ABSTRACT

A land-surface scheme that may be run with or without a tiled representation of subgrid heterogeneity and includes an implicit atmospheric coupling scheme is described. Simulated average surface air temperatures and diurnal temperature ranges in a GCM using this surface model are compared with climatology. Surface tiling is not found to give a clear improvement in the simulated climate but offers more flexibility in the representation of heterogeneous land-surface processes. Using the same meteorological forcing in off-line simulations using versions of the surface model with and without tiling, the tiled model gives slightly lower winter temperatures at high latitudes and higher summer temperatures at mid-latitudes. When the surface model is coupled to a GCM, reduced evaporation in the tiled version leads to changes in cloud cover and radiation at the surface that enhance these differences.

1. Introduction

Land-surface models, which calculate exchanges of heat, moisture, momentum and CO_2 between the surface and the atmosphere, are important elements of the General Circulation Models (GCMs) used in climate modelling and numerical weather prediction. With resolution constrained by computational expense, GCM gridboxes cover large areas; a single land gridbox will almost invariably contain surfaces with widely varying characteristics, possibly leading to large subgrid variations in surface temperatures and fluxes. Most current GCMs assume that land surface properties such as albedo, roughness length and moisture conductance can be characterized by effective parameters; the Met Office Surface Exchange Scheme (MOSES; Cox et al. 1999), recently developed for use in the Met Office GCM, is in this category. Gridbox-average fluxes of sensible heat, moisture and momentum are calculated from gridbox-average vertical gradients of temperature, humidity and windspeed using parametrizations similar to those used to relate local fluxes to local gradients over homogeneous surfaces. Local fluxes, however, depend non-linearly on local gradients, and average fluxes may not be simply related to average gradients. It has been suggested that the problem of calculating gridbox-average fluxes can be addressed by gathering distinct surface types within a gridbox into homogeneous ‘tiles’ in a ‘mosaic’ (Avisar and Pielke 1989, Koster and Suarez 1992a). Surface temperatures and fluxes are calculated using parameters characteristic of each surface type; average fluxes are then found by summing the fluxes from the tiles, weighted by the fractional areas that they cover. The performance of tile models has been investigated in many off-line studies (Koster and Suarez 1992b; Desborough 1999; van den Hurk et al. 2000; Molod and Salmun 2003) and boundary-layer or mesoscale atmospheric models (Avisar and Pielke 1989; Claussen 1991; Klink 1995; Blyth 1995; Mölders et al. 1996; Essery 1997). Although tile models have been implemented in several GCMs (Verseghy et al. 1993; Koster and Suarez 1996; Desborough et al. 2001), their influence on simulated climates has not yet been widely reported. In this paper, we discuss a development of MOSES, designated MOSES 2, that includes a tile model of surface heterogeneity and a new numerical scheme for coupling between the land surface and the atmosphere. MOSES 2 is described and contrasted with the original MOSES in Section 2, and results of climate simulations are presented in Section 3.

To assess the impact of surface tiling, MOSES 2 is run in both tiled and aggregated modes. In the aggregate model, resistances for different surface types are added in parallel before being used in single surface energy and moisture budgets for each gridbox. The tiled and aggregated versions of MOSES 2 are thus equivalent to the ‘mosaic’ and ‘mixture’ strategies of Koster and Suarez (1992b), who derived analytical and numerical solutions for these modelling strategies in a restricted range of circumstances. They concluded that an aggregate model produces more evaporation and lower average surface temperatures, but the dif-

ferences are small in most conditions. Running global off-line simulations we find similar results, except that the aggregate model can produce *higher* surface temperatures than the tile model for gridboxes with large subgrid contrasts in albedo, a situation not explored by Koster and Suarez (1992b). Desborough (1999) found monthly evaporation to be largely insensitive to the introduction of separate energy balances for vegetated and non-vegetated fractions of the surface in off-line simulations. Desborough et al. (2001), however, found a much larger sensitivity when the same surface model was coupled to a GCM; they attributed this to differences in calibration between the off-line and coupled simulations. We find larger differences between the tile and aggregate models when coupled to the GCM even when the same surface parameters are used in off-line and coupled simulations, and we show this to be due to feedbacks through the atmosphere.

