11 **Abstract.** 1. Standardised data on flock husbandry were recorded on 149 broiler farms
12 during the 4 days prior to slaughter.

13
14 2. Birds were examined at the slaughterhouse for contact dermatitis lesions. Foot pad
15 dermatitis score (FPDS) and hock burn score (HBS) were measured on five point scales.
16
17 Carcase rejection data were also collected.

18
19 3. The mean percentage of birds in each flock with: moderate or severe foot lesions was
20 11.1% (range 0% - 71.5 %); moderate or severe hock burn was 1.3% (range 0% - 33.3%);
21 and, breast burn was 0.02%.

22
23 4. A general linear model was developed to examine factors associated with mean flock
24 FPDS. Assuming a linear relationship, within the range of data collected and with all
25 other factors remaining the same, every 1% increase in the proportion of Genotype A
26 birds in the flock was associated with an increase in mean FPDS of 0.003, every 1-point
27 increase in litter score was associated with a 0.326 increase in mean FPDS and every 1-
28 point increase in flock mean HBS was associated with a 0.411 increase in mean FPDS.
29
30 Flock mean FPDS was associated with feed supplier and was higher in winter.

31
32 5. The general linear model developed for flock mean HBS, found that every 1-point
33 increase in mean FPDS increased mean HBS by 0.090, every 1-point increase in litter
34 score increased HBS by 0.119 and, every 1% increase in small/emaciated birds decreased
35 mean HBS by 0.333. Reduced HBS was also associated with increased final litter depth,
36
37 younger slaughter age and an increased percentage of dietary wheat. For every 1%
38 increase in Genotype A birds, a decrease in flock mean HBS of 0.003 would be expected.

39
40 6. An effect of hatchery was also identified.

INTRODUCTION

1
2 58 Contact dermatitis is an ulcerative condition of the skin affecting the plantar surface of
3
4 59 the feet (foot pad dermatitis), the hock (hock burn) and the breast (breast burn). All
5
6 60 conditions may occur together in a single bird. Contact dermatitis lesions are thought to
7
8 61 be caused by a combination of litter moisture and the chemical burning effect of
9
10 62 ammonia from urea in the litter (Tucker and Walker, 1992; Gordon and Tucker, 1993)
11
12 63 and are therefore likely to cause pain, as a result of tissue trauma, the degree of which
13
14 64 will vary with lesion severity. In addition, there is some evidence that the incidence and
15
16 65 severity of contact dermatitis may reflect litter and air quality in the house over the flock
17
18 66 cycle, thus reflecting welfare aspects other than pain (Martland, 1985; Tucker and
19
20 67 Walker, 1992). For this reason, the incidence and severity of contact dermatitis may be
21
22 68 used as a welfare assessment measure in commercial broiler production systems in the
23
24 69 UK, either by individual companies or by accreditation schemes, such as (RSPCA, 2002).
25
26 70 Currently hock burn lesions, rather than foot or breast burn, are routinely measured and
27
28 71 recorded in the UK.

29
30 72 In the Swedish broiler industry, incidence and severity of foot pad dermatitis are
31
32 73 measured routinely for all flocks and the scores used to determine permitted stocking
33
34 74 density on farm, as part of the Swedish Care Program (Ekstrand *et al.* 1998). For this
35
36 75 Program, the maximum permitted stocking density may be abated, for subsequent flocks
37
38 76 in a house, in response to a combined measure of the incidence and severity of foot pad
39
40 77 dermatitis in birds from the house, as measured at the processing plant. The poorest-
41
42 78 performing farms are limited to stock at 20 kg per m², whereas the best are permitted to
43
44 79 stock at 36 kg per m², with gradations between these (Ekstrand *et al.* 1998). The
45
46 80 provisions of the current draft of the proposed EU Broiler Directive are based on the
47
48 81 Swedish Care Program and include, among other provisions, a requirement for the
49
50 82 measurement of the incidence and severity of foot pad dermatitis at processing plants,
51
52 83 which would then be used to determine permitted stocking density of birds in subsequent
53
54 84 flocks on farm.

55
56 85 Factors affecting the incidence and severity of contact dermatitis for a broiler
57
58 86 flock have been reviewed by Bray and Lynn (1986) and by Tucker and Walker (1992).
59
60 87 These authors concluded that hock, foot and breast burn are primarily affected by: drinker
88 | design; feed composition (including fat and protein quality and [inclusion rates](#), and salt

1
2
3 89 content); house temperature and relative humidity, as affected by provision of heating,
4 90 ventilation system specification, design and operation and thermal quality of wall and
5 91 ceiling materials; litter type and quality; floor permeability; and stocking density. The
6 92 effect of leg weakness on contact dermatitis lesions was not examined in these studies.
7
8 93 However, a high incidence of leg weakness was weakly but significantly correlated with
9
10 94 increased hock burn and foot pad dermatitis in two later studies (Sorensen and Kestin
11 95 1999; Su *et al.* 1999). The use of very shallow litter has been shown to produce dry litter
12 96 (von Wachenfelt 1993) through aeration by birds and to reduce footpad dermatitis
13 97 (Ekstrand *et al.*, 1997). Deficiencies in some micronutrients, including biotin, zinc,
14 98 copper, molybdenum and sulphur-containing amino acids, have been shown to increase
15 99 contact dermatitis by various authors, reviewed by Haslam (2003), and may account for
16 100 the finding that feed supplier has been found to be correlated with the incidence and
17 101 severity of hock burn (McIlroy *et al.*, 1987) and foot pad dermatitis (Ekstrand *et al.*,
18 102 1998). Thus, there is evidence that the incidence and severity of contact dermatitis may
19 103 reflect many aspects of bird welfare, as well as being a direct source of pain, and so may
20 104 indeed be a valid assessment measure for broiler welfare.

