Extending a CIP framework to solve MIQCP_s

EXTENDING A CIP FRAMEWORK TO SOLVE MIQCPs*

TIMO BERTHOLD[†], STEFAN HEINZ[†], AND STEFAN VIGERSKE[‡]

Abstract. This paper discusses how to build a solver for mixed integer quadratically constrained programs (MIQCPs) by extending a framework for constraint integer programming (CIP). The advantage of this approach is that we can utilize the full power of advanced MIP and CP technologies. In particular, this addresses the linear relaxation and the discrete components of the problem. For relaxation, we use an outer approximation generated by linearization of convex constraints and linear underestimation of nonconvex constraints. Further, we give an overview of the reformulation, separation, and propagation techniques that are used to handle the quadratic constraints efficiently.

We implemented these methods in the branch-cut-and-price framework SCIP. Computational experiments indicate the potential of the approach.

Key words. mixed integer quadratically constrained programming, constraint integer programming, branch-and-cut, convex relaxation, domain propagation, primal heuristic, nonconvex

AMS(MOS) subject classifications. 90C11, 90C20, 90C26, 90C27, 90C57.

1. Introduction. In recent years, substantial progress has been made in the solvability of generic *mixed integer programs (MIPs)* [2, 10]. Furthermore, it has been shown that successful MIP solving techniques can often be extended to the more general case of *mixed integer nonlinear programs (MINLPs)* [1, 4, 11]. Analogously, several authors have shown that an integrated approach of *constraint programming (CP)* and mixed integer programming (MIP) can help to solve optimization problems that were intractable with either of the two methods alone, for an overview see [15, 28].

The paradigm of *constraint integer programming (CIP)* [2, 3] combines modeling and solving techniques from the fields of constraint programming (CP), mixed integer programming, and the solution of *satisfiability problems (SAT)*. The concept of CIP aims at restricting the generality of CP modeling as little as needed to retain the full performance of all MIP solving techniques. This still allows for a wide range of optimization problems. For example, in [2], it is shown that CIP includes MIP and constraint programming over finite domains as special cases.

The goal of this paper is to show, how a framework for CIPs can be extended towards a competitive solver for *mixed integer quadratically constrained programs (MIQCPs)*, which are an important subclass of MINLPs. This allows to utilize the complete power of already existing MIP and CP technologies for handling the linear and the discrete parts of the problem.

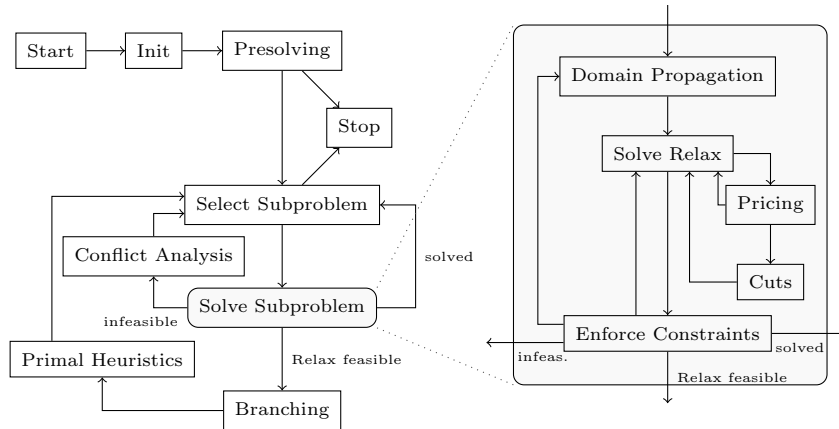

FIG. 1. Flowchart of the main solving loop of SCIP

For this purpose, we use the branch-cut-and-price framework SCIP (Solving Constraint Integer Programs). SCIP incorporates the idea of CIP and implements several state-of-the-art techniques for MIP solving. Due to its plugin-based design, it can be easily customized, e.g., by adding problem specific separation, presolving, or domain propagation algorithms.