2. Model description

a. Surface parameters

In MOSES, a set of surface parameters was assigned to each of the 23 classes in the Wilson and Henderson-Sellers (1985) $1^\circ \times 1^\circ$ land-cover archive and aggregated at the GCM resolution of 2.5° latitude by 3.75° longitude. MOSES 2, in contrast, was designed to complement the TRIFFID vegetation dynamics model (Cox et al. 2000; Cox 2001) and so represents each gridbox as a mixture of the five TRIFFID vegetation types (broadleaf trees, needleleaf trees, temperate C_3 grass, tropical C_4 grass and shrubs) and four non-vegetated surface types (urban, inland water, soil and ice). Vegetation distributions may be obtained from observations or modelled by TRIFFID; this study uses a University of Maryland dataset with 14 land-cover classes at 1 km resolution derived from AVHRR data (Hansen et al. 2000). Mappings between these classes and assumed fractions of the MOSES 2 surface types are given in Table 1; grasses were partitioned into C_3 and C_4 types using a function of latitude.

A leaf area index L for each vegetation tile is read from maps based on those used by SiB2 (Sellers et al. 1996a), again derived from AVHRR data. Seasonal variations in L for deciduous trees are calculated by a leaf phenology model (Cox 2001). Vegetation tiles are assigned a canopy height h , a snow-free roughness length z_o and a canopy water capacity C_M parametrized as functions of L (Essery et al. 2001). Evaporation from transpiring vegetation is controlled by a canopy conductance, g_c , calculated by a photosynthesis model (Cox et al. 1998; Cox 2001) depending on temperature, humidity deficit, incident radiation, soil moisture availability and vegetation type. The ability of vegetation to access moisture at each level in the soil is determined by a root density distribution; in place of the uniform distribution in MOSES, root density is assumed to follow an exponential distribution with depth (Thornley and Johnson 1990).

For each non-vegetated tile, a snow-free albedo and a roughness length are

specified; albedos for bare soil depend on the soil colour as specified by Wilson and Henderson-Sellers (1985). Bare-soil evaporation is drawn from the surface soil layer only. Lakes and urban surfaces cover relatively small fractions of gridboxes at GCM resolution and are very simply represented: lake tiles are smooth and wet; urban tiles are rough and have a small surface water capacity. More sophisticated representations are being considered for higher-resolution applications.

b. Surface net radiation

MOSES used a single albedo for each gridbox and for all spectral bands. Albedos for gridboxes with snowcover were interpolated between specified snow-free and deep-snow values, with snow aging represented by a simple linear function of surface temperature (Cox et al. 1999). In MOSES 2, separate direct-beam and diffuse albedos in visible and near-infrared bands are used for each tile. Vegetation albedos are calculated using the Sellers (1985) canopy radiative transfer model with spherical leaf distributions, and snow albedos are calculated using the Marshall (1989) parametrization of the Wiscombe and Warren (1980) spectral albedo model, in which the albedo depends on a prognostic snow grain size that increases with the age of the snow surface. Snow-free tile albedos and snow albedos are weighted by a fraction

$$f_s = \frac{d}{d + 10z_o} \quad (1)$$

to give an albedo $\alpha = f_s\alpha_s + (1 - f_s)\alpha_o$ for a tile with snow depth d , deep-snow albedo α_s and snow-free albedo α_o . A forest tile with snowcover is thus given a lower albedo than a smoother tile with the same depth of snow but smaller z_o (Pomeroy and Dion 1996, Viterbo and Betts 1999, Betts 2000).

