is computed as an aggregation of the branch distance applied to the component logical expressions.

For the Java logical operators `&&` and `||`, we define the branch distance as

$$bd(a \&\& b) = bd(a) + bd(b), \quad (2)$$

$$bd(a || b) = \min(bd(a), bd(b)), \quad (3)$$

where  $a$  and  $b$  are logical expressions.

In order to completely specify the branch distance, we need to define its value in the base case of the recursion, that is, for atomic conditions. The particular expression used for the branch distance in this case depends on the operator of the atomic condition. The operands of the condition appear in the expression. Many research has been devoted in the past to the study of appropriate branch distances in software testing. An accurate branch distance considering the value of each atomic condition and the value of its operands can better guide the search. In procedural software testing, these accurate functions are well known and popular in the literature. They are based on distance measures defined for relational operators such as `<` and `>` [25]. We use here these distance measures described in the literature.

When a test datum does not reach the branching condition of the target branch, we cannot use the branch distance as objective function. In this case, we identify the branching condition  $c$  whose value must first change in order to cover the target branch (critical branching condition), and we define the objective function as the branch distance of this branching condition plus the *approximation level*. The approximation level, denoted here with  $ap(c, b)$ , is defined as the number of branching nodes lying between the critical one ( $c$ ) and the target branch ( $b$ ) [26].

In this paper, we also add a real-valued penalty in the objective function to those test data that do not reach the branching condition of the target branch. With this penalty, denoted by  $p$ , the objective value of any test datum that does not reach the target branching condition is higher than the one of any test datum that reaches the target branching condition. The exact value of the penalty depends on the target branching condition, and it is always an upper bound of the target branch distance. Finally, the expression for the objective function is as follows:

$$f_b(x) = \begin{cases} bd_b(x) & \text{if } b \text{ is reached by } x, \\ bd_c(x) + ap(c, b) * p & \text{otherwise,} \end{cases} \quad (4)$$

where  $c$  is the critical branching condition and  $bd_b$  and  $bd_c$  are the branch distances of branching conditions  $b$  and  $c$ . The use of the penalty  $p$  could be avoided by normalizing the branch distance to the interval  $[0, 1)$  (see [27] for example). However, in this work, we do not normalize the branch distance, thus requiring the penalty value  $p$ , which is set to  $p = 10,000$  in the experiments.

Nested branches pose a great challenge for the search. For example, if the condition associated with a branch is nested within three conditional statements, all the conditions of these statements must be true in order for the program flow to proceed onto the next one. Therefore, for the purposes of computing the objective function, it is not possible to compute the branch distance for the second and third nested conditions until the first one is true. This gradual release of information might cause efficiency problems for the search (what McMinn calls the *nesting problem* [28]), which forces us to concentrate on satisfying each predicate sequentially.

In order to alleviate the nesting problem, the test data generator selects as objective in each loop one branch whose associated condition has been previously reached by other test data stored in the coverage table. Some of these test data are inserted in the initial population of the EA used for solving the optimization problem. The percentage of individuals introduced in this way in the population is called the *replacement factor* and is denoted by  $Rf$ . In the beginning of the generation process, some random test data are generated in order to reach some branching conditions.

### 5.3. Mono-objective algorithms

We use two EAs inside the test data generator used in the mM approach: a GA and an ES. Let us first describe the general structure of an EA, and then we detail the differences between the EAs used here. In Algorithm 6, we show the main loop of an EA.

---

#### Algorithm 6 Pseudocode of an EA.

---

```

1: proc Input: (ea)
2: t:=0:
3: P(t) ← Create_Population() // P = population
4: Q ← ∅ // Q = auxiliar population // Creates an initial solution
5: while not Termination_Condition() do
6:   for i ← 1 to (ea.popSize) do
7:     parents ← Selection(P(t))
8:     offspring ← Recombination(ea.Pc, parents)
9:     offspring ← Mutation(ea.Pm, offspring)
10:    Evaluate_Fitness(offspring)
11:    Insert(offspring, Q(t))
12:   end for
13:   P(t+1) := Replace (Q(t), P(t))
14:   t = t + 1
15: end while
16: end_proc

```

---

Initially, the algorithm creates a population of  $\mu$  individuals randomly or by using a seeding algorithm. At each step, the algorithm applies stochastic operators such as selection, recombination, and mutation in order to compute a set of  $\lambda$  descendant individuals  $Q$ . The objective of the selection operator is to select some individuals from the population to which the other operators will be applied. The recombination operator generates a new individual from several ones by combining their solution components. This operator is able to put together good solution components that are scattered in the population. On the other hand, the mutation operator modifies one single individual and is the source of new different solution components in the population. The individuals created are evaluated according to the fitness function. The last step of the loop is a replacement operation in which the individuals for the new population  $P(t + 1)$  are selected from the offspring  $Q(t)$  and the old one  $P(t)$ . This process is repeated until a stop criterion is fulfilled, such as reaching a preprogrammed number of iterations of the algorithm or finding an individual with a preset target quality. In this work, we use two EAs as the optimization algorithm of the test data generator: an ES and a GA. In the following, we focus on the details of the ES. We defer the details of the GA to the parameterization section.

In an ES [29], each individual is composed of a vector of real numbers representing the problem variables ( $\mathbf{x}$ ), a vector of standard deviations ( $\sigma$ ), and a vector of angles ( $\omega$ ). These two last vectors are used as parameters for the main operator of this technique: the Gaussian mutation. They evolved together with the problem variables themselves, thus allowing the algorithm to self-adapt the search to the landscape. The mutation operator is governed by the three following equations:

$$\sigma'_i = \sigma_i \exp(\tau N(0, 1) + \eta N_i(0, 1)), \tag{5}$$

$$\omega'_i = \omega_i + \varphi N_i(0, 1), \tag{6}$$

$$\mathbf{x}' = \mathbf{x} + \mathbf{N}(\mathbf{0}, C(\sigma', \omega')), \tag{7}$$

where  $C(\sigma', \omega')$  is the covariance matrix associated with  $\sigma'$  and  $\omega'$ ;  $N(0, 1)$  is the standard univariate normal distribution; and  $\mathbf{N}(\mathbf{0}, C)$  is the multivariate normal distribution with mean  $\mathbf{0}$  and covariance matrix  $C$ . The subindex  $i$  in the standard normal distribution indicates that a new random number is generated anew for each component of the vector. The notation  $N(0, 1)$  is used for indicating that the same random number is used for all the components. The parameters  $\tau$ ,  $\eta$ , and  $\varphi$  are set to  $(2n)^{-1/2}$ ,  $(4n)^{-1/4}$ , and  $5\pi/180$ , respectively, as suggested in [30]. For the recombination operator of an ES, there are many alternatives: each of the three real vectors of an individual can be recombined in a different way. In our particular implementation, we use discrete uniform recombination for the solution vector  $\mathbf{x}$ , where each component is selected from the best parent with a predefined probability, called *bias*. For the vector of standard deviations and angles, we use arithmetic recombination. The exact expressions for the components of the vectors are the following:

$$\mathbf{x}_i = \begin{cases} \mathbf{x}_i^1 & \text{if } U(0, 1) < \textit{bias}, \\ \mathbf{x}_i^2 & \text{otherwise,} \end{cases} \tag{8}$$

$$\sigma_i = (\sigma_i^1 + \sigma_i^2)/2, \tag{9}$$

$$\omega_i = (\omega_i^1 + \omega_i^2)/2, \tag{10}$$

where the superindices are used to denote the two parent solutions ( $\mathbf{x}^1$  is the best one) and  $U(0, 1)$  denotes a random sample of a uniform distribution in the interval  $[0, 1)$ . With respect to the replacement operator, there is a special notation to indicate whether the old population is taken into account or not to form the new population. When only the new individuals are used, we have a  $(\mu, \lambda)$ -ES; otherwise, we have a  $(\mu + \lambda)$ -ES. Regarding the representation, because all the test programs have integer parameters, each component of the vector solution  $\mathbf{x}$  is rounded to the nearest integer and used as actual parameter of the program. There is no limit in the input domain, thus allowing the ES to explore the whole solution space.