The framework SCIP solves CIPs by a branch-and-bound algorithm. The problem is recursively split into smaller subproblems, thereby creating a branching tree and implicitly enumerating all potential solutions. At each subproblem, domain propagation is performed to exclude further values from the variables' domains, and a relaxation may be solved to achieve a local lower bound – assuming the problem is given in minimization form. The relaxation may be strengthened by adding further valid constraints, which cut off the optimum of the relaxation. In case of an infeasible subproblem, conflict analysis is performed to learn additional valid constraints. Primal heuristics are used as supplementary methods to improve the upper bound. Figure 1 illustrates the interdependencies between the main algorithmic components of SCIP. In the context of this article, the relaxation employed in SCIP is a linear program (LP).

The integration of MIQCP is a first step towards the incorporation of MINLP into the concept of constraint integer programming. The remainder of this article is organized as follows. In Section 2, we give the necessary definitions of MIQCP and CIP, in Sections 3 and 4, we show how to handle quadratic constraints inside SCIP, and in Section 5, we present computational results.

2. Problem definition. A mixed integer quadratically constrained program (MIQCP) is an optimization problem of the form

$$\begin{aligned}
 \min \quad & d^T x & (2.1) \\
 \text{s.t.} \quad & x^T A_i x + b_i^T x + c_i \leq 0 & \text{for } i = 1, \dots, m \\
 & x_k^L \leq x_k \leq x_k^U & \text{for all } k \in N \\
 & x_k \in \mathbb{Z} & \text{for all } k \in I,
 \end{aligned}$$

where $I \subseteq N := \{1, \dots, n\}$ is the index set of the integer variables, $d \in \mathbb{Q}^n$, $A_i \in \mathbb{Q}^{n \times n}$ and symmetric, $b_i \in \mathbb{Q}^n$, $c_i \in \mathbb{Q}$ for $i = 1, \dots, m$, $x^L \in \overline{\mathbb{Q}}^n$ and $x^U \in \overline{\mathbb{Q}}^n$, with $\overline{\mathbb{Q}} := \mathbb{Q} \cup \{\pm\infty\}$, are the lower and upper bounds of the variables x , respectively. Note that we do not require the matrices A_i to be positive semidefinite, hence we also allow for nonconvex quadratic constraints.

The definition of CIP, as given in [2], requires a linear objective function. This is, however, just a technical prerequisite, as a quadratic (or more general) objective $f(x)$ can be modeled by introducing an auxiliary objective variable z that is linked to the actual nonlinear objective function with a constraint $f(x) \leq z$. Thus, formulation (2.1) also covers the general case of mixed integer all quadratic problems.

In this article, we use a definition of CIP which is slightly different from the one given in [2, 3].

A constraint integer program (CIP) consists of solving

$$\begin{aligned}
 \min \quad & d^T x \\
 \text{s.t.} \quad & \mathcal{C}_i(x) = 1 & \text{for } i = 1, \dots, m \\
 & x_k \in \mathbb{Z} & \text{for all } k \in I,
 \end{aligned}$$

with a finite set of constraints $\mathcal{C}_i : \mathbb{Q}^n \rightarrow \{0, 1\}$, for $i = 1, \dots, m$, the index set $I \subseteq N$ of the integer variables, and an objective function vector $d \in \mathbb{Q}^n$.

In [2, 3], it is required that the remaining subproblem after fixing all integer variables is a linear program – in order to guarantee finite solvability. In this article, we require, however, the remaining subproblem to be a *quadratically constrained program (QCP)*. Note that, using *spatial* branch-and-bound algorithms, QCPs with finite bounds on the variables can be solved in finite time up to a given tolerance [16].

3. A constraint handler for quadratic constraints. A constraint handler defines the semantics and the algorithms to process constraints of a certain class. A single constraint handler is responsible for all the constraints belonging to its constraint class. Each constraint handler has to implement an enforcement method. In enforcement, the handler has to decide whether a given solution, e.g., the optimum of a relaxation, satisfies all of its constraints. If the solution violates one or more constraints, the handler may resolve the infeasibility by adding another constraint, performing a domain reduction, or a branching.

For speeding up the computation, a constraint handler may further implement additional features like presolving, cut separation, and domain propagation for its particular class of constraints.