For downward shortwave and longwave radiation fluxes SW_\downarrow and LW_\downarrow , the net radiation absorbed by a tile with surface temperature T_* is

$$R_N = \sum_i (1 - \alpha_i)SW_{\downarrow i} + LW_\downarrow - \sigma T_*^4, \quad (2)$$

where the summation is over shortwave bands and σ is the Stefan-Boltzmann constant. All surfaces are assumed to have unit emissivity. Linearizing about surface soil layer temperature T_s gives

$$R_N \approx R_s + 4\sigma T_s^3(T_s - T_*), \quad (3)$$

with

$$R_s = \sum_i (1 - \alpha_i)SW_{\downarrow i} + LW_\downarrow - \sigma T_s^4. \quad (4)$$

c. Surface heat and moisture fluxes

Given temperature T_1 and specific humidity q_1 at reference height z_1 in the atmosphere, expressions for surface fluxes of sensible heat and moisture over each tile are derived from the bulk aerodynamic formulae

$$H = c_p \frac{\rho}{r_a} \left[T_* - T_1 - \frac{gz_1}{c_p} \right] \quad (5)$$

and

$$E = \psi \frac{\rho}{r_a} [q_{\text{sat}}(T_*, p_*) - q_1] \quad (6)$$

respectively, where ρ and c_p are the density and heat capacity of air, g is the gravitational acceleration, r_a is an aerodynamic resistance, T_* is the tile surface temperature and $q_{\text{sat}}(T_*, p_*)$ is the saturation humidity at temperature T_* and surface pressure p_* . The factor ψ in Eq. (10) is set to 1 for saturated surfaces (snow, ice and water), giving evaporation at the potential rate, but otherwise is

$$\psi = f_a + (1 - f_a) \frac{g_c}{g_c + r_a^{-1}}, \quad (7)$$

assuming a fraction $f_a = C/C_M$ of the surface to be saturated for a tile with canopy moisture C and capacity C_M . The aerodynamic resistance is calculated as a function of surface roughness, windspeed and atmospheric stability through a Richardson number formulation (Louis 1979).

Although surface temperatures and parameters differ between tiles within a gridbox, T_1 , q_1 and the windspeed at height z_1 are assumed to be homogeneous. In principle, z_1 should be set to the ‘blending height’ (Mason 1988; Claussen 1991; Wood and Mason 1991); this is an approximate height scale high enough above the surface that the temperature, humidity and windspeed are nearly homogeneous but low enough that their profiles are nearly in equilibrium with the local surface. Blending heights depend on surface roughness, atmospheric stability and heterogeneity length scales; as an example, values calculated from the Institute of Terrestrial Ecology 25 m landuse map of the UK range between 5 and 30 m (Phil Hopwood 2001, personal communication). At present, MOSES 2 simply sets z_1 to the height of the lowest atmospheric level in the GCM (typically around 25 m above the surface), but the high resolution of the AVHRR land cover data will allow information on subgrid heterogeneity length scales to be used in future. Extensions to the tile model concept for blending heights lying below and above the lowest model level are discussed by Blyth (1995) and Arola (1999).

Precipitation is applied uniformly to the tiles within a gridbox, although an assumed subgrid distribution of precipitation could be used. The method used for partitioning precipitation into interception by vegetation canopies, throughfall, runoff and infiltration is unchanged from MOSES (Dolman and Gregory 1992) but is applied separately on each tile. MOSES 2 uses the same model for vertical transfers of heat and moisture and phase changes in the soil as MOSES (Cox et al.

1999) but replaces the explicit numerical solution with an implicit scheme (Essery et al. 2001); this improves the stability of the model and allows greater flexibility in the choice of model levels. By default, four soil layers with thicknesses of 0.1, 0.25, 0.65 and 2 m are used. The heat flux from the surface into the top soil layer is parametrized as

$$G = \frac{2\lambda}{\Delta z_s}(T_* - T_s), \quad (8)$$

where Δz_s is the thickness of the layer and the thermal conductivity λ depends on soil type, moisture content and snow depth (Cox et al. 1999). The temperature and moisture content of each subsurface layer are assumed to be homogeneous across a gridbox, but a representation of subgrid hydrology using TOPMODEL (Beven 1997) is being considered for future use (Nic Gedney 2001, personal communication).

d. Surface energy balance

Surface temperature T_* is taken to be the skin temperature of an infinitesimal surface layer. The energy balance of this layer is

$$R_N - H - LE - G - L_f S_M = 0, \quad (9)$$

where L is the latent heat of condensation (L_c) for an unfrozen surface or of sublimation (L_s) for snow or ice, L_f is the latent heat of fusion and S_M is the rate of surface snowmelt. R_N and G are defined to be positive when directed downward; H and E are positive upward. The optional inclusion of a canopy heat capacity for vegetated tiles is discussed by Essery et al. (2001).