**Algorithm 7** Pseudocode of RNDMono.

---

```

1: proc
2: conditionTable  $\leftarrow \emptyset$ 
3: currentSolution  $\leftarrow$  Create_Solution() // Creates an initial solution
4: while not Termination_Condition() do
5:   newSolution  $\leftarrow$  Create_Solution()
6:   Insert(conditionTable, newSolution)
7: end while
8: end_proc

```

---

We also apply a random algorithm (RNDMono) as search engine of our test data generator (see Algorithm 7). This is again merely a ‘sanity check’. The final result of this random search is the set of all the created solutions.

## 6. EXPERIMENTAL METHODOLOGY

This section is aimed at presenting the indicators used to measure the quality of the obtained results and the benchmark programs we have used. It also describes how the solutions of the problem have been encoded and the genetic operators employed, the configuration of the algorithms, and the methodology we have followed.

### 6.1. Quality indicators

Two different issues are normally considered for assessing the quality of the results computed by a multi-objective optimization algorithm:

- to minimize the distance of the computed solution set by the proposed algorithm to the optimal Pareto front (convergence towards the optimal Pareto front); and
- to maximize the spread of solutions found, so that we can have a distribution of vectors as smooth and uniform as possible (diversity).

A number of quality indicators have been proposed in the literature. Among them, we can distinguish between *Pareto-compliant* and *non-Pareto-compliant* indicators [31]. Given two Pareto fronts, A and B, if A dominates B, the value of a Pareto-compliant quality indicator is higher for A than for B; meanwhile, this condition is not fulfilled by the noncompliant indicators. Thus, the use of Pareto-compliant indicators should be preferable. In this work, we apply the hypervolume (HV) [32] (Pareto-compliant), which takes into account the convergence as well as the diversity of the solutions; and empirical attainment surfaces (EASs) [33], which measures the probability of being dominated by the approximated Pareto front. Both indicators are defined as follows:

- **Hypervolume.** This indicator calculates the volume (in the objective space) covered by members of a nondominated set of solutions  $Q$  (the region enclosed into the discontinuous line in Figure 5(a),  $Q = \{A, B, C\}$ ) for problems where all objectives are to be minimized. Mathematically, for each solution  $i \in Q$ , a hypercube  $v_i$  is constructed with a reference point  $W$  and the solution  $i$  as the diagonal corners of the hypercube. The reference point can simply be found by constructing a vector of the worst objective function values. Thereafter, a union of all hypercubes is found, and its HV is calculated as follows:

$$HV = \text{volume} \left( \bigcup_{i=1}^{|Q|} v_i \right). \quad (11)$$

We apply this metric after a normalization of the objective function values to the range [0..1]. A Pareto front with a higher HV than another one could be due to some solutions in the better front dominate solutions in the other or solutions in the better front are more widely distributed than in the other. Because both properties are considered to be good, algorithms with larger values

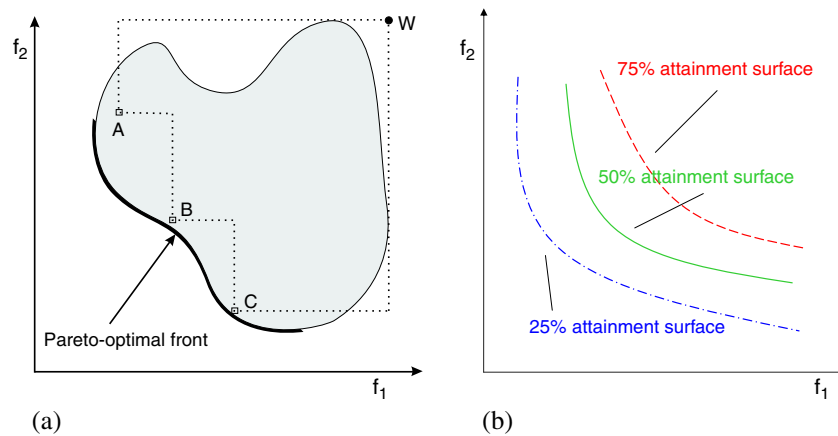

Figure 5. Examples of hypervolume and attainment surfaces.

of HV are considered to be desirable. For this quality indicator to be applied, it is usually necessary to know the optimal Pareto front (for normalization purposes). Of course, typically, we do not know the location of the optimal front. Therefore, we employ as a *reference Pareto optimal front* the front composed of all the nondominated solutions out of all the executions carried out (i.e., the best front known until now).

- Empirical attainment surfaces:** In the related literature, the trade-off among several objectives in a MOP is usually presented by showing one of the approximated Pareto fronts obtained in one single run of a given algorithm. However, the optimization algorithms used are stochastic; therefore, there is no warranty that the same result is obtained after a new run of the algorithm. Thus, a single run of a stochastic algorithm gives no information about the average performance of the algorithm. We need a way of representing the results of a multi-objective algorithm that allows us to observe the expected performance and its variability, in the same way as the average and the standard deviation are used in the single-objective case. To do this, we use the concept of empirical attainment function (EAF) [33]. In short, the EAF is a function  $\alpha$  from the objective space  $\mathbb{R}^n$  to the interval  $[0, 1]$  that estimates for each vector in the objective space the probability of being dominated by the approximated Pareto front of one single run of the multi-objective algorithm. Given the  $r$  approximated Pareto fronts obtained in the different runs, the EAF is defined as

$$\alpha(z) = \frac{1}{r} \sum_{i=1}^r I(A^i \leq \{z\}), \quad (12)$$

where  $A^i$  is the  $i$ th approximated Pareto front obtained with the multi-objective algorithm and  $I$  is an indicator function that takes value 1 when the predicate inside it is true and 0 otherwise. The predicate  $A^i \leq \{z\}$  means  $A^i$  dominates solution  $z$ . Thanks to the attainment function, it is possible to define the concept of  $k\%$  attainment surface [33]. The attainment function  $\alpha$  is a scalar field in  $\mathbb{R}^n$ , and the  $k\%$  attainment surface is the level curve with value  $k/100$  for  $\alpha$ . Informally, the 50% attainment surface in the multi-objective domain is analogous to the median in the single-objective one. In a similar way, the 25% and 75% attainment surfaces can be used as the first and third ‘quartile fronts’, and the region between them could be considered a kind of ‘interquartile region’ (see Figure 5(b)). When the number of objectives is one, the 50% attainment surface is the median, and the ‘interquartile region’ is the interquartile range.