In the following, we discuss the presolving, separation, propagation, and enforcement algorithms that are used in our handler for quadratic constraints.

3.1. Presolving. During the presolving phase, a set of reformulations and simplifications are tried. When SCIP fixes or aggregates variables, then the corresponding reformulations are also realized in the quadratic constraints. Bounds on the variables are tightened using the domain propagation method described in Section 3.3. If – due to reformulations – the quadratic part of a constraint vanishes, it is replaced by the corresponding linear constraint. Furthermore, the following reformulations are performed.

Binary Variables. Squares of binary variables are replaced by the binary variable itself. Further, if a constraint contains a product of a binary variable with a linear term, i.e., $x \sum_{i=1}^k a_i y_i$, where x is a binary variable, y_i are variables with finite bounds, and $a_i \in \mathbb{Q}$, $i = 1, \dots, k$, this product is replaced by a new variable z and the linear constraints

$$\begin{aligned}
 y^L x &\leq z \leq y^U x \\
 \sum_{i=1}^k a_i y_i - y^L(1-x) &\leq z \leq \sum_{i=1}^k a_i y_i - y^U(1-x), \text{ where} \\
 y^L &:= \sum_{\substack{i=1, \\ a_i > 0}}^k a_i y_i^L + \sum_{\substack{i=1, \\ a_i < 0}}^k a_i y_i^U, \text{ and} \\
 y^U &:= \sum_{\substack{i=1, \\ a_i > 0}}^k a_i y_i^U + \sum_{\substack{i=1, \\ a_i < 0}}^k a_i y_i^L.
 \end{aligned} \tag{3.1}$$

In the case that $k = 1$ and y_1 is also a binary variables, the product $x y_1$ is replaced by a new variable z and the constraint $z = x \wedge y_1$ by using SCIP's handler for AND constraints [9].

Second-Order Cone Constraints. Constraints of the form

$$\sum_{i=1}^k (\alpha_i x_i)^2 \leq (\beta y)^2, \quad y \geq 0, \tag{3.2}$$

where $\alpha_i \in \mathbb{Q}$, $i = 1, \dots, k$, and $\beta \in \mathbb{Q}$ are recognized as second-order cone constraints. For the case $k = 2$, we add a linear outer-approximation as suggested in [5] as follows: A parameter $N > 0$ determines the number of additional variables. We add variables y_0, y_1, \dots, y_N and z_0, z_1, \dots, z_N and

the following linear constraints:

$$\begin{aligned}
 y_0 &\geq |\alpha_1 x_1|, \\
 z_0 &\geq |\alpha_2 x_2|, \\
 y_j &= \cos\left(\frac{\pi}{2^{j+1}}\right) y_{j-1} + \sin\left(\frac{\pi}{2^{j+1}}\right) z_{j-1}, \quad j = 1, \dots, N, \\
 z_j &\geq \left| -\sin\left(\frac{\pi}{2^{j+1}}\right) y_{j-1} + \cos\left(\frac{\pi}{2^{j+1}}\right) z_{j-1} \right|, \quad j = 1, \dots, N, \\
 y_N &\leq \beta x_3, \\
 z_N &\leq \tan\left(\frac{\pi}{2^{N+1}}\right) y_N.
 \end{aligned} \tag{3.3}$$

The gap between the outer-approximation given by (3.3) and the set given by the original constraint (3.2) is of order $O(4^{-N})$. In our implementation, we add the constraint set (3.3) during the presolving phase. Note that we also keep the original quadratic constraint (3.2). The idea is to use all MIP features such as presolving and cut generation on the linear relaxation (3.3). Furthermore, separation, propagation, and branching routines for the quadratic constraint (3.2) ensure feasibility w.r.t. the original formulation.

For the general case of a second-order cone constraint of dimension $k > 2$, we first add new positive variables w_1 and w_2 and the linear approximation of the second-order cone constraint $w_1^2 + w_2^2 \leq (\beta y)^2$. Then the method is applied recursively to the constraints $\sum_{i=1}^{\lfloor k/2 \rfloor} (\alpha_i x_i)^2 \leq w_1^2$ and $\sum_{i=\lfloor k/2 \rfloor + 1}^k (\alpha_i x_i)^2 \leq w_2^2$.