Substituting Eqs (3) and (8) in Eq. (9), the surface temperature is diagnosed as

$$T_* = T_s + \frac{1}{A_*}(R_s - H - LE - L_f S_M), \quad (10)$$

with

$$A_* = \frac{2\lambda}{\Delta z_s} + 4\sigma T_s^3. \quad (11)$$

Linearizing q_{sat} about T_1 and using Eq. (10) to eliminate T_* from Eqs (5) and (6) then gives

$$H = c_p \frac{\rho}{r_a} \left[\frac{\tilde{R} - L_f S_M - L\psi(\rho/r_a)\Delta q_1}{(c_p + LD\psi)\rho/r_a + A_*} \right] \quad (12)$$

and

$$E = \psi \frac{\rho}{r_a} \left[\frac{D(\tilde{R} - L_f S_M) + (c_p \rho/r_a + A_*)\Delta q_1}{(c_p + LD\psi)\rho/r_a + A_*} \right] \quad (13)$$

where

$$D = \left. \frac{dq_{\text{sat}}}{dT} \right|_{T=T_1}, \quad (14)$$

$$\Delta q_1 = q_{\text{sat}}(T_1, p_*) - q_1 + D \frac{gz_1}{c_p} \quad (15)$$

and

$$\tilde{R} = R_s - A_* \left(T_1 - T_S + \frac{gz_1}{c_p} \right). \quad (16)$$

For tiles with snowcover, setting $S_M = 0$ in Eqs (10), (12) and (13) gives a first estimate for the surface temperature. Snow is melted if this exceeds the melting point T_m . The melt rate is calculated from the heat flux required to set $T_* = T_m$ or exhaust the available snow, whichever is smaller. Similar adjustments are made if the initial evaporation estimate exceeds the canopy or soil moisture stores for snow-free tiles.

e. Boundary-layer fluxes and increments

The GCM's boundary-layer scheme calculates the increment in the temperature of the lowest atmospheric model layer over a timestep δt as

$$\delta T_1 = \frac{\delta t}{c_p z_1} (\bar{H} - H_1), \quad (17)$$

where H_1 is the heat flux at the top of the layer and

$$\bar{H} = \sum_j \nu_j H_j \quad (18)$$

is the surface sensible heat flux averaged over tiles with fractions ν_j and local fluxes H_j . Similar equations give temperature and humidity increments for all model levels in the boundary layer. An implicit numerical scheme is used in which fluxes are calculated from weighted timestep-average temperatures

$$T = T^{(n)} + \gamma \delta T \quad (19)$$

and humidities, where $T^{(n)}$ is the temperature of a layer at the beginning of the timestep and γ is set to 2 (Girard and Delage 1990). Substitution in Eq. (12) gives an equation of the form

$$\bar{H} = \sum_j \nu_j H_j^{(n)} + A_1 \delta T_1 + B_1 \delta q_1. \quad (20)$$

$H_j^{(n)}$ is the 'explicit' flux calculated using $T_1^{(n)}$ and $q_1^{(n)}$. The complete set of equations for boundary-layer temperature and humidity increments forms a tridiagonal system, solved by Gaussian elimination; details are given by Essery et al. (2001).

In coupling MOSES 2 to the GCM, a split boundary-layer scheme has been introduced following the recommendations of Polcher et al. (1998). A downward sweep through the atmospheric matrix gives expressions for δT_1 and δq_1 in terms

of the gridbox-average fluxes \overline{H} and \overline{E} . These are combined with Eq. (20) for \overline{H} and the equivalent expression for \overline{E} to obtain a set of equations that can be solved for δT_1 , δq_1 , \overline{H} and \overline{E} . The implicit values of the fluxes and surface temperatures on each tile are then diagnosed, and back-substitution in the matrix gives increments at all boundary-layer levels.