## 6.2. Automatic program generator

We designed an automatic program generator able to generate programs similar to the ones of the real-world software. To achieve this goal, we focus on measures, made on source code pieces, that

do not require the execution of the program, called static measures. Once we have computed these static measures in real-world software, we generate programs having values of the static measures that are similar to the ones of the real-world programs. The main characteristic of our program generator is that it is able to create programs for which total branch coverage is possible, but they do not solve any concrete problem. We propose this generator with the aim of generating a big benchmark of programs with certain characteristics chosen by the user.

In a first approximation, we could create a program by using a representation based on a syntax tree and a table of variables. The tree stores the sentences that are generated, and the table of variables stores basic information about the variables declared and their possible use. With these structures, we are able to generate programs, but we cannot ensure that all the branches of the generated programs are reachable. The unreachability of all the branches is a quite common feature of real-world programs, so we could stop the design for the generator at this stage. However, another objective of the program generator is to be able of creating programs that can be used to compare the performance of different algorithms for test data generation. In this case, programs for which total coverage is reachable are desirable, because we can use the coverage obtained by a test suite as a measure of its quality.

Let us illustrate this with an example. Let us suppose that a given tool for automatic test case generation is able to find test suites that cover 80% of the branches of program *A* and 90% of the branches of program *B* (a test suite for each program). It seems that the tool is more effective in program *B*, because it is able to generate a test suite with higher coverage. Now, imagine that 20% of the branches of program *A* are unreachable and all the branches of program *B* are reachable. Then, the tool obtained the maximum possible coverage in program *A* but not in program *B*. Thus, we would say that the tool is more effective for program *A*.

This example shows that coverage is not a good measure of the performance of an automatic tool for test case generation if we do not know the maximum reachable coverage for each program. In previous work, alternative measures, such as corrected coverage [34] have been used to alleviate this problem. In this work, we adopt a different approach. Because we automatically generate the programs of the benchmark, we decided to generate programs for which the maximum coverage is always 100%. This way, we can safely use the coverage as a measure of performance of the automatic test data generators, and we can compare these generators among them using coverage.

An alternative approach would be to generate programs for which there is no warranty that 100% of branch coverage can be obtained and then to analyze these programs in order to find the maximum possible coverage and to use a corrected coverage measure. However, the drawback of this alternative approach is that the size of the benchmark would be limited, because we should check all the programs by hand (the automatic determination of the maximum branch coverage is an undecidable problem), and we would lose statistical confidence in the results. It would be unviable to generate 800 programs (as we did in this work) and analyze them manually.

With the goal of generating programs for which total coverage is reachable, we thought in the way the variables are treated in symbolic execution [35, 36] and some methods of formal derivation of programs [37–39]. Unlike the formal derivation of programs, our generator is not guided by a specification. Therefore, at the end, we introduce logic predicates in the program generation process in order to generate programs for which total coverage is always ensured.

The program generator is parameterizable, the user can fix several parameters of the program under construction (*PUC*). Thus, we can assign the probability distributions of the number of sentences of the *PUC*, the number of variables, the maximum number of atomic conditions per condition, and the maximum nesting degree. Another parameter the user can tune is the percentage of control structures or assignment sentences that will appear in the code. With this parameter being tuned, the program will contain the desired density of decisions.

Once the parameters are fixed, the program generator builds the general scheme of the *PUC*. It stores in the syntax tree the program structure and creates a main method where the local variables are first declared. Then, the program is built through a sequence of basic blocks of sentences where, according to a probability, the program generator decides which sentence will be added to the program. The creation of the entire program is performed in a recursive way. The user can decide whether all the branches of the generated program are reachable or not.

```

/* CP1 ≡ x ≤ 3 */
if (x < 0)
{
  /* CP2 ≡ TP1 ≡ x ≤ 3 ∧ x < 0 ≡ x < 0 */
  y=5;
  /* CP3 ≡ x < 0 ∧ y = 5 */
}
else
{
  /* CP4 ≡ FP1 ≡ x ≤ 3 ∧ x ≥ 0 ≡ 0 ≤ x ≤ 3 */
  x=x-3;
  /* CP5 ≡ -3 ≤ x ≤ 0 */
}
/* CP6 ≡ x < 0 ∧ y = 5 ∨ -3 ≤ x ≤ 0 */

```

Figure 6. Illustration of the predicates transformation.

If total reachability is desired, logic predicates are used to represent the set of possible values that the variables can take at a given point of the PUC. Using these predicates, we can know the range of values that a variable can take. This range of values is useful to build a new condition that can be *true* or *false*. For example, if at a given point of the program we have the predicate  $x \leq 3$ , we know that a forthcoming condition  $x \leq 100$  will be always true, and if this condition appears in an `if` statement, the `else` branch will not be reachable. The predicates are thus used to guide the program construction to obtain a 100% coverable program.

In general, at each point of the program, the predicate is different. During the program construction, when a sentence is added to the program, we need to compute the predicate at the point after the new sentence. For this computation, we distinguish two cases. First, if the new sentence is an assignment, then the new predicate  $CP'$  is computed after the previous one  $CP$  by updating the values that the assigned variable can take. For example, if the new sentence is  $x = x + 7$  and  $CP \equiv x \leq 3$ , then we have  $CP' \equiv x \leq 10$ .

Second, if the new sentence is a control statement, an `if` statement, for example, then the program generator creates two new predicates called True-predicate ( $TP$ ) and False-predicate ( $FP$ ). The  $TP$  is obtained as the result of the AND operation between  $CP$  and the condition related to the control statement. The  $FP$  is obtained as the result of the AND operation between the  $CP$  and the negated condition. In order to ensure that all the branches can be traversed, we check that both  $TP$  and  $FP$  are not equivalent to *false*. If any of them were false, this new predicate is not valid, and a new control structure would be generated.

Once these predicates are checked, the last control statement is correct, and new sentences are generated for the two branches. The predicates are computed inside the branches in the same way. After the control structure is completed, the last predicates of the two branches are combined using the OR operator, and the result is the predicate after the control structure. In Figure 6, we illustrate the previous explanation with one example.

### 6.3. Benchmark of test programs

In Section 7, we use two benchmarks. The first one is composed of 800 synthetic programs.<sup>§</sup> They are described in the next section. The second one is composed of 13 real-world programs that are described in Section 6.3.2.

<sup>§</sup>They are available at <http://neo.lcc.uma.es/mase/index.php/component/content/article/48-problems/121-source-of-800-synthetic-programs>

*6.3.1. Synthetic programs.* The program generator can create programs having the same value for the static measures, as well as programs having different values for the measures. In addition, the generated programs are characterized by having a 100% coverage, thus all possible branches are reachable.

Our program generator takes into account the desired values of some static measures. The static measures selected are the following: the number of atomic conditions, the nesting degree, the number of sentences, and the number of variables. The main features of the generated programs are the following: they deal with integer input parameters, their conditions are joined by whichever logical operator, they are randomly generated, and all their branches are reachable.