Disaggregation. Assume that a quadratic constraint has the block-separable form

$$c_i + b_i^T x + \sum_{k=1}^p x_{J_k}^T A_{i,k} x_{J_k} \leq 0, \tag{3.4}$$

where J_k , $k = 1, \dots, p$, are pairwise-disjoint subsets of $\{1, \dots, n\}$, $p > 1$ is the number of blocks, and x_{J_k} denotes the vector $\{x_j\}_{j \in J_k}$. In this case, we introduce new variables z_2, \dots, z_p and replace the constraint (3.4) by the equivalent set of constraints

$$\begin{aligned}
 c_i + b_i^T x + \sum_{k=2}^p z_k + x_{J_1}^T A_{i,1} x_{J_1} &\leq 0 \\
 x_{J_k}^T A_{i,k} x_{J_k} - z_k &\leq 0 \quad k = 2, \dots, p.
 \end{aligned} \tag{3.5}$$

There is computational evidence that this reformulation reduces the number of cuts needed to obtain a tight linear outer-approximation of the set defined by (3.4). Note, that requiring the sets J_k , $k = 2, \dots, p$, to be pairwise disjoint ensures that convexity of a quadratic expression in a block of (3.4) is not destroyed by the reformulation (3.5). This can also lead to further bound tightenings in the domain propagation process.

Convexity. After the presolving phase is finished, each quadratic constraint is checked for convexity by computing the sign of the minimal eigenvalue of the coefficient matrix A . This information will be used for separation.

3.2. Separation. If the current LP solution \tilde{x} violates some constraints, a constraint handler may add valid cutting planes in order to strengthen the formulation.

For a violated convex constraint i , this is always possible by linearizing the constraint function at \tilde{x} . Thus, we add the valid cutting plane

$$c_i - \tilde{x}^T A_i \tilde{x} + (b_i^T + 2\tilde{x}^T A_i)x \leq 0$$

to separate \tilde{x} . In the important special case that $x^T A_i x \equiv ax_j^2$ for $a > 0$ and some $j \in I$ with fractional value \tilde{x}_j , we generate the tighter cut

$$c_i + b_i^T x + a(2\lfloor \tilde{x}_j \rfloor + 1)x_j - a\lceil \tilde{x}_j \rceil(\lceil \tilde{x}_j \rceil + 1) \leq 0.$$

For a violated nonconvex constraint i , we currently underestimate each term of $x^T A_i x$ separately. A term ax_j^2 with $a > 0$, $j \in N$, is underestimated as just discussed. However, for the case $a < 0$, the tightest linear underestimation for the term ax_j^2 is given by the secant approximation $a(x_j^L + x_j^U)x_j - ax_j^L x_j^U$, if x_j^L and x_j^U are finite. Otherwise, if $x_j^L = -\infty$ or $x_j^U = \infty$, we skip separation for constraint i . For a bilinear term $ax_j x_k$ with $a > 0$, we utilize the McCormick underestimators [21]

$$\begin{aligned} ax_j x_k &\geq ax_j^L x_k + ax_k^L x_j - ax_j^L x_k^L, \\ ax_j x_k &\geq ax_j^U x_k + ax_k^U x_j - ax_j^U x_k^U. \end{aligned}$$

If $(x_j^U - x_j^L)\tilde{x}_k + (x_k^U - x_k^L)\tilde{x}_j \leq x_j^U x_k^U - x_j^L x_k^L$ and the bounds x_j^L and x_k^L are finite, the former is used for cut generation, otherwise the latter is used. If both x_j^L or x_k^L and x_j^U or x_k^U are infinite, we skip separation for constraint i . Similar, for a bilinear term $ax_j x_k$ with $a < 0$, the McCormick underestimators are

$$\begin{aligned} ax_j x_k &\geq ax_j^U x_k + ax_k^L x_j - ax_j^U x_k^L, \\ ax_j x_k &\geq ax_j^L x_k + ax_k^U x_j - ax_j^L x_k^U. \end{aligned}$$

If $(x_j^U - x_j^L)\tilde{x}_k - (x_k^U - x_k^L)\tilde{x}_j \leq x_j^U x_k^L - x_j^L x_k^U$ and the bounds x_j^U and x_k^L are finite, the former is used for cut generation, otherwise the latter is used.