21
22
23
24
25
26
27 105 The prevalence of footpad dermatitis in the Swedish broiler flock has been
28 106 determined (Ekstrand *et al.* 1998) and incidence and severity of breast burn and hock
29 107 burn in commercial flocks in Northern Ireland recorded, before and following an
30 108 incentive scheme for farmers to reduce hock burn levels (McIlroy *et al.*, 1987; Menzies *et*
31 109 *al.*, 1998). However, the incidence and severity of these contact dermatitis lesions in the
32 110 UK was not known, with the consequence that the effect of the draft Broiler Directive on
33 111 the UK broiler chicken industry could not be predicted. Furthermore, previously, there
34 112 was insufficient scientific evidence of the extent to which incidence of contact dermatitis,
35 113 recorded at the processing plant, reflect leg health and bird welfare or how various
36 114 aspects of husbandry on farm affect contact dermatitis. Existing studies, discussed above,
37 115 were scant, several were old and many were not relevant to current bird genotypes and
38 116 contemporary husbandry systems or were based on studies in European countries other
39 117 than the UK, where husbandry systems, bird stocking densities and slaughter weights
40 118 often differ from those usual in the UK broiler industry. In addition, experimental studies
41 119 on contact dermatitis are not always directly relevant to birds in commercial conditions.

1
2
3 120 This paper reports on a study to determine the incidence and severity of contact
4 121 dermatitis lesion in the UK broiler flock, measured at the processing plant, and examines
5 122 the effect of various aspects of flock health and husbandry on these.
6
7 123

8 124 MATERIALS AND METHOD

9
10 125 This study made use of some of the data collected for a large on-farm,
11 126 epidemiological study of broiler leg health (Knowles *et al.*, 2007). Five major UK broiler
12 127 companies took part in these studies: these companies allowed access to any of their
13 128 contract or company farms and to their processing plants. A random selection of farms
14 129 was surveyed. The 5 companies supplied full lists of their farms and flock visits by
15 130 assessors were randomised to farms and to a unit within the farm. The number of farms
16 131 visited per company was weighted by the number of birds produced by each company.
17 132 The survey unit was a flock of birds within a growing house within a farm: a total of 206
18 133 visits were made to each of 206 flocks, which were timed to occur within 4 d of
19 134 slaughter.

20 135 Farm data were collected by veterinary surgeons with postgraduate qualifications
21 136 in Poultry Medicine and Production or Welfare Science, Ethics and Law. The survey
22 137 team was comprised of 18 veterinary surgeons from a wide variety of backgrounds. To
23 138 ensure standardisation of assessment and data collection a formal, 5-d, training course
24 139 was established. The course included training on completion of on-farm assessment
25 140 forms and assessment of bird gait. Training in gait scoring was by means of on-farm
26 141 visits and video training sessions. The veterinary surgeons were continually assessed
27 142 during the training course until they had developed a uniform scoring technique. At the
28 143 end of the course, average scores given by all the assessors for video clips of 100 lame
29 144 birds, for each 'gait score', were within half a score. During the main phase of the survey,
30 145 which took place over a period of 18 months, assessors were sent, at approximately 6 and
31 146 12 months, a tape containing video sequences of the range of gait scores. The scoring of
32 147 the tapes was monitored to ensure that the assessors remained standardised (Knowles *et*
33 148 *al.* 2007).

34 149 Each farm visit consisted of 4 main stages: completion of an epidemiological
35 150 recording form, with the assistance of a representative of the farm, which provided a

1
2 151 description of the farm, house and flock; assessments made by the recorder alone;
3 152 assessment of the gait score of 250 birds, selected at random, within one house; and,
4 153 selection of 10 birds for *post mortem* examination.
5
6

7 154 The on-farm recording form consisted of 134 questions and included: parent flock
8 155 information, including genotype/strain, health history and age; hatchery information,
9 156 including hatchery, distance and time transported and hatchery chick vaccination
10 157 programme; general information including number and weight of chicks placed, sex, time
11 158 of year, age at assessment and slaughter; specific husbandry practices including stocking
12 159 density and thinning practice; brooding conditions; a detailed nutritional profile,
13 160 including type of feed (pellet or meal) and fibre, vitamin and mineral content in each of
14 161 the feeds provided; litter substrate; feeder and drinker design and type; lighting
15 162 programme; house age and construction details; target temperature and ventilation
16 163 profiles; water source; and, vaccination programme, coccidiostats used, diseases
17 164 diagnosed during the flock cycle and medication history. During this visit information on
18 165 flock performance was collected, including growth profile from weekly weighings,
19 166 weekly mortality pattern and weekly cull patterns, categorised by cause for culling,
20 167 including culling for leg weakness. Background information about the management of the
21 168 flock, was also recorded, including: bird:stockperson ratios; age and broiler growing
22 169 experience of stock people and their training and qualifications; background information
23 170 about the site and company, including size of sheds, number of birds on site; and, types of
24 171 biosecurity measures in place. Fifteen additional assessments were made by the recorder
25 172 alone, covering aspects such as air quality, cleanliness and feed quality. Air quality,
26 173 cleanliness and feed quality were assessed on 4-point simple descriptive scales. Two
27 174 hundred and fifty birds were gait scored within the house, selected at random, by
28 175 reference to a pre-randomised location identifier. Birds were selected from 10 locations,
29 176 in groups of 25 to 30, by corralling at each location using a hinged catching pen. Each
30 177 bird was individually encouraged to walk out of the pen and was scored as it did so
31 178 (Knowles *et al.* 2007). At each location, litter quality was assessed by the method
32 179 described by (Tucker and Walker 1992) on a Numerical Rating Scale of between 1 (dry
33 180 and crumbly) and 5 (capped and wet). Eight lame and two sound birds were selected,
34 181 killed using intravenous barbiturates and weighed prior to *post mortem* examination.