The methodology applied for the program generation was the following. First, we analyzed a set of Java source files from the Java Development Kit 1.5 (java.util.\*, java.io.\*, java.sql.\*, etc.), and we computed the static measures on these files. Next, we used the ranges of the most interesting values, obtained in this previous analysis as a guide to generate Java source files having values in the same range for the static measures. This way, we generated programs with the values in these ranges, for example, nesting degree in 1–4 (25% for each value), atomic conditions per condition in 1–4 (68.43% with four conditions per decision), and statements in 25, 50, 75, or 100 (25% for each value). The percentage of control flow statements is 32.23% (in this work, we use IF statements), this means that the test case generator should cover around 64 different branches (32 true and 32 false) in programs with 100 statements. The previous values are realistic with respect to the static measures, making our study meaningful. Besides, we generated 50 programs for each size and nesting degree ( $50 \times 4$  sizes  $\times 4$  nesting degrees = 800), which is a total of 800 Java programs.

*6.3.2. Real programs.* In order to improve the interest of our work, we propose an additional benchmark of real programs. It is composed of 13 real programs extracted from the literature [40–42]. Some of them have been extracted from the book *C Numerical Recipes*, available online at <http://www.nr.com/>. They deal with real and integer input values and some of them also contain loops. The programs are listed in Table I, where we inform on the maximum nesting degree, the lines of code, the number of branches, and the number and type of input arguments.

#### 6.4. Solution encoding, genetic operators, and configuration

Here, we detail the configuration of the operators and the encoding of the solutions used in the algorithms.

*6.4.1. Details of the mono-objective algorithms.* In this work, each solution is encoded as an integer/real vector of length  $n$  (the number of arguments). As we said in Section 5.1, the generator breaks down the global objective (to cover all the branches) into several partial objectives consisting

Table I. Characteristics of the real programs.

Name	ND	LOC	Branches	Arguments	Description
calday	2	47	22	3 integer	Calculate the day of the week
complex	3	74	24	6 integer	Calculate complex arithmetic functions
gcd	2	28	8	2 Integer	Greatest common denominator
line	8	92	36	8 integer	Check if two rectangles overlap
numbers	3	71	28	1 integer	Parse a big number from integer to string
qformula	2	24	4	3 double	Solve real equations
qformulas	2	22	6	3 integer	Solve integer equations
remainder	6	49	18	2 integer	Calculate the remainder of an integer division
tmichael	5	69	20	3 integer	Classify triangles in four types: Michael
tmyers	6	54	12	3 integer	Classify triangles in four types: Myers

tsthamer	3	76	26	3 integer	Classify triangles in five types: Sthamer
twegener	3	46	26	3 double	Classify triangles in five types: Wegener

ND, nesting degree; LOC, lines of code.

of dealing with only one branch of the program. Thus, two stopping conditions exist: one for partial objectives and the other one for the whole test data generation process. The search for one partial objective stops when 1000 evaluations are performed, whereas the test data generation process ends after 150,000 evaluations.

In our GA, we use as a recombination operator the uniform crossover in which each component of the new solution is randomly selected from the two parents. The formal definition is the same as Equation (8) with  $bias = 0.5$ . The mutation operator adds a random value to the components of the vector, that is,

$$x_i = x_i + U(-500, 500), \tag{13}$$

where the probability distribution of these random values is a uniform distribution in the range  $[-500, 500]$ . However, not all the components of the individual are perturbed, only half of them are. In our ES, we use a discrete crossover operator and a Gaussian mutation. We show in Table II a summary of the parameters used by the two EAs in Section 7.

After the execution of the test data generator, we obtain a huge table of coverage where the test data that satisfy a concrete branch during the execution are saved. This table is filtered in order to remove those test data for which a different test exist in the table traversing the same branches, as explained in Section 5. Then, a test data selection is performed over this set by using a standard NSGA-II.

**6.4.2. Details of the multi-objective algorithms.** In the multi-objective approach, each individual is encoded as a set of test data. In Table III, the parameters of the multi-objective EAs used in Section 7 can be seen. As genetic operators, the *binary tournament* was used as the selection scheme. This operator works by randomly choosing two individuals from the population, and the one dominating the other is selected; if both solutions are nondominated, one of them is randomly selected.

We created some crossover operators to increase the efficiency of the algorithm. The best results were obtained with the *union crossover*. It takes two solutions,  $C_1$  and  $C_2$ , and creates a new one  $C$ , which is the union of both, that is,  $C = C_1 \cup C_2$ . If the resulting solution  $C$  has more coverage than  $C_1$  and  $C_2$ , then  $C$  is the new offspring. Otherwise, the solution with more coverage ( $C_1$  or  $C_2$ ) is the new child.

Table II. Parameters of the two mono-objective evolutionary algorithms used in Section 7.

	Evolutionary strategy	Genetic algorithm
Population	25 individuals	25 individuals
Selection	Random, 5 individuals	Random, 5 individuals
Mutation	Gaussian	Add $U(-500, 500)$
Crossover	discrete ( $bias = 0.6$ ) + arithmetic + arithmetic	Uniform
Replacement	Elitist	Elitist
Stopping condition	1000 evaluations	1000 evaluations
Total evaluations	150,000 evaluations	150,000 evaluations

Table III. Parameters of the multi-objective evolutionary algorithms used in Section 7.

	NSGA-II	MOCeII	SPEA2	PAES
Population	20 individuals	20 individuals	20 individuals	20 individuals
Selection	BT, 2 individuals	BT, 2 individuals	BT, 2 individuals	BT, 2 individuals
Mutation	Adaptive mutation	Adaptive mutation	Adaptive mutation	Adaptive mutation
Crossover	Union crossover	Union crossover	Union crossover	—
Replacement	Elitist	Elitist	Elitist	Elitist
Total evaluations	150,000 evaluations	150,000 evaluations	150,000 evaluations	150,000 evaluations

NSGA-II, Nondominated Sorting Genetic Algorithm II; MOCeII, Multi-Objective Cellular Genetic Algorithm; SPEA2, Strength Pareto Evolutionary Algorithm 2; PAES, Pareto Archived Evolution Strategy; BT, binary tournament.

Finally, the mutation operator adds new test data to the solution with probability 0.6, deletes one test datum with probability 0.2, and keeps the individual unchanged with probability 0.2. In the case of adding test data, the number of new test data is 30% of the test data present in the solution.

If the resulting individual has the same coverage and more test data, at the end of the iteration, the algorithm deletes it from the population because this solution is dominated.

All the multi-objective algorithms have been implemented using jMetal [43], a Java framework aimed at the development, experimentation, and study of metaheuristics for solving MOPs.

## 7. EXPERIMENTAL ANALYSIS

In this section, we present the results of the two proposed approaches. In Section 7.1, we analyze the MM approach, and we compare the performance of the multi-objective algorithms. In Section 7.2, we study the mM approach, and we compare the performance of the mono-objective algorithms used as the base for the approach. Then, in Section 7.3, we compare the two proposed approaches for the academic benchmark, and finally, in Section 7.4, we compare both approaches with a benchmark of real programs.