In the case that a linear inequality generated by this method does not cut off the current LP solution \tilde{x} , the infeasibility has to be resolved in enforcement, see Section 3.4. Besides others, the enforcement method may apply a spatial branching operation on a variable x_j , creating two subproblems, which both contain a strictly smaller domain for x_j . This results in tighter linear underestimators.

3.3. Propagation. In the domain propagation call, the constraint handler may infer deductions of the variables' local domains. Domain deductions can yield stronger linear underestimators in the separation procedures, they may cut off nodes due to infeasibility of a constraint, and can result in further domain deductions on other constraints. For quadratic constraints, we implemented an interval-arithmetic based method similar to [14].

To allow for an efficient propagation, we write a quadratic constraint in the form

$$\sum_{j \in J} d_j x_j + \sum_{k \in K} (e_k + p_{k,k} x_k + \sum_{r \in K} p_{k,r} x_r) x_k \in [\ell, u], \quad (3.6)$$

such that $\ell, u \in \overline{\mathbb{Q}}$, $J \cup K \subseteq N$, $J \cap K = \emptyset$, and $p_{k,r} = 0$ for $k > r$. For a number a , an interval $[b^L, b^U]$, and a variable y with domain $[y^L, y^U]$, we denote by $q(a, [b^L, b^U], y)$ the interval $\{by + ay^2 : y \in [y^L, y^U], b \in [b^L, b^U]\}$. This can be computed analytically [14].

The forward propagation step aims at tightening the bounds $[\ell, u]$ in (3.6). For this purpose, we replace the variables x_j and x_r in (3.6) by their domain to obtain the ‘‘interval-equation’’

$$\sum_{j \in J} d_j [x_j^L, x_j^U] + \sum_{k \in K} ([f_k^L, f_k^U] x_k + p_{k,k} x_k^2) \in [\ell, u],$$

where $[f_k^L, f_k^U] := [e_k, e_k] + \sum_{r \in K} p_{k,r} [x_r^L, x_r^U]$ is computed by interval-arithmetic. Computing $[h^L, h^U] := \sum_{j \in J} d_j [x_j^L, x_j^U] + \sum_{k \in K} q(p_{k,k}, [f_k^L, f_k^U], x_k)$ yields an interval that contains all values that the left hand side of (3.6) can take w.r.t. to the current variables' domains. If $[h^L, h^U] \cap [\ell, u] = \emptyset$, then the constraint (3.4) cannot be satisfied for any $x \in [x^L, x^U]$. In this case, the current branch-and-bound node can be cut off. Otherwise, we can tighten $[\ell, u]$ to $[\ell, u] \cap [h^L, h^U]$.

The backward propagation step aims at inferring domain deductions on the variables in (3.4) from the bounds $[\ell, u]$. For a linear variable x_j , $j \in J$, we can easily infer the bounds

$$\frac{1}{d_j} \left([\ell, u] - \sum_{j' \in J, j' \neq j} d_{j'} [x_{j'}^L, x_{j'}^U] - \sum_{k \in K} q(p_{k,k}, [f_k^L, f_k^U], x_k) \right).$$

For a quadratic variable x_k , $k \in K$, one way to compute tight bounds is by solving the quadratic interval-equation

$$\begin{aligned} \sum_{j \in J} d_j [x_j^L, x_j^U] + \sum_{k' \in K, k' \neq k} q(p_{k',k'}, [e_{k'}, e_{k'}] + \sum_{r \in K, r \neq k'} p_{k',r} [x_r^L, x_r^U], x_{k'}) \\ + ([e_k, e_k] + \sum_{r \in K} (p_{k,r} + p_{r,k}) [x_r^L, x_r^U]) x_k + p_{k,k} x_k^2 \in [\ell, u] \end{aligned}$$