182 Of the 206 flocks visited on farm, 149 were scored for contact dermatitis lesions at
183 the processing plant. Three observers were trained to record levels of foot pad dermatitis
184 and hock burn by standardised methods, using 5-point scales: scores given on these scales
185 were termed the Foot Pad Dermatitis Score (FPDS) and Hock Burn Score (HBS),
186 respectively. The photographic system used for the collection of foot pad dermatitis was
187 that used routinely by the Division of Farm Animal Science at the University of Bristol
188 and that used to collect hock burn data was that used routinely at the Agricultural
189 Development and Advisory Service (ADAS), Gleadthorpe, (Tucker and Walker, 1992).

Deleted: \

190 A breast burn recording system was not developed as very few lesions were seen
191 during pilot visits to plants. For the final plant visit protocol, the period assigned to breast
192 burn recording was reduced, from a total period per flock of 15 min to a total period of
193 three minutes, all birds passing the assessment point during the assessment period were
194 assessed, rather than a subsection as for hock burn and foot pad dermatitis: breast burn
195 was recorded as either as “absent” or “present”.

196 The three plant data observers were standardised for recording contact dermatitis
197 lesions during a number of pilot plant visits. The degree to which the observers were in
198 agreement was examined statistically, by calculating the Coefficient of Concordance
199 (Kendall’s *W*), where 0 indicates no agreement and 1 indicates complete agreement.

200 Agreement for foot pad dermatitis and hock burn recording, on a 3-point scale was poor
201 during three pilot visits while agreement for recording on the 5-point scale was good. The
202 5-point FPDS for foot pad dermatitis recording and the 5-point HBS for hock burn
203 recording, discussed earlier, were therefore adopted for data collection for this study.
204 Several standardisation and re-standardisation visits were made between November 2002
205 and March 2003. For these trials, Kendall’s *W* was found to range between 0.55 and 1.0,
206 but with most values between 0.8 and 0.9.

Deleted: three

Deleted: hock burn

207 For the final protocol, the standardised recorders conducted three recording
208 cycles, scoring foot pad dermatitis lesions and hock burn lesions for 5 min, for a
209 proportion of birds passing the inspection point immediately after bird defeathering at the
210 processing plant. The recording periods were made near the beginning, at the end and in
211 the middle of the flock to ensure that the samples taken were representative of the whole
212 flock and not just one part of the flock or loading cycle. A proportion, selected at random,

1
2
3 213 of the birds passing the observation point in the allocated time was assessed, because the
4 214 speed of the line precluded assessment of every bird. The total number of birds with each
5 215 lesion score was expressed as a percentage of the total number of birds assessed, as the
6
7 216 total number of birds assessed in the time allocated varied with line speed and lesion
8
9 217 distribution (if most birds had lesion scores 0, for example, the speed of assessment was
10 218 greater than where the lesion scores were more varied).

11 219 Breast burn lesions were assessed immediately after bird defeathering for all birds
12 220 for a period of one minute, for three different periods. The line speed was then calculated
13 221 by measuring the number of birds passing the observation point during one minute. The
14 222 total number of birds with breast lesions was expressed as a percentage of the total
15 223 number of birds assessed, which was calculated using the line speed.

16
17
18
19 224 When the entire flock had been processed, the recorder collected the Meat Hygiene
20 225 Service (MHS) carcass rejection data recorded by MHS personnel on the plant, including
21 226 the total number of carcasses rejected, the number of birds found Dead on Arrival (DoAs)
22 227 and the number birds classified as small or emaciated.

23 228 **Data analysis**

24
25
26 229 For each flock, contact dermatitis data collected at the processing plant was converted to
27 230 a percentage of the total birds assessed, for hock burn, foot pad dermatitis and breast
28 231 burn. The mean, standard error and range of levels of each class of contact dermatitis,
29 232 were calculated. The Kolmogorov—Smirnov test statistic was calculated for flock mean
30 233 FPDS and HBS, to test for normality of frequency distribution.

31
32
33 234 Several measures of stocking density were calculated, including: stocking rate
34 235 (birds placed per square metre); Biological Load Index (BLI) (stocking rate minus
35 236 mortality x weight at kill); stocking density (bird weight per square metre) at age of
36 237 inspection; stocking density at kill; projected stocking density at kill on the day of the
37 238 farm visit; stocking density prior to each thinning; average stocking density prior to
38 239 thinning; and, highest stocking density throughout flock cycle. These were calculated
39 240 using recorded or predicted weights and bird numbers at the specific times during the
40 241 flock cycle, recorded during the farm visits. Predicted weights were calculated using
41 242 standard growth curves. Bird numbers were adjusted according to mortality figures and

243 birds removed during previous thinnings, as recorded on house records. The utility and
244 accuracy of using BLI in analysis of these data is discussed later.