3. Results

a. Comparisons with climatology

An initial test of MOSES 2 coupled to the HadAM3 GCM (Pope et al. 2000) gave some large errors; summer temperatures at northern midlatitudes were too high, and July and August had excessive diurnal temperature ranges in Southern Europe. Comparisons with fields of downward shortwave radiation derived for the International Satellite Land Surface Climatology Project (ISLSCP; Sellers et al. 1996b) showed that the spatial and temporal distributions of these temperature errors were closely associated with excess solar radiation at the surface, a common feature of GCMs (Wild et al. 1995; Wild 2000). Excessive radiative forcing in the surface energy balance is inconvenient for our focus here of assessing the model’s near-surface temperature climatology, so the GCM’s cloud cover was artificially increased by using random overlapping of clouds in different model layers; the standard scheme used in the initial simulation maximally overlaps clouds in contiguous layers. Considerable effort has been put into improving the representations of cloud and aerosol radiative properties for future versions of the GCM (Cusack et al. 1998, 1999; Webb et al. 2001), and results from recent modelling and observational studies (Barker et al. 1999; Hogan and Illingworth 2000) will allow the development of improved representations of vertical cloud distributions. Although less physical, a simple increase in cloud cover still improved the simulation of surface shortwave radiation. Not all of the impacts were beneficial; a reduction in tropical convective precipitation, for example, worsened the agreement with observations. The reduction in shortwave radiation did, however, improve the simulation of summer temperatures over North America and Europe, and decreased the excessive European temperature range.

The tiled version of MOSES 2 and the modified GCM were run for 15 years with sea-surface temperatures and sea-ice extents prescribed from climatology. The first 5 years of the simulation were discarded to allow for spin-up of deep soil temperatures and moisture contents. Average surface air temperatures for DJF and JJA seasons over the last 10 years are compared with the Climate Research Unit 1961-1990 climatology (New et al. 1999) in Fig. 1; positive values indicate areas where the model is warmer than the climatology. Differences between the model and climatology are smaller in summer than in winter, with the simulation generally showing a cold bias. Similar patterns in simulations using MOSES were related to errors in low-level advection by Pope et al. (2000), but the cold biases

are smaller than in earlier versions of the GCM that did not include latent heat release by freezing of soil moisture (Cox et al. 1999). It should be noted that the station network used in deriving the climatology is very sparse in some areas, such as northern high latitudes and the Himalayan plateau, where the model and the climatology differ. Covey et al. (2002) have estimated the uncertainty in observed climatologies by comparing different data sets.

Annual cycles of average temperature and diurnal temperature range over land within the boxes marked on Fig. 1 are shown in Figs 2 and 3; the climatology is shown by solid lines and GCM averages are shown by circles. The largest discrepancies in simulated temperature ranges are underestimates over North America and an excessive seasonal variation for the Sahel. Average minimum temperatures over Canada and the USA (not shown) appear to be well simulated, but underestimation of daytime maximum temperatures during winter leads to the underestimates in both temperature range and average temperature. Taylor and Clark (2001) found that Sahel temperature and precipitation simulations could be improved by using a better characterization of surface parameters in that region.

b. Characterization of subgrid heterogeneity

Surface temperatures and fluxes differ between tiles within a gridbox because of differences in their albedos, roughness lengths and moisture conductances. Particularly large differences can be expected between forests and bare ground; the greater roughness of forests gives a closer coupling to the air temperature, trees can access deep soil moisture when bare-soil evaporation is limited by moisture deficits near the surface, and forests retain low albedos when snow covered. Figure 4 shows differences between forest and bare-ground surface temperatures within gridboxes, averaged over the month of March from one year of the simulation. Bare ground is generally warmer than forests at low latitudes with high surface temperatures but is colder in snow-covered regions, the temperature difference changing sign close to the 0°C isotherm. Albedo contrasts have less influence at high latitudes with low insolation, but temperature differences are maintained because bare ground also receives less sensible heat from the atmosphere to offset radiative cooling under stable conditions.