However, since evaluating the coefficient of x_k for each $k \in K$ may produce a huge computational overhead, especially for constraints with many bilinear terms, we resort to compute the solution set of

$$\sum_{j \in J} d_j [x_j^L, x_j^U] + \sum_{\substack{k' \in K \\ k' \neq k}} \left(q(p_{k',k'}, [e_{k'}, e_{k'}], x_{k'}) + \sum_{\substack{r \in K \\ r \neq k'}} p_{k',r} [x_{k'}^L, x_{k'}^U] [x_r^L, x_r^U] \right) + ([e_k, e_k] + \sum_{r \in K} (p_{k,r} + p_{r,k}) [x_r^L, x_r^U]) x_k + p_{k,k} x_k^2 \in [\ell, u], \quad (3.7)$$

which can be performed more efficiently. If the intersection of the current domain $[x_k^L, x_k^U]$ of x_k with the solution set of (3.7) is empty, we can deduce infeasibility and cut off the corresponding node. Otherwise, we may be able to tighten the bounds of x_k .

As in [14], all interval operations detailed in this section are performed in outward rounding mode.

3.4. Enforcement. In the enforcement call, the constraint handler has to check whether the current LP solution \tilde{x} is feasible for the constraints of the constraint handler. If it is not feasible, it can resolve this infeasibility by either adding cutting planes that separate \tilde{x} from the relaxation, by tightening bounds on a variable such that \tilde{x} is separated from the current domain, by cutting off the current node from the branch and bound tree, or by performing a branching operation.

We have configured SCIP to call the enforcement method of the quadratic constraint handler with a lower priority than the enforcement method for the handler of integrality constraints. Thus, at the point where quadratic constraints are enforced, all integer variables take an integral value in the LP optimum \tilde{x} . For a violated quadratic constraint, we first perform a forward propagation step, see Section 3.3), which may cut off the current node. If the forward propagation does not declare infeasibility, we call the separation method, see Section 3.2. If the separator fails to cut off \tilde{x} , we perform a spatial branching operation. We use the following branching rule to resolve infeasibility in a nonconvex quadratic constraint.

Branching Rule. We consider each unfixed variable x_j that appears in a violated nonconvex quadratic constraint as branching candidate. Let $x_j^l, x_j^u \in \mathbb{Q}$ be the lower and upper bounds of x_j , and $x_j^b \in (x_j^l, x_j^u)$ be the potential branching point for branching on x_j . Usually, we choose $x_j^b = \tilde{x}_j$. If, however, \tilde{x}_j is very close to one of the bounds, x_j^b is shifted inwards the interval.

As suggested in [4], we select the branching variable w.r.t. its pseudocost values. The pseudocosts are used to estimate the objective change in the LP relaxation when branching downwards and upwards on a particular variable. The pseudocosts of a variable are defined as the average objective

gains per unit change, taken over all nodes, where this variable has been chosen for branching, see [6] for details.

In classical pseudocost branching for integer variables, the distances of \tilde{x}_j to the nearest integers are used as multipliers for the pseudocosts. For continuous variables, we use another measure similar to “rb-int-br-rev” which was suggested in [4]: the distance of x_j^b to the bounds x_j^L and x_j^U for a variable x_j . This is motivated by the observation that the width of the domain determines the quality of the convexification. If the domain of x_j is unbounded, then the “convexification error of the variable x_j ” is used as multiplier. This value is computed by assigning to each variable the gap evaluated in \tilde{x} that is introduced by using a secant or McCormick underestimator for a nonconvex term in which this variables appears.

We combine the two estimates for downwards and upwards branching by multiplication rather than by a convex sum, since this usually performs much better [2].

4. Primal heuristics. When solving MIQCPs, we still make use of all default MIP primal heuristics of SCIP. Most of these heuristics base on the LP relaxation and aim at finding good integer-feasible solutions starting from the optimum of the LP relaxation. For a detailed description and computational study of the primal MIP heuristics available in SCIP, see [7].

So far, we implemented two additional primal heuristics for solving MIQCPs in SCIP, both of which base on a *large neighborhood search*.