245 The average litter quality score was calculated as the mean of the individual litter
246 scores.

247 Scatterplots were first examined for all correlations in order to check for non-
248 linear relationships between the variables. Bivariate correlations were carried out between
249 each class of contact dermatitis and: each measure of stocking density; bird weight and
250 age; mean gait score of the birds assessed by the veterinary assessor; and, mean litter
251 quality score. The Spearman's rho statistic was calculated for each significant correlation,
252 to give an indication of the strength of all significant associations.

253 Finally, the plant data were analysed in conjunction with data gathered during farm
254 visits. Univariate general linear models were constructed to determine the aspects of
255 house specification and flock husbandry which accounted for most of the variability
256 found in the data affecting incidence of flock mean FPDS and HBS. Variables were
257 entered into the model pre-selected on the basis of the bivariate correlation results and
258 retained if $P \leq 0.05$. The procedure was stepwise and P -values of 95% or greater were
259 accepted as significant.

260 From the model developed, the effect on each lesion score of a change in each
261 variable included in the model, for an otherwise average flock, was calculated. This was
262 done by first calculating the sum of the variable weightings in the model to give the f
263 value. The difference between the f value in the model and the f value for an increase in
264 that variable by one unit (the weighting of each variable), was then calculated to give the
265 change in lesion score which would result from a change in each variable of 1 unit,
266 expressed in the units used in development of the model.

267 Hock burn and foot pad dermatitis were recorded by trained, standardised
268 observers for 149 flocks. Data were collected from 8 different slaughter plants belonging
269 to 5 different companies, between September 2003 and March 2005, regularly throughout
270 the year: visits were suspended between the end of the standardisation period, February
271 2003, and September 2003 due to the risk of spreading avian influenza and a heat wave.
272 Foot pad dermatitis, hock burn and breast burn data were collected from approximately
273 149 000 birds.

RESULTS

5
6 276 **Descriptive statistics and distribution frequencies**

7
8 277 The mean, standard error and range of each class of contact dermatitis are summarised in
9
10 278 Table 1. Thus, for the UK flocks studied, the mean percentage of birds with moderate
11 279 (FPDS 3) or severe (FPDS 4) foot lesions was 11.02%, ranging from 0% to 71.51%. The
12
13 280 mean percentage of the flock found to have moderate or severe hock burn was
14 281 considerably less, at 1.29%, ranging from 0% to 33.33% while the mean percentage of
15
16 282 the flock found to have breast burn was very small, at only 0.02%.

17 283 The frequency distributions for flock mean FPDS from this study and the flock mean
18
19 284 HBS are presented in Figures 1 and 2.

20 285 **Bivariate correlations**

21
22 286 The Kolmogorov—Smirnov test statistics for foot pad dermatitis, hock burn and breast
23
24 287 burn, and most other variables, were greater than 0.210 and were significant, indicating
25
26 288 that they did not have normal distributions. It was therefore necessary to use
27
28 289 nonparametric tests for testing for correlations between variables, which do not make
29
30 290 distributional assumptions (Petrie and Watson 1999). The significant bivariate
31
32 291 correlations between flock mean FPDS and HBS with the different measures of stocking
33
34 292 density, bird weight and age, and litter quality are presented in Table 2. The Spearman's
35
36 293 rho statistic, for analysis of bivariate correlations between nonparametric variables, is
37
38 294 presented for each significant, or close to significant, correlation.

39 295 Flock mean FPDS and HBS were very weakly, and close to significantly correlated,
40
41 296 in this study, although each of these contact dermatitis measures showed significant or
42
43 297 very significant correlations with different variables. Flock mean FPDS had a fairly
44
45 298 strong, and very significant, positive correlation with litter quality and was weakly,
46
47 299 positively correlated with stocking rate. Mean flock HBS was not correlated with either
48
49 300 of these variables, but did have very significant correlations with other variables,
50
51 301 including strong and fairly strong positive correlations with live weight and age at
52
53 302 slaughter and a very significant, weak correlation with BLI: flock mean FPDS was not
54
55 303 correlated with these variables. Flock mean HBS was weakly or very weakly negatively
56
57
58
59
60

304 correlated with many other measures of stocking density, which was an unexpected
 305 finding. There was a fairly weak, very significant positive association between birds that
 306 were DoA at the processing plant and flock mean HBS and a very weak, significant
 307 positive association between total carcass rejection rate and flock mean HBS: neither of
 308 these variables was associated with flock mean FPDS. Mean bird gait score was weakly
 309 associated with flock mean HBS but was not associated with FPDS.

310 **Univariate general linear model**

311 The GLM Univariate procedure provides regression analysis and analysis of variance
 312 (ANOVA) for one dependant variable by one or more variables. ANOVA calculations are
 313 robust for departures of a variable from a normal distribution. Inspection of the residuals
 314 from the models developed for flock mean FPDS and HBS indicated that these variables
 315 could satisfactorily be treated as continuous. The univariate model developed to account
 316 for the variability in the data with respect to flock mean FPDS is presented in Table 3.