For the study, we use the 800 Java programs automatically generated and another benchmark composed of 13 real programs. Both benchmarks were described in Section 6.3. Because we are dealing with stochastic algorithms, we need to perform several independent runs of each algorithm and program, 30 in our case, in order to obtain a very stable average of the measures. All test data generators used in this work proceed by generating test data until a maximum of 150,000 test data are generated. We also perform a multiple comparison statistical test for each program on the obtained results to compare the algorithms among them. We set a confidence level of 95% ( $p$ -value under 0.05) for the whole comparison (all the algorithms acting on a program), and we used the Bonferroni correction for each particular comparison.

### 7.1. Evaluation of the MM approach

In this section, we analyze the behavior of the multi-objective algorithms with the aim of highlighting the algorithm that works better. We have analyzed 800 programs, so we cannot represent all HV values for all the programs. For this reason, we summarize in Table IV the times one algorithm has better median HV than the others. We have classified the results according to the nesting degree and the size of the PUT. For this indicator, the higher the value, the better the quality of the obtained results. Thus, by looking at the tables, we can see that MOCeII was usually the algorithm computing clearly the best results regarding HV. However, when the programs are small (25–50 statements) and complex (nesting degree 4), the NSGA-II algorithm has a better behavior. We must highlight the big difference among MOCeII (443), NSGA-II (198), and the others altogether (43).

Then, we compare the HV values of all the programs and independent executions with the Kruskal–Wallis test. In each cell of a table of statistics, we have a pair (number, triangle). The number indicates how many programs are significantly different, and the triangle indicates that the program in the row is significantly better ( $\blacktriangle$ ) or worse ( $\nabla$ ) than the program in the column. The results are summarized in Table V. Although the previous values set a clear tendency, the absence of significant differences among MOCeII, NSGA-II, and SPEA2 does not allow us to say that MOCeII is better than the other two. However, we can mention that RNDMulti is the worst algorithm in all the programs (800) and PAES is worse than MOCeII in 18 programs, NSGA-II in 9 programs, and SPEA2 in only 2 programs.

With the aim of showing an example of the computed fronts for the instances, we selected one program for each nesting degree that can represent the typical behavior of the different algorithms in this kind of instance. Figure 7 depicts the 50% attainment surfaces of these selected programs. In the instance with low nesting degree, MOCeII dominates the others and has a good performance because it reaches almost the same or better coverage with the same test data. NSGA-II has a similar behavior except in the right extreme of the figure where it is not able to reach the same maximum coverage as MOCeII. On the other hand, in the program with nesting degree 4, NSGA-II is the algorithm that is able to reach the best coverage and dominates all the other fronts. The other two

multi-objective algorithms (SPEA2 and PAES) have problems finding the solutions with high coverage, in the upper-right bound of the figure, and are worse than MOCcell and NSGA-II. RNDMulti is always the worst. MOCcell has been able to find nondominated solutions in the right area where SPEA2, PAES, and RNDMulti have not found any of them (solutions in the extremes of the front). This is related to a better exploration of the search space by MOCcell. Specifically, this is one of the properties of the cGA model, on which MOCcell is based. This fact has been reported in many studies on single-objective optimization (see [44]). There is only one exception, when a program has nesting degree 4 and it is more difficult to obtain high coverage, NSGA-II has the best performance.

We have also analyzed the reduction obtained in the number of test cases, because one of our goals is to minimize the number of test cases. We analyze the reduction experienced using our approaches compared with the use of all the generated test cases. It is very difficult to analyze this reduction because not all the algorithms achieve a 100% coverage in all the programs. For this

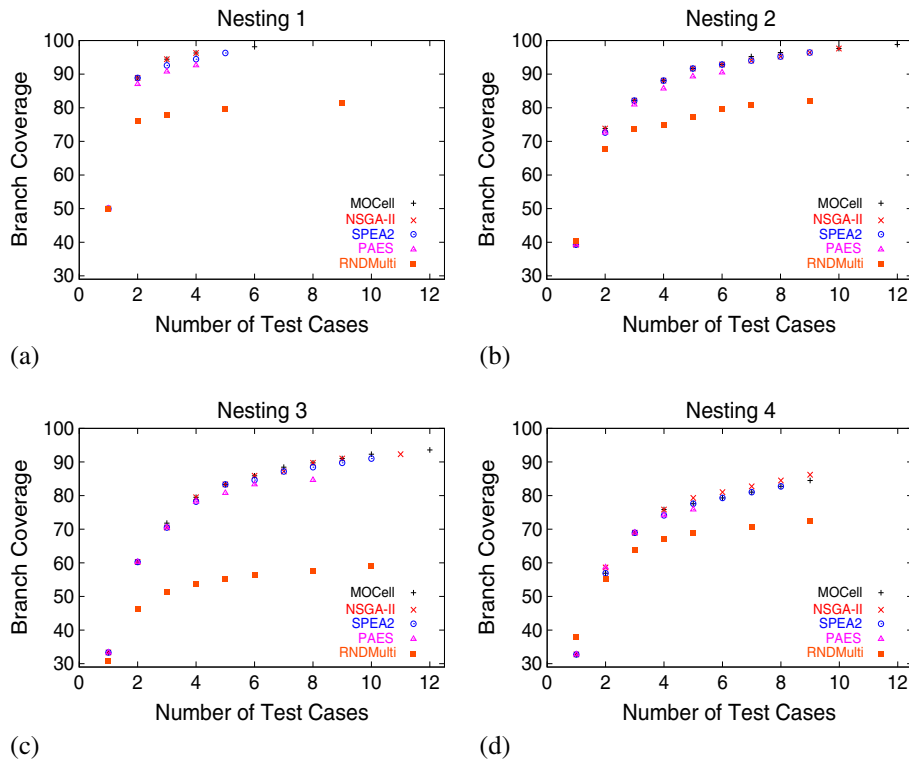

Figure 7. Fifty percent attainment surfaces: coverage against the number of test cases. MOCeII, Multi-Objective Cellular Genetic Algorithm; NSGA-II, Nondominated Sorting Genetic Algorithm II; SPEA2, Strength Pareto Evolutionary Algorithm 2; PAES, Pareto Archived Evolution Strategy.

reason, we cannot simply average the number of test cases, but we must take into account the maximum obtained coverage in order to give the real reduction made by the multi-objective algorithm. The total reduction is from thousands of test cases generated to around 10, but this reduction could also be easily computed on the basis of the *table of coverage* of the algorithms by choosing one test case per branch. The drawback of the latter approach is that the minimization of the test suite would be far from optimal. For this reason, we establish a theoretical upper bound of the required number of test cases needed. This upper bound is the number of branches that were achieved by the algorithm. We compute the real oracle cost of the test suites generated by any algorithm according to the next expression:

$$\begin{aligned} upper\_bound(P, A) &= B_P * MaxCov(P, A), \\ oracle\_cost(P, A) &= \frac{tc(P, A)}{upper\_bound(P, A)}, \end{aligned} \quad (14)$$

where  $P$  is a program,  $A$  is an algorithm,  $B_P$  is the number of branches of the program  $P$ ,  $MaxCov(P, A)$  is the maximum coverage obtained by the algorithm  $A$  in the program  $P$ , and  $tc(P, A)$  is the number of test cases needed by the algorithm  $A$  to obtain the maximum coverage in program  $P$ .