QCP local search. There are several cases, where the MIP primal heuristics already yield feasible solutions for the MIQCP. However, the heuristics usually construct a point \hat{x} which is only feasible for the MIP relaxation, hence the LP relaxation plus the integrality requirements, but violate some of the quadratic constraints. Such a point may, nevertheless, still provide useful information, since it can serve as starting point for a local search.

The local search we currently use considers the space of continuous variables. That is, if there are continuous variables in a quadratic part of a constraint, we solve a QCP obtained from the MIQCP by fixing all integer variables to the values of \hat{x} , using \hat{x} as starting point for the QCP solver. Each feasible solution of this QCP also is a feasible solution of the MIQCP.

Relaxation enforced neighborhood search. Furthermore, we implemented an extended form of the relaxation enforced neighborhood search (RENS) heuristic [8]. This heuristic creates a sub-MIQCP problem by exploiting the optimum of the LP relaxation \tilde{x} at some node of the branch-and-bound-tree. In particular, it fixes all integer variables which take an integral value in \tilde{x} and restricts the bounds of all integer variables with fractional LP solution value to the two nearest integral values. This – hopefully much easier – sub-MIQCP is then partially solved by a separate

SCIP instance. Obviously, each feasible solution of the sub-MIQCP is a feasible solution of the original MIQCP.

Note that, during the solution process of the sub-MIQCP, the QCP local search heuristic may be used next to the SCIP default heuristics. For some instances this works particularly well since, amongst others, RENS performs additional presolving reductions on the sub-MIQCP– which yields a better performance of the QCP solver.

5. Numerical Experiments. We conducted numerical experiments on three different testsets. The first is a testset of H. Mittelmann of *mixed integer quadratic programs (MIQPs)* [22], i.e., problems with a quadratic objective function and linear constraints. Second, we have selected a testset of *mixed integer conic programs (MICPs)*, which have been formulated as MIQCP. They represent three different classes of portfolio optimization problems and have been introduced in [26]. Finally, we have assembled a testset of general MIQCPs from the MINLPLib [12] and an IBM-CMU project on MINLP [13].

We will refer to these testsets as MIQP, MICP, and MINLP. In each of the following sections, detailed problem statistics are presented. The “presolved problem” columns show statistics about the MIQCP after SCIP has applied its presolving routines, including the ones described in Section 3.1. The columns “vars”, “int”, and “bin” show the number of all variables, the number of integer variables, and the number of binary variables, respectively. The columns “linear” and “quad” show the number of linear and quadratic constraints, respectively. The column “conv” indicates whether all quadratic constraints of the presolved MIQCP are convex or whether at least one of them is nonconvex. In the tables with computational results, each entry shows the number of seconds to solve a problem, or the lower and upper bounds at termination, if the problem was not solved.

For our benchmark, we ran SCIP 1.1.0.10 using CPLEX 11.2.1 [17] as LP solver and `lpopt` 3.6 [27] as QCP solver for the heuristics, see 4. For comparison, we ran CPLEX 11.2.1, BARON 8.1.5 [25], and LindoGlobal 5.0.1 [20]. All solvers were run with a time limit of one hour, a final gap tolerance of 10^{-4} , and a feasibility tolerance of 10^{-6} on a 2.66 GHz Intel Core2 Quad CPU with 4 GB RAM and 4 MB Cache.

Mixed Integer Quadratic Programs. Table 4 presents the 24 instances from the MIQP testset [22]. Note that we consider the `clay*` instances in the MINLP testset, since they are not MIQPs.

We observe, that due to the reformulation (3.1), seven instances could be reformulated as mixed integer linear programs in the presolving state. For some instances, e.g. `ibell3a`, there is an increase in the number of variables and quadratic constraints. This is due to the disaggregation step (3.5).

Table 1 compares the performance of SCIP, BARON, and CPLEX on MIQP. We did not run LindoGlobal since many of the MIQP instances ex-

ceed limitations of our LindoGlobal license. Note that some of the instances are nonconvex before applying the reformulation described in Section 3.1, so that we did not apply solvers which have only been designed for convex problems. Altogether, SCIP performs much better than BARON and slightly worse than CPLEX w.r.t. the number of solved instances of this testset. Although there are some examples which SCIP solves faster, CPLEX performs better w.r.t. average computation time.