317 Thus the percentage of birds that were Genotype A, the average litter score, feed
 318 supplier, HBS and the season of the year accounted for 36.6% of the variability in flock
 319 mean FPDS between farms. The equation for the univariate general linear model for flock
 320 mean FPDS is:

$$321 \text{ FPDS} = -0.806 + 0.003 \text{ GENOTYPEA} + 0.360 \text{ SAMPLEDL} + 0.387 \text{ FEEDSUPPLY} + \\ 322 \quad 0.411 \text{ HOCKSC} + 0.150 \text{ SEASONS} + 0.221 \text{ SEASONC} \dots\dots\dots$$

323 The model was based on data in which the percentage of Genotype A birds ranged
 324 between 0% and 100%, mean litter scores ranged between 1 and 4.9 and mean flock HBS
 325 ranged between 0% and 1.8%. From this model, assuming a linear relationship, all other
 326 factors constant, an increase in percentage Genotype A birds of 1% will result in an
 327 increase in mean FPDS of 0.003, an increase in litter score of 1.0 will result in an
 328 increase in mean FPDS of 0.360 and an increase in mean HBS of 1.0 will be associated
 329 with an increase in mean FPDS of 0.411. Feed supplier was also associated with foot pad
 330 dermatitis score, such that integrated, rather than independent, suppliers were associated
 331 with an increase in mean FPDS of 0.387, although this was strongly associated with one
 332 independent supplier which supplied just one of the companies and so could be
 333 confounded. The model also identified a significant seasonal variation in incidence of
 334 foot pad dermatitis, which could account for up to 5% of variation in flock mean FPDS
 335 and which was not identified using the bivariate correlations, due to the cyclical nature of

336 the seasonal effect. The incidence of foot pad dermatitis was significantly higher in the
337 winter than in the summer.

338 The univariate model developed to account for the variability in the data with respect to
339 flock mean HBS is presented in Table 4. Thus, the percentage of birds which were
340 Genotype A , percentage of wheat in diet 3, bird age at slaughter, foot pad dermatitis
341 score, final litter depth, percentage of birds which were classed by the MHS as small or
342 emaciated birds, average litter score, and the hatchery of origin, accounted for 56.0% of
343 the variability in mean HBS between flocks. The equation for the model for flock mean
344 HBS is:

$$\begin{aligned} \text{HBS} = & -0.887 - 0.002 \text{ GENOTYPEA} - 0.022 \text{ WHETDT3} + 0.037 \text{ AGEATSLA} + 0.090 \\ & \text{FOOTSCOR} - 0.015 \text{ FNLTDPTH} - 0.333 \text{ RC6} + 0.119 \text{ SAMPLEDL} + 2.459 \\ & \text{HATCHERY} \end{aligned}$$

348 The model was based on data in which the percentage of Genotype A birds ranged
349 between 0% and 100%, the percentage of wheat in diet 3 ranged between 0% and 30%,
350 age at slaughter ranged between 33 days and 58 days, average FPDS ranged between 0
351 and 3, litter depth ranged between 1cm and 20cm, percentage of small or emaciated birds
352 ranged between 0% and 2.15% and litter scores ranged between 1 and 4.9. From this
353 model, assuming a linear relationship, an increase in average FPDS of 1.0, within an
354 average flock, will result in an increase in flock mean HBS of 0.090, an increase in litter
355 score of one will result in an increase in flock mean HBS of 0.119 and, for every
356 percentage increase in birds which were classed by the MHS as small or emaciated birds,
357 a decrease in flock mean HBS of 0.333 would be expected. Similarly, for every
358 centimetre increase in final litter depth, within an average house, a decrease in average
359 flock mean HBS of 0.015 would be expected, an increase in age at slaughter of one day
360 will result in an increase in flock mean HBS of 0.037 and an increase in the percentage of
361 wheat in diet 3 of 1% will result in a decrease in flock mean HBS of 0.022. For every
362 percentage increase in Genotype A birds, within a house, a decrease in flock mean HBS
363 of 0.003 would be expected. This model also identified an effect of the hatchery from
364 which the chicks were derived on flock mean HBS, with each hatchery having a different
365 degree of effect.

366

367

DISCUSSION

1
2
3 368 The mean flock percentage of moderate plus severe foot pad dermatitis lesions found in
4 369 this study was 11.02%, ranging from 0 to 71.51%. This is very similar to that found in
5 370 Swedish flocks, by Ekstrand *et al.* (1997), who also quantified foot pad dermatitis of
6
7 371 birds at the slaughter plant and found the mean prevalence of mild and severe lesions to
8
9 372 be 38%. However, these studies were carried out in Swedish flocks over 10 years ago (in
10 373 1994 and 1996) and husbandry conditions and bird genotypes may have differed from
11 374 those examined in this current study. In particular, it is uncommon for flocks to be
12
13 375 thinned in Sweden (Ekstrand, personal communication).

14 376 A very recent study of UK flocks, measured at two processing plants, found that the
15 377 prevalence of foot pad dermatitis was twice as high in flocks from one of the plants than
16 378 from the other (Pagazaurtundua and Warriss, 2006). However, for their study birds were
17 379 taken from only two plants and collected from one plant in September and October, and
18 380 from the other in June, July and August, the authors therefore concluded that the results
19 381 may not be representative of the whole UK broiler flock. They suggested 18.1% as an
20 382 initial indication of the overall incidence of foot pad dermatitis in UK broilers, with
21 383 10.2% being scored as 3 or 4 on the 4-point scale used in their study.