The subgrid variability of surface temperatures can be characterized by the standard deviation

$$\sigma_T = \left[\sum_j \nu_j T_{*j}^2 - \left(\sum_j \nu_j T_{*j} \right)^2 \right]^{1/2}, \quad (21)$$

which is plotted in Fig. 5(a) for July. Areas of high temperature variability reflecting large evaporation differences between surface types with different root depths in the western US, southern Africa and continental midlatitudes over Asia

correspond with fractional surface soil layer moisture deficits shown in Fig. 5(b). Although the Sahara also has a large soil moisture deficit, the subgrid temperature variability is small on account of the lack of vegetation. In March, Fig. 6 shows that dry-season soil moisture deficits give increased temperature variability for the Sahel, India and Thailand. Snow-covered land, delimited by the 10 kg m^{-2} contour line on Fig. 6 (a), also has large temperature contrasts between tiles because of albedo contrasts between tall vegetation, short vegetation and bare ground with snow cover.

Spatial variances of temperatures and fluxes are related through Eq. (10). Using Eq. (4) for R_s and neglecting snowmelt, taking the variance of Eq. (10) gives

$$A_*^2 \sigma_T^2 = SW_{\downarrow}^2 \sigma_{\alpha}^2 + \sigma_H^2 + \sigma_{LE}^2 - 2SW_{\downarrow} [\text{cov}(\alpha, H) + \text{cov}(\alpha, LE)] - 2\text{cov}(H, LE), \quad (22)$$

where α is the effective tile albedo and cov denotes the covariance of two fields. Contrasts in the turbulent fluxes dominate for snow-free land, but the radiative term becomes important for snow-covered gridboxes when SW_{\downarrow} is large.

c. Influence of subgrid heterogeneity

As described in Section 2, MOSES 2 differs from MOSES in a number of ways other than the surface tiling, so a gridbox-aggregate version of MOSES 2 was developed to isolate the influence of tiling. In this version, surface parameters are still calculated separately for each surface type within a gridbox but are aggregated as in MOSES before being used in calculating surface fluxes. Surface albedos, moisture capacities and conductances are simply area-averaged. Roughness lengths are aggregated at the reference height using the method of Mason (1988) to give

$$z_o = z_1 \exp \left\{ - \left[\sum_j \frac{\nu_j}{\ln^2(z_1/z_{oj})} \right]^{-1/2} \right\}. \quad (23)$$

This is equivalent to adding aerodynamic resistances for neutral stability in parallel.

Many investigations of tile model behaviour have been performed off-line, i.e. using prescribed air temperatures, humidities, windspeeds, radiative fluxes and precipitation to drive the model rather than coupling it to an atmospheric model. A rough prediction of the impact of aggregation on an off-line simulation can be obtained from a simplified analysis of Eqs (5) and (12). Neglecting heat fluxes into the ground and differences in upward longwave radiation between tiles gives the tile surface temperature as

$$T_{*j} = T_1 + \frac{gz_1}{c_p} + \frac{R_{Nj} r_{aj} / \rho - L\psi_j \Delta q_1}{c_p + LD\psi_j} \quad (24)$$

in the absence of snowmelt, and taking a gridbox average gives

$$\overline{T}_* = T_1 + \frac{gz_1}{c_p} + \frac{1}{\rho} \sum_j \frac{\nu_j R_{Nj} r_{aj}}{c_p + LD\psi_j} - L\Delta q_1 \sum_j \frac{\nu_j \psi_j}{c_p + LD\psi_j}. \quad (25)$$

For snow-free, unstressed vegetation there will be little contrast in R_N and ψ between tiles, and Eq. (25) gives

$$\overline{T}_* \approx T_1 + \frac{gz_1}{c_p} + \frac{\overline{R_N}}{\rho(c_p + LD\overline{\psi})} \sum_j \nu_j r_{aj} - \frac{L\overline{\psi}\Delta q_1}{c_p + LD\overline{\psi}}, \quad (26)$$

but the surface temperature in the aggregate model is

$$T_* = T_1 + \frac{gz_1}{c_p} + \frac{\overline{R_N}}{\rho(c_p + LD\overline{\psi})} r_a^0 - \frac{L\overline{\psi}\Delta q_1}{c_p + LD\overline{\psi}}, \quad (27)$$

where r_a^0 is the aggregated aerodynamic resistance. Resistances combined in parallel give