We can state that the oracle cost of the test suite generated by all the multi-objectives algorithms can be reduced by our approach; only 15.12% of the test cases are needed in comparison with the computed upper bound. This reduction is computed in the case of the maximum coverage and hence the largest number of computed test cases. But we must bear in mind that our solution is a complete Pareto front offered to the expert to make a decision about the test suite that best fits his or her needs; therefore, a similar percentage of reduction is carried out for each couple *coverage number of test cases* that appears in the Pareto front.

In the TDGP, it is particularly hard to achieve a 100% branch coverage, specially if one uses a multi-objective algorithm because its execution is not entirely guided to obtain a total coverage. The multi-objective approach deals with all the branches at the same time, and this provokes a lack of information. In addition, the search does not spend most of its effort to cover the most complex branches. In Table VI, we show the average of maximum coverage (among the solutions in the front) obtained with the solutions for all the programs with different nesting degree. We highlight the maximum values in the table for each nesting degree. As we expected, MOCcell's performance is the best on nesting degrees 1, 2, and 3. On the other hand, NSGA-II obtains the best coverage with nesting degree 4. Because the differences are low, we compared the coverage values of all the programs and independent executions with the Kruskal–Wallis test. The results are summarized in Table VII. As we expected, MOCcell obtains significant differences in more programs with respect to PAES and RNDMulti, than NSGA-II and SPEA2.

If we consider the HV obtained (Table IV), the significant HV differences (Table V), the attainment surfaces and the average maximum coverage (Table VI), it is clear that the ranking of the performance of the algorithms is as follows: MOCcell is the best, NSGA-II is the second, SPEA2 is the third, PAES is the fourth, and finally, RNDMulti is the worst one, as expected.

## 7.2. Evaluation of mM approach

In this section, we analyze the mM approach. First of all, we study the values of HV. We show in Table VIII the programs in which one algorithm has a better value of HV.

It is noteworthy that when the nesting degree is the smallest (1), the ES obtains better results and when the nesting degree is large (3 and 4), the GA is better than the others. In other words, when the program is more complex, the GA is clearly the best. The ES is better in large programs (100 statements) except when the program has nesting degree 4. Then, we compared the HV values of all the programs and independent executions with the Kruskal–Wallis test. The results indicate that there is no significant difference between GA and ES (Table IX). As we expected, the results of RNDMono are worse than that of ES in 786 programs and that of GA in 765 programs.

Table VIII. Programs in which the median hypervolume of one algorithm is better than that of the others.

Second, we show the 50% attainment surfaces of four representative programs with different nesting degree in Figure 8. In the instance with nesting degree 1, the attainment surfaces are very similar between GA and ES. RNDMono is far from the behavior of the others. In the instance with nesting degree 2, the three algorithms obtain similar results. The instances with nesting degrees 3 and 4 represent the general behavior of the algorithms in most of the programs. The RNDMono is far from the others, and the ES obtains similar values of coverage to the GA with the same number of test cases, but GA can achieve the best value of coverage. The GA is the best algorithm in maximum obtained coverage. This is related to a better exploitation of the search space by GA.

In order to highlight the reduction of the test cases needed to achieve the maximum coverage, we have applied Equation (14). We can state that the oracle cost of the test suite generated by the three studied mono-objective algorithms can be reduced by our approach; only 19.32% of the test cases are needed in comparison with the computed upper bound. This percentage of test cases needed to achieve a concrete coverage is larger than the one obtained with the MM approach (15.12%).

Now, let us analyze the best value of coverage obtained with the three algorithms. In Table X, we show the average of maximum coverage of the three algorithms. As is known, achieving a total coverage is a great challenge for the search; for this reason, we consider that an algorithm must focus on obtaining a high value of coverage. In this sense, the GA and ES obtain very good values of coverage, both above 90% in all the cases. However, the average coverage obtained by the GA is always

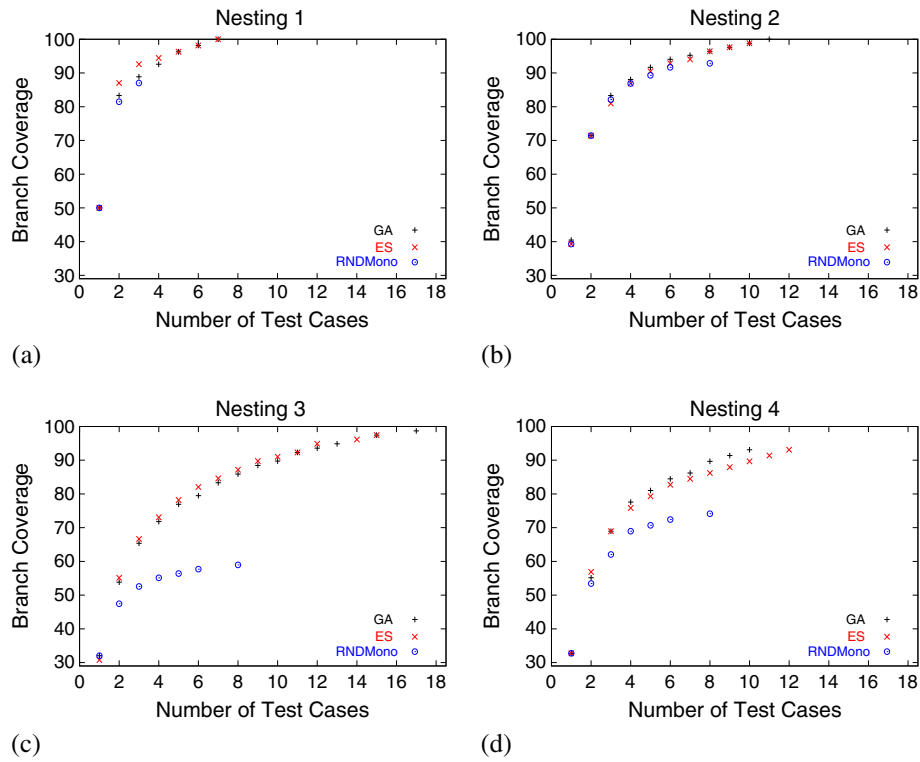

Figure 8. Fifty percent attainment surfaces: coverage against the number of test cases. GA, genetic algorithm; ES, evolutionary strategy.

the best. This advantage of the GA increases in programs with higher nesting degree where high values of coverage are very difficult to obtain. We performed a statistical test (Table XI); however, although the GA obtains the best results, significant differences only exist in 23 programs between GA and ES. Thus, it seems that GA is the best in obtaining a high value of coverage, specifically in more complex programs.

### 7.3. MM versus mM approaches

In the previous sections, we have performed a comparison between the algorithms used in each of the approaches. In the mM approach, GA seems to be the best algorithm in most of the programs, and ES is the best algorithm in programs with the lowest nesting degree. Regarding the MM approach, MOCeII was the best in most of the programs, except in a few programs with high nesting degree. In this section, we compare all the algorithms together, with the aim of showing what technique is the overall best.

First of all, we analyze the HV indicator. In Table XII, we summarize the number of times where the HV value of an algorithm is better than that of the rest. The results show that, on the one hand, MOCeII is better for programs with low nesting degree (1 and 2). On the other hand, the GA is better for programs with high nesting degree (3 and 4). The performance of the MOCeII algorithm and of the GA is similar, but they work better in different kind of programs. This performance depends on the maximum nesting degree of the program. NSGA-II and the ES have similar performances among them; however, they are clearly worse than MOCeII and GA. Finally, the performance of SPEA2, PAES, RNDMono, and RNDMulti is clearly worse than that of the previous algorithms (MOCeII, GA, NSGA-II, and ES).