22 384 The flock mean percentage of moderate plus severe hock burn lesions found in this
23 385 current study was 1.29%, ranging from 0 to 33.33%. This is low in comparison to that
24 386 reported for flocks in Northern Ireland by McIlroy *et al.* (1987), of 21% and by Menzies
25 387 *et al.* (1998), of 7%, although, for these studies, hock burn was measured on a two-point
26 388 scale (0 or 1) and it is unclear whether very mild or mild lesions were scored as 0 or 1.
27 389 All of these studies recorded the hock burn incidence of birds at the slaughter plant.
28 390 However, details of the scale(s) used were not reported.

29 391 The flock mean percentage of birds with breast burn lesions found in the current
30 392 study was 0.002%, ranging from 0 to 0.12%. This is very low in comparison to that
31 393 reported by McIlroy *et al.* (1987), of 0.3%, and by Bruce *et al.* (1990), of 0.2%, but
32 394 similar to that found by, Menzies *et al.* (1998), of 0%, in flocks in Northern Ireland. No
33 395 ranges were reported for these studies.

34 396 However, it is possible that the flocks examined for this study may not completely
35 397 reflect the full cross section of UK poultry flocks. For example, the Broiler Production
36 398 Companies collaborating with this project volunteered to do so rather than being selected

1
2
3 399 at random, and they therefore may represent those companies with a more positive
4 400 interest in broiler health and welfare. Farmers supplying these companies might therefore
5 401 receive both more information concerning preventative health strategies, and more
6 402 encouragement to use them, than farmers supplying companies which were not involved
7 403 with this project. There exists, therefore, the possibility that the results presented for this
8 404 study may underestimate the incidence of hock burn and foot pad dermatitis in the UK
9 405 boiler industry. However, the sample taken for this study was selected at random from 5
10 406 of the largest broiler production companies in the UK, which between them slaughter an
11 407 estimated 420 million birds annually (Cook, personal communication 2006), and
12 408 therefore represents approximately 50 per cent of the UK's annual production of broiler
13 409 chicken, estimated in 2004 to be 805 million birds (Leidahl 2005).

14
15
16 410 The positive bivariate correlation found between flock mean FPDS and litter quality
17 411 is unsurprising, as it might be expected that poorer litter quality would result in an
18 412 increase in contact dermatitis. Similarly, the correlation found between flock mean FPDS
19 413 and stocking rate is expected, as a greater density of birds would be likely to cause poorer
20 414 litter quality due to the production of a greater volume of faeces, with a resulting increase
21 415 in contact dermatitis. However, where flocks have been thinned, a very common
22 416 procedure in the UK, such an association is not as clear cut as it would depend on how
23 417 long before slaughter a house was thinned and on how rapidly, post thinning, litter quality
24 418 improves and lesions heal, if at all.

25
26
27 419 Live weight and age at slaughter and BLI are likely to co-vary, which accounts for
28 420 them all having significant positive correlations with flock mean HBS (see Table 2). This
29 421 covariance may also account for the fact that neither BLI nor bird weight appeared in the
30 422 univariate linear model developed to account for the variation in flock mean HBS,
31 423 discussed below, while bird age did. Clearly as bird age at slaughter increased, so weight
32 424 and BLI increase, so age accounted for a large part of the variation of all of these
33 425 variables.

34
35
36 426 The negative correlation of some other measures of stocking density with flock mean
37 427 FBS may appear, superficially, to be counterintuitive, because it might be expected that
38 428 greater density of birds would be likely to cause poorer litter quality with a resulting
39 429 increase in contact dermatitis. However, it may be that the effect of bird age and/or

59
60

1
2 430 weight has a much greater effect on incidence of hock burn than litter quality, so
3
4 431 “swamping” any effect that there might be, for flocks used in this study. It is of interest,
5
6 432 in this respect, that a very significant strong positive association between mean flock
7 433 HBS and BLI was found in this study. It is possible that BLI more closely reflects the
8
9 434 biological load going through a house during a flock cycle, and so the total volume of
10 435 faecal material deposited on the litter, than stocking density measured at one point in
11 436 time. Increased faecal deposition would be likely to cause poorer litter quality and
12 437 increased bacterial load. However, BLI is an artificial measure which does not take
13 438 account of birds removed due to thinning.

16 439 Alternatively, the method by which producers predict stocking density, using
17 440 standard growth curves, may account for the counter-intuitive negative association
18 441 between flock mean HBS and several measures of stocking density. Producers aim for a
19 442 target final stocking density, usually 38 kg per m² in the UK, using standard growth
20 443 curves that predict average performance for the bird genotype used, to determine the
21 444 stocking rate at which birds are placed and number of birds to be thinned prior to final
22 445 slaughter. Birds which perform better than the average, and so have a greater final
23 446 slaughter weight and possibly lower flock mortality, are likely to be birds least affected
24 447 by disease. They might therefore be more mobile, spending more time walking between
25 448 feeders and drinkers and so less time with hocks in contact with the litter, when hock
26 449 lesions might develop.