$$r_a^0 = \left(\sum \frac{\nu_j}{r_{aj}} \right)^{-1} < \sum \nu_j r_{aj}, \quad (28)$$

and the tile model thus has a higher average surface temperature than the aggregate model when the net radiation is positive. Koster and Suarez (1992b) found this same result for the restricted case of two tiles with the same albedo. With snowcover, however, there are large differences between the albedos of tiles with tall vegetation and those without. Equation (25), with $\psi = 1$ for snow, then gives

$$\overline{T}_* = T_1 + \frac{gz_1}{c_p} + \frac{1}{\rho(c_p + LD)} \sum_j \nu_j R_{Nj} r_{aj} - \frac{L\Delta q_1}{c_p + LD} \quad (29)$$

for the tile model and

$$T_* = T_1 + \frac{gz_1}{c_p} + \frac{1}{\rho(c_p + LD)} \overline{R_N} r_a^0 - \frac{L\Delta q_1}{c_p + LD} \quad (30)$$

for the aggregate model. Since tall vegetation will have the highest net radiation and the lowest aerodynamic resistance, it is possible to have $\sum \nu_j R_{Nj} r_{aj} < \overline{R_N} r_a^0$, and the tile model can have lower temperatures than the aggregate model for partially forested gridboxes with snowcover.

The tile model structure allows the introduction of ‘diagnostic’ tiles with zero area that thus respond to but do not influence the model’s meteorology; this feature was used to run an off-line aggregate model alongside the tile model in the GCM. The conclusions above are broadly confirmed by Fig. 7, which shows DJF and JJA differences in average surface temperatures between the coupled tile model and the off-line aggregate model. The tile model is generally warmer in JJA but shows lower DJF temperatures over forested areas in high northern

latitudes. Differences between the two models are small, only exceeding 1°C for a few gridboxes.

d. Influence of atmospheric feedbacks

The discussion in Section 3c relies on the downward radiation, air temperature and humidity being the same for the tiled and aggregated models. This simplifies the analysis but may not give an accurate indication of the behaviour of a GCM with an aggregated surface model because surface fluxes calculated off-line do not influence the atmosphere. When the aggregate model is fully coupled to the atmospheric model, feedbacks through the atmosphere can modify the differences between the surface models. Figure 8 compares the tile model and the coupled aggregate model. The differences show similar patterns to Fig. 7 but are amplified (note the change in scale), and the area of winter warming in the aggregate model is more extensive.

As noted by Koster and Suarez (1992b), the aggregate model gives greater evaporation; averaging the surface conductances gives moisture fluxes which are dominated by the less stressed parts of the gridbox. Increased evaporation in the aggregate model is recycled through an increase in precipitation over land. Higher humidities and increased cloud cover at low levels in the atmosphere decrease incoming solar radiation in the summer, leading to a cooling relative to the tile model, but can decrease the loss of longwave radiation from the surface in winter and give a warming. Regional averages from the simulation using the aggregate model are shown by crosses on Figs 2 and 3. The aggregate model generally has a reduced annual temperature range at mid-latitudes, decreased diurnal temperature range, increased precipitation and decreased shortwave radiation in comparison with the tile model. Considering uncertainties in the surface radiative forcing and the climatology, it is not possible to show that the tile model gives a clear improvement in the simulated climate.

The influence of atmospheric feedbacks on the surface is illustrated in Fig. 9, which shows average annual cycles of daily maximum and minimum air temperatures, precipitation and surface energy fluxes for a gridbox centred on 108.75°W, 40°N (Colorado). Results are shown for both the tile model (solid lines) and the aggregate model (dashed lines) coupled to the atmosphere. This gridbox has the pattern of winter cooling and summer warming of the tile model relative to the aggregate model characteristic of northern midlatitudes in Fig. 8. Decreased surface evaporation and precipitation in the tile model lead to warmer and dryer conditions in the lower atmosphere with less low cloud cover during most of the year. As a result, downward shortwave fluxes are increased and longwave fluxes are decreased. This leads to an increase in summer maximum temperatures and a decrease in winter minimum temperatures which are reflected in the average temperatures. The off-line aggregate model also shows differences from the tile model in surface sensible heat and moisture fluxes (dotted lines on Fig. 9), but

air temperatures, precipitation and downward radiative fluxes are not affected.