In order to clarify the obtained results, we have performed the statistical test to check if there exist significant differences among the HV values. In Table XIII, we can see that there is just a small significant difference among the main EAs. However, there are significant differences between the worse algorithms (the two random algorithms and PAES) and the rest. In Table XIII, we show that the HV values of GA are significantly better than that of the others, except that of ES. The same observation can be made on ES: it is significantly better than the others (except the GA). NSGA-II, MOCeII, and SPEA2 are worse than GA and ES, but for most of the programs, their HV values are better than that of the random algorithms. In some programs, there are significant differences between MOCeII and PAES and also between NSGA-II and PAES.

Table XII. Programs in which the median hypervolume of one algorithm is better than that of the others.

MOCeII, Multi-Objective Cellular Genetic Algorithm; NSGA-II, Nondominated Sorting Genetic Algorithm II; SPEA2, Strength Pareto Evolutionary Algorithm 2; PAES, Pareto Archived Evolution Strategy; GA, genetic algorithm; ES, evolutionary strategy.

In summary, the mM approach using the EAs (GA and ES) always achieves good HV values. We observed that MOCeII, NSGA-II, and SPEA2 are significantly better than PAES in more programs than GA and ES. In this case, the HV values of the mM approach are worse; concretely, they do not obtain a good diversity because the Pareto fronts are computed from a finite subset of test cases obtained by the mono-objective algorithms. However, the MM approach takes better care of the convergence as well as the diversity of the Pareto front; consequently, their HV values will be better. For the purpose of illustrating this issue, we plot in Figure 9 the 50% attainment surfaces for the best algorithms: MOCeII, NSGA-II, GA, and ES.

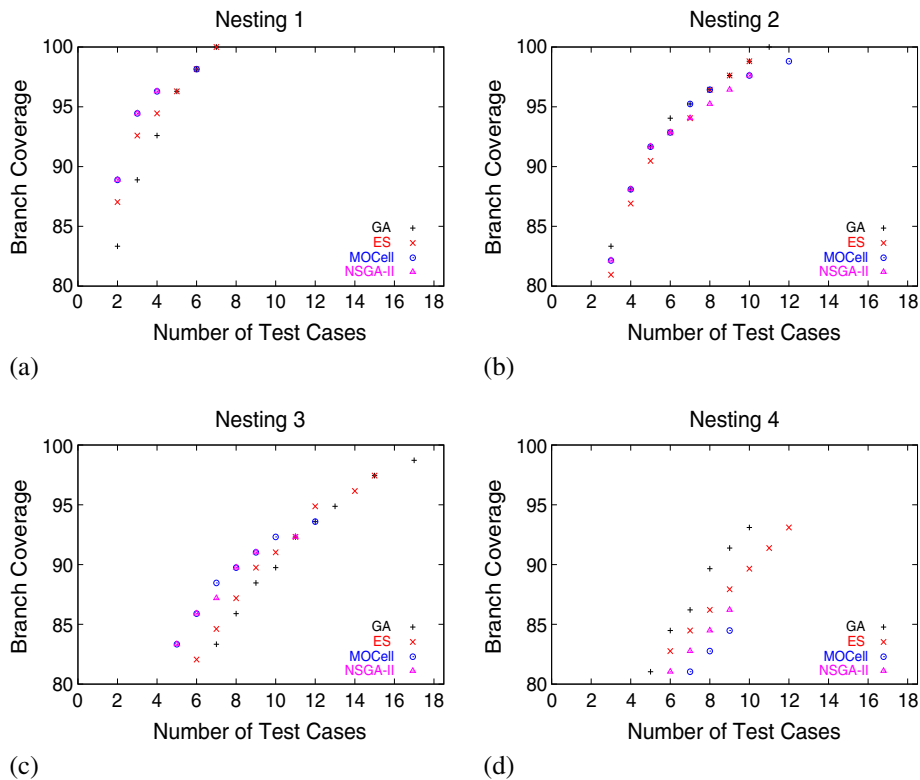

Figure 9. 50% attainment surfaces: coverage against the number of test cases of all the algorithms. GA, genetic algorithm; ES, evolutionary strategy; MOCeII, Multi-Objective Cellular Genetic Algorithm; NSGA-II, Nondominated Sorting Genetic Algorithm II.

We focus on the most interesting area (80%–100% coverage) of the plots in Figure 9. In all the pictures, we appreciate that MOCeII and NSGA-II have the best fronts in the programs with nesting degrees 1, 2, and 3, although they do not obtain the best coverage in all cases. In addition, we must highlight that the fronts of GA and ES are dominated in this case. We find the exception when the program has nesting degree 4, where the GA is the best algorithm because its solutions dominate the others. The second in performance is the ES, which close to the values of GA. The other algorithms only find solutions with middle values of coverage and more test cases.

At this stage of the study, we know that the MM approach provides more diversity in the solutions. In other words, it is able to find a test suite with few test cases, but the obtained coverage is not very large. On the other hand, the mM approach is able to better explore the search space to find solutions with a high coverage, but it needs more test cases than the MM approach. The MM approach obtains worse average coverage because nested statements pose a great challenge for the search. We think that the main reason for this fact is that the multi-objective algorithms deal with all the branches at the same time and less information is obtained to guide the search.

As we previously said, automatically generating a test suite that covers the entire program is a hard task. When a program has high nesting degree and the decisions are very complex, the task of covering all the program code requires much effort. It is important for an algorithm to be able to find test cases to cover all the program's branches. We show in Table XIV a comparison of the average maximum coverage obtained for all the algorithms and all the programs. It is clear that the best algorithm, if coverage is the main objective, is GA. It obtains the best results in all the groups of programs with different nesting degree and therefore in the complete benchmark. The performance of ES is also very good because it is always better than the multi-objective algorithms. If the nesting degree increases, the distance between the average coverage of GA and ES increases. In other words, the ES has a similar performance to GA in low complexity programs, and it is worse than GA in complex programs. On the other hand, MOCeII and NSGA-II have almost the same coverage; it only varies at the decimal level. SPEA2 is only 1% worse in the entire benchmark with respect to MOCeII and NSGA-II. The results of the PAES algorithm are in the middle between the best (GA) and the worst (RNDMulti).

In order to provide a high level of confidence to these results, we have performed statistical tests. The results are shown in Table XV. There are some differences among the best algorithms; we can take as a reference the column of the GA values. This column can be seen as a ranking of the performance of all algorithms. The GA has the best results and outperforms the rest of the algorithms in average maximum coverage. ES is the second in average maximum coverage (with significant difference), next MOCeII, then NSGA-II, and finally SPEA2. As we expected, the statistical test does not show significant differences among MOCeII, NSGA-II, and SPEA2, but if the number of independent runs were higher, the significant differences would appear. We should highlight that PAES is not much better than the random algorithms. The differences in average maximum coverage shown in Table XIV have been confirmed by the statistical tests: using a GA is the best way to obtain high branch coverage.