33 450 Furthermore, where birds grow more slowly due to enteric disease, or increase their
34 451 water consumption and excretion due to other types of disease, litter quality may
35 452 deteriorate for periods during the flock cycle, giving both lower stocking densities,
36 453 through slower growth and higher mortality, and higher incidence of hock burn. This
37 454 hypothesis is supported by the finding of a fairly weak, very significant association
38 455 between birds DoA and flock mean HBS and a weak, significant association between
39 456 total percentage of carcasses rejected and flock mean HBS. Such increases in DoA and
40 457 carcass rejection rates may reflect diseased or injured birds which were immobile and so
41 458 sat with hocks in contact with poor litter causing an increase in the prevalence of hock
42 459 burn: a higher proportion of such diseased flocks are likely to die during transport or be
43 460 rejected for human consumption. It is significant that stocking density does not appear in

1
2
3 461 the univariate general linear model developed to account for variability of flock mean
4 462 HBS, discussed below. Published studies also report inconsistent correlation of hock burn
5 463 with stocking density: one study reported no correlation for flocks in Northern Ireland in
6 464 1994, but a significant correlation in 1993 (Menzies *et al.* 1998) while another found no
7 465 significant correlation for the same flocks in 1986/7 (Bruce *et al.* 1990): a third study did
8 466 find such an association (McIlroy *et al.* 1987).

9
10 467 As with many measures of stocking density, the lack of significant bivariate
11 468 correlation between incidence of flock mean HBS and litter quality appears counter
12 469 intuitive. However, for this study, litter quality was measured on one occasion only,
13 470 immediately prior to slaughter, and it is possible that hock lesions are initiated earlier in
14 471 the flock cycle so that litter quality measures taken late in the cycle do not consistently
15 472 reflect prevalence of hock burn at slaughter. However, McIlroy *et al.* (1987) and Bruce *et*
16 473 *al.* (1990) both found more hock and breast burn in flocks which had experienced an
17 474 episode of 'acute litter deterioration', although during 1993 and 1994 no acute outbreaks
18 475 of litter deterioration occurred for the same flocks. For these studies, the exact nature of
19 476 these 'acute outbreaks', is not described in terms of litter quality, but it may be that, for
20 477 flocks used in our study, no such 'outbreaks' occurred and so no significant correlation
21 478 was found. However, a very significant effect of litter quality on hock burn prevalence
22 479 was identified in our study in the general linear model developed for flock mean HBS.

23 480 From the differences in the aspects of flock husbandry for which significant bivariate
24 481 correlations were identified for each condition, it is clear that the aetiology and
25 482 pathogenesis of foot pad dermatitis and hock burn are not identical. However, because
26 483 our study measured prevalence of these lesions only after slaughter, we do not know
27 484 when in the flock cycle the lesions first appeared or which husbandry conditions
28 485 determined whether or not lesions would develop. In order to identify the husbandry
29 486 changes which might be made to reduce final incidence of foot pad dermatitis and hock
30 487 burn, and when during the flock cycle they should be made, it would be necessary to
31 488 carry out a longitudinal study, of the development and progression of each type of contact
32 489 dermatitis lesion.

33 490 One of the aims of our study was to determine the extent to which contact dermatitis
34 491 levels, recorded at the processing plant, reflect bird welfare on farm. In this respect, it is

1
2 492 of interest that a significant positive bivariate correlation was found between bird gait
3
4 493 score measured on farm and flock mean HBS. This is likely to be due to lame birds
5
6 494 spending longer periods sitting with hocks in contact with the letter. No association
7
8 495 between flock mean FPDS and gait score was found.

9 496 Clearly, the results of simple bivariate correlations may be misleading, as several
10 497 factors which all appear to have an overwhelming effect may simply be co-varying as a
11 498 group, and factors which have a small effect may be swamped by the effect of another
12 499 which has a much larger effect. For this reason, univariate general linear models were
13
14 500 developed, for foot pad dermatitis and hock burn, which eliminate these problems. Such
15
16 501 models seek to account for the variations in the target variable due to changes in other
17
18 502 measured variables, thus eliminating the effect of variables which co-vary. Clearly, there
19
20 503 is likely to be some variation of the target variable which is due to factors not measured
21
22 504 for any given study

23 505 In many respects the univariate general linear model developed to account for the
24 506 variability in flock mean FPDS is explicable. The variation with season may be a result of
25
26 507 poorer litter quality, due to ventilation rates being reduced in order to maintain house
27
28 508 temperatures. Clearly, reduction in ventilation rate is likely to reduce the rate of removal
29
30 509 of moisture and ammonia from the house, causing poorer litter. Other published studies
31
32 510 have also reported a significant correlation between litter quality and prevalence of foot
33
34 511 pad dermatitis (Ekstrand *et al.* 1997; Haslam 2006).

35 512 Feed supplier is likely to have an effect through feed quality, either because the
36 513 consistency and constituents of the faeces are likely to affect the moisture content and pH
37 514 of the litter, or through an effect on skin integrity, possibly due to micronutrient
38 515 concentrations, reviewed by Mayne (2005). An effect of feed supplier on occurrence of
39 516 foot pad dermatitis has also been identified by Ekstrand *et al.* (1998). However, in the
40 517 current study, the effect of feed supplier might have been confounded by the effect of
41 518 producer as each producer used specific feed companies. Ekstrand *et al.* (1997) also
42 519 found that birds given nipple, rather than cup, drinkers and shallower litter depths were
43 520 associated with less foot pad dermatitis: this was not found in the current study.