4. Conclusions and discussion

In addition to several other enhancements over the MOSES land-surface scheme, MOSES 2 introduces a tiled representation of heterogeneous surfaces. Land gridboxes are characterized as mosaics of distinct surface types, and separate surface temperatures, sensible and latent heat fluxes, snow depths and canopy moisture loads are calculated for each surface type. Coupled to the HadAM3 GCM, MOSES 2 simulates average surface air temperatures and diurnal temperature ranges that are in reasonable agreement with climatology, once the GCM's cloud cover has been adjusted to remove a bias in the solar radiation reaching the surface. Aggregating the surface parameters within gridboxes but still using the same meteorological forcing in an off-line simulation gives slightly lower summer temperatures at mid-latitudes and higher winter temperatures at high northern latitudes. When the aggregate model is coupled to the GCM, atmospheric feedbacks involving changes in radiative fluxes reaching the surface enhance these differences.

Although the choice of an aggregated or tiled surface representation certainly influences the simulated climate, the explicit representation of surface heterogeneity by tiling does not give a clear improvement in the simulation. The implementation of tiling in a GCM, however, makes the specification of surface parameters easier, provides potentially useful information on subgrid temperature and flux variations, and allows models of processes for distinctive surface types to be introduced in a more direct way than through effective parameters for mixed surfaces. Surface types for which improved models are being developed for use in MOSES 2 include vegetation canopies (Best 1998a; Best and Hopwood 2001; Essery et al. 2001), urban surfaces (Best 1998b) and coastal gridboxes containing both land and sea (Nic Gedney 2001, personal communication). MOSES 2 has been implemented in the Met Office operational mesoscale model (Best et al. 2000), and an early version of the tile scheme is being used in a site-specific model to add local detail to numerical weather forecasts (Best et al. 1997; Hopwood 1998).

Land-surface schemes influence not only the climatology of GCMs but also their climate sensitivity (Cox et al. 1999; Crossley et al. 2000; Gedney et al. 2000). Future work will investigate the impact of MOSES 2 on climate change simulations.

Acknowledgements. This work was supported by the UK DEFRA Climate Prediction Programme under contract PECD 7/12/37. The vegetation maps were prepared by Mike Dunderdale (Department of Geomatic Engineering, University College London). John Edwards, Nic Gedney and Phil Hopwood provided useful advice. Jan Polcher and two anonymous reviewers made many useful comments on a draft of this paper.

FIGURE CAPTIONS

FIG. 1. Differences ($^{\circ}\text{C}$) between 10-year mean simulated temperatures and climatology for DJF and JJA seasons. Positive values indicate gridboxes where the simulation is warmer. Results in Figs 2 and 3 are averages over land points within the areas labelled ‘Ca’ (Canada), ‘US’ (USA), ‘Am’ (Amazon), ‘SE’ (Southern Europe), ‘Sa’ (Sahel) and ‘Au’ (Australia).

FIG. 2. Simulated surface air temperatures (circles) compared with climatology (lines) for the regions shown in Fig. 1. Crosses show results from a simulation with aggregated surface parameters.

FIG. 3. As Fig. 2, but for diurnal temperature range.

FIG. 4. Differences within gridboxes between average March surface temperatures for forests and bare ground.

FIG. 5. (a) Subgrid standard deviation of tile surface temperatures for July. (b) Fractional soil moisture deficit in the surface layer.

FIG. 6. As Fig. 5, but for March. The heavy line on (a) shows the extent of snowcover.

FIG. 7. Differences in average DJF and JJA surface temperatures between the tile model and the off-line aggregate model. Positive values indicate gridboxes where the tile model is warmer.

FIG. 8. Differences in average DJF and JJA surface temperatures between the tile model and the coupled aggregate model.

FIG. 9. Maximum and minimum daily air temperatures, precipitation and surface energy fluxes for a gridbox in Colorado. Solid lines are from the simulation with the tile model, dashed lines from the coupled aggregate model and dotted lines from the off-line aggregate model.