Finally, we have considered in this experimental study the obtained HV, the significant differences, the attainment surfaces and the average maximum coverage achieved with all the algorithms,

and the benchmark of 800 programs. After analyzing the experimental results, we can state that the GA is the best mono-objective algorithm and MOCcell is the best multi-objective algorithm. We expected that an algorithm such as MOCcell would be clearly superior to all the mono-objective ones in the MOTDGP, but, in fact, this is not true. In addition, the GA is clearly superior in HV and in average maximum coverage when we are testing programs with high nesting degree. This fact is due to a better exploration of the search space because this algorithm is able to find solutions for the most complex branches that appear in the code. It uses most of its evaluations in most complex branches, in order to achieve a high coverage. However, the multi-objective algorithms deal with all the branches at the same time; for this reason, they do not use most of its evaluations trying to cover a concrete complex branch. This fact suggests that if there exist hard requirements of coverage and if the program has high nesting degree, we should use the GA as search engine of an automatic test data generator. Nevertheless, a second phase of multi-objective test case selection must be performed in order to minimize the oracle cost. On the other hand, if there are cost requirements, we highly recommend the use of MOCcell algorithm.

#### 7.4. Real programs

In this section, we analyze the two proposed approaches by using some real programs. We study 13 real programs extracted from the literature and with characteristics similar to the artificial programs used in the previous sections. The reader must take into account that the number of programs used in the previous sections gives us the chance to average among 800 programs and extract statistically more reliable results. Although in this section we only analyze the performance of the proposed approaches and algorithms over 13 programs, most of the conclusions are similar to the ones we have obtained with the synthetic programs.

Once again, we start the analysis with the HV indicator. In Table XVI, we summarize the number of programs where the HV value of an algorithm is better than that of the others. There are six programs where an algorithm is the best. The GA outperforms the other algorithms in four programs,

Table XVI. Real programs in which the median hypervolume of one algorithm is better than that of the others and average maximum coverage of all the real programs.

	MOCcell	NSGA-II	SPEA2	PAES	RNDMulti	GA	ES	RNDMono
Hypervolume better	1	0	0	0	0	<b>4</b>	2	0
Average maximum coverage	87.26	91.35	89.31	72.43	76.84	<b>94.14</b>	92.27	80.09

then the ES in two programs, and the MOCcell in only one program. In the previous results, these three algorithms also obtain the best results.

In order to validate these previous results, we compared the HV values of all the real programs by using the multiple comparison statistical test. In Table XVII, we show the existing differences among the HV value of all the algorithms. We can observe that the GA outperforms the other algorithms in at least one program. Then, there is a group of algorithms composed of ES, NSGA-II, SPEA2, MOCcell, and RNDMono that are better than PAES and RNDMulti, but the statistical test does not show significant differences among them. In addition, we can analyze the PAES column in order to obtain an informal ranking of algorithms according to the HV indicator.

Let us analyze the average maximum coverage obtained by the algorithms when applied to real programs (Table XVI). We must highlight that the GA and the ES are the best algorithms in coverage for the real programs. In contrast, the PAES has obtained the worst results, even worse than the random algorithms. In Table XVIII, we show the results of a statistical test to compare the maximum coverage. Once again, the GA is the best algorithm: it obtains significant differences in 40 comparisons. NSGA-II obtains significant differences in 30 comparisons. Next, SPEA2 and ES are better than the others in 18 comparisons. Most of these significant differences are obtained in comparison with PAES or the random algorithms. Only a few differences exist among the best algorithms. Nevertheless, the performance of GA seems to be better than that of the other algorithms. On the other hand, the PAES has obtained the worst results. We think that these results are due to the absence of a crossover operator and the nature of the selected programs (i.e., number of equalities in the code).

Finally, with the aim of showing an example of the computed fronts for the instances, we selected the *line* program. This program can represent the typical behavior of the different algorithms in this kind of instance. In Figure 10, the 50% attainment surfaces of the best algorithms are depicted. In this instance, GA dominates the others and has a good performance because it always reaches the

best coverage with the same test data. MOCeII is the only algorithm able to obtain all the points of the front. This is a desirable property for a solution of a multi-objective problem.

## 8. CONCLUSIONS

In this paper, we have studied the multi-objective TDGP with the aim of analyzing the performance of a direct multi-objective approach (MM) versus the application of mono-objective algorithms followed by a test case selection (mM). Previous results in the literature have only focused on the coverage of a program, although the oracle cost is a significant cost that has been ignored in most of the previous studies. For this reason, in this work, we have dealt with the coverage and the oracle cost as equally important targets.

Our study has been performed on 800 synthetic programs. We designed a program generator able to produce programs ensuring a 100% of branch coverage. This kind of programs is very useful because all the branches are reachable, and we can compare the algorithms in a fair way using coverage. In addition, we have also analyzed the two proposed approaches with a benchmark of 13 real and popular programs in the literature. We have evaluated four state-of-the-art multi-objective optimization algorithms, MOCeII, NSGA-II, SPEA2, and PAES; two mono-objective algorithms GA and ES; and two random algorithms as merely a ‘sanity check’. This comparison has been carried out on the basis of three quality indicators: the HV, the 50% EASs, and the average maximum coverage obtained by those algorithms. We can see a final ranking of algorithms in Table XIX.

In terms of convergence towards the optimal Pareto front, GA and MOCeII have been the best solvers in our comparison. On the one hand, MOCeII has obtained the best fronts in programs with nesting degrees 1 and 2, values commonly found in practice. On the other hand, the GA is the best algorithm for facing programs with high nesting degree, and it is the algorithm that is significantly better in most of the programs attending to the HV indicator and to the average maximum coverage. This fact indicates that GA is the best alternative if the tested program has a high nesting degree or if we need a high coverage. But, if we have time restrictions, we highly recommend the use of MOCeII as a search engine for an automatic test data generator. Although the multi-objective approach is working very well in most of the programs, we realized that dealing with only one branch at the same time (mono-objective approach) can be more effective when the program under test has high nesting degree. In addition, we must highlight that both approaches (MM and mM) are quite good at reducing the number of test cases needed to obtain a given coverage. The oracle cost can be greatly reduced because the mM approach only needs 19.32% of the upper bound of test cases needed for obtaining the maximum value of coverage, and the MM approach, only needing a 15.12% of the test cases, is even better. This improvement justifies the use of our approaches to deal with the MOTDGP.

Table XIX. Ranking of algorithms according to maximum coverage and hypervolume grouped by nesting degree.

Rank	Coverage					Hypervolume				
	ND 1	ND 2	ND 3	ND 4	All	ND 1	ND 2	ND 3	ND 4	All

ND, nesting degree; MOCeII, Multi-Objective Cellular Genetic Algorithm; NSGA-II, Nondominated Sorting Genetic Algorithm II; SPEA2, Strength Pareto Evolutionary Algorithm 2; PAES, Pareto Archived Evolution Strategy; ES, evolutionary strategy; GA, genetic algorithm.

Future work will verify these findings with still larger real-world software. Also, we should find a set of representative software programs because research community has not established a standard benchmark of well-known programs. We also want to advance in designing better evolutionary operators in order to deal with programs with high nesting degree that could pose a challenge for our algorithms, especially for the multi-objective ones.