44 521 It is initially surprising that no measure of stocking density appeared in the model
45 522 developed to account for the variation in flock mean FPDS, while a significant

1
2 523 association was identified between flock mean FPDS and stocking rate from the bivariate
3
4 524 correlations. This is likely to be because stocking rate was significantly correlated with
5
6 525 litter quality (Spearman's rho 0.38, $P = 0.01$): thus these two variables co-varied and only
7
8 526 one of these accounted for the variation of them both. The correlation of flock mean
9
10 527 FPDS with litter quality was stronger than that with stocking rate, presented in Table 2:
11
12 528 litter quality thus appeared in the model rather than stocking rate. However, no
13
14 529 association was found between any measure of stocking density or stocking rate and
15
16 530 incidence of foot pad dermatitis by Ekstrand *et al.* (1997), which was also reported by
17
18 531 Martrenchar *et al.* (2002) and Dawkins *et al.* (2004): this in spite of the fact that several
19
20 532 studies have identified associations between stocking density and litter quality (Martland
21
22 533 1985; Bruce *et al.* 1990; Tucker and Walker 1992; Gardbo Thomsen 1993), as found for
23
24 534 all measures of stocking density in this study. It would seem that variables other than
25
26 535 stocking density or stocking rate predominantly affect prevalence of foot pad dermatitis
27
28 536 in broilers when measured close to slaughter.

29
30 537 The model developed to account for variability in flock mean HBS is also explicable.
31
32 538 Factors which increase bird weight or age at slaughter, or which are related to reduced
33
34 539 litter quality, tend to increase hock burn, whilst those which tend to reduce weight at
35
36 540 slaughter, such as increasing percentage of wheat in feed or a greater proportion of small
37
38 541 and emaciated birds, tended to reduce it. Indeed whole grain or cracked wheat may be
39
40 542 incorporated into broiler diets for the purposes of slowing growth, as well as to stimulate
41
42 543 the gizzard and to encourage a healthy gut micro flora, at inclusion rates varying from 0
43
44 544 to 30% of the total feed. The model also identified a very significant effect of genotype,
45
46 545 with decreasing percentages of Genotype A birds in a flock, as opposed to Genotype B,
47
48 546 causing an increase in flock mean HBS although the effect was small. This may be due
49
50 547 to Genotype A birds having improved leg health, as found from data collected on farm
51
52 548 (Knowles *et al.* In prep. 2006), also reported by Kestin *et al.* (1992; 1999), and so
53
54 549 spending longer periods standing and walking, thus increasing contact time of feet with
55
56 550 litter with the full weight of the bird forcing the pad on to the litter, which in turn implies
57
58 551 they might have more foot pad dermatitis.

59
60 552 Surprisingly, no seasonal effect on hock burn was identified in this study.
61
62 553 However, published studies also show an inconsistent association between hock burn and

1
2 554 season. Bruce *et al.* (1990) also found no significant seasonal effect on hock burn in
3
4 555 flocks in Northern Ireland in 1987/8, while McIlroy *et al.* (1987) had found such an
5
6 556 association, for the same flocks, in 1984/5. Menzies *et al.* (1998) found a seasonal effect
7
8 557 on contact dermatitis, in 1994, but no such correlation in 1993.

9 558 The inclusion of hatchery in the univariate model accounting for variation in hock
10
11 559 burn levels may result from differences in the ages of parent flocks supplying different
12
13 560 hatcheries, variation in chick quality or relative distance to each hatchery, although
14
15 561 further research would be required to determine which aspects of the hatchery affect
16
17 562 incidence of hock burn.

18 563 In conclusion, the current draft of the EU Broiler Directive proposes that incidence
19
20 564 of foot pad dermatitis be monitored in birds going through processing plants, and that this
21
22 565 incidence be used to determine the subsequent permitted stocking density of birds on the
23
24 566 farm of origin. Our study has found that, using combined measures of severity and
25
26 567 prevalence, foot pad dermatitis is more prevalent in UK flocks than hock burn. The
27
28 568 prevalence of breast burn in UK flocks is very low. Several factors have been identified,
29
30 569 from examination of bird husbandry conditions on the farm, which affect foot pad
31
32 570 dermatitis and hock burn and which are different for the two conditions. The results of
33
34 571 our study suggest that changes in some aspects of flock management, specifically
35
36 572 measures which improve litter quality, may reduce the incidence of foot pad dermatitis
37
38 573 and hock burn lesions. A strong seasonal effect on foot pad dermatitis was found which
39
40 574 was additional to the effect of litter quality. Litter quality may be improved using
41
42 575 ventilation and heating so as to maintain house temperatures and relative humidity,
43
44 576 although it is not clear when during the flock cycle litter quality is critical. A change of
45
46 577 feed supplier may reduce foot pad dermatitis and the use of Genotype B, rather than
47
48 578 Genotype A birds will reduce foot pad dermatitis, although the effect is small.

49
50
51
52
53
54
55
56
57
58
59
60
579 Factors which might be manipulated to reduce hock burn at slaughter are those
580
581 measures which improve litter quality, including increasing depth of litter at the end of
582
583 the flock cycle, possibly by adding fresh litter, and taking measures to reduce bird weight
at slaughter, including slaughtering at an earlier age, feeding meal rather than pelleted
food, increasing the percentage of wheat in the diet and using Genotype A, rather than

1
2 584 Genotype B, birds. Further research would be required to determine what aspects of
3 585 hatchery and transport of chicks to farms affect incidence of hock burn.