Mixed Integer Conic Programs. The MICEP testset consists of three types of optimization problems, see Table 5. The `classical_XXX_YY` instances contain only one convex quadratic constraint of the form $\sum_{j=1}^k x_j^2 \leq u$ for some $u \in \mathbb{Q}$, where `XXX` stand for the dimension k and `YY` is a problem index. The instances `robust_XXX_YY` and `shortfall_XXX_YY` additionally contain a second-order cone constraint of dimension k . Due to its formulation as quadratic constraint with the term $(\beta y)^2$ on the right hand side of (3.2), it is categorized as nonconvex constraint. The large increase in the number of linear constraints is due to adding the linear relaxation (3.3) to the problem formulation, while the increase in the number of quadratic constraints is due to the disaggregation (3.5).

Table 2 compares the performance of SCIP, BARON, and LindoGlobal

on MICP. We observe that SCIP outperforms the other two solvers on this specific testset.

Mixed Integer Quadratically Constrained Programs. For the MINLP testset, we took 24 instances from the MINLPLib [12] and six convexified constrained layout problems (*clay**) from [13].

The instances *lop97ic*, *lop97icx*, *pb302035*, *pb351535*, *qap*, and *qapw* were transformed into MIPs after presolving – which is due to the reformulation (3.1). The instances *nuclear**, *space25*, *space25a*, and *waste* are particularly difficult since they contain continuous variables that appear in quadratic terms with at least one bound at infinity. This prohibits to use the reformulation (3.1) for products of binary variables with a linear term. Further, cut generation for nonconvex terms is not possible. Thus, if the propagation algorithm cannot find domain reductions for such unbounded variables, it may require many branching operations until meaningful variable bounds and a corresponding lower bound can be computed.

Table 3 compares the performance of SCIP, BARON, and LindoGlobal on MINLP. Figure 2 shows a performance profile for this testset. Again, SCIP performs better than BARON. Taking the number of solved instances into account, LindoGlobal slightly wins: it could solve one instance more than SCIP, which solved one instance more than BARON. Other compari-

son criteria rather indicate a tie between SCIP and LindoGlobal which are both slightly better than BARON. SCIP is the fastest solver eleven times, LindoGlobal six times. There are five cases where SCIP has the best dual bound, versus five for LindoGlobal and two for BARON. Five times, SCIP has the best primal bound, compared to four times for LindoGlobal and two times for BARON. No solver, however, strictly dominates the others on this particular testset.

BARON wrongly declared the instance `product` to be infeasible and hit the time limit while parsing the instance `pb302035`. For the instances `pb302035` and `pb351535`, LindoGlobal did not stop after 4000 seconds (using a 3600 seconds time limit) and did not report any bounds in the log file.

6. Conclusions. In this paper, we have shown how a framework for constraint integer programming can be extended towards a solver for general MIQCPs. We added the necessary methods to correctly handle the quadratic constraints, see Section 3.4. To speed up computations we fur-

FIG. 2. *Performance profile for MINLP testset.*

ther implemented MIQCP specific presolving, propagation, and separation methods, see Sections 3.1–3.3. Furthermore, we discussed two large neighborhood search heuristics for MIQCP, see Section 4. The computational results indicate that this already suffices to get a solver which is competitive to state-of-the-art solvers like CPLEX, BARON, and LindoGlobal. SCIP performed particularly well on the MIQP and MIP testsets, which contain a linear core that is complemented by a few quadratic constraints. This confirms our expectations, since SCIP already features several sophisticated MIP technologies.

We conclude that the extension of a full-scale MIP solver for handling MIQCP is a promising approach. The next step towards a full-scale MIQCP solver will be the incorporation of further MIQCP specific components into SCIP, e.g., advanced reformulations [18], more sophisticated separation routines [23], simplicial branching [19], and constraint handlers for specific types, e.g., bilinear covering constraints [24].

Acknowledgment. We like to thank Marc E. Pfetsch for contributing the implementation of the linear outer approximation for second-order cones and Ambros M. Gleixner for his valuable comments on the paper.
