ABSTRACT

In recent years, Colombia has grown relatively rapidly, but it has been a biased growth. The energy sector (the “*locomotora minero-energetica*,” to use the rhetorical expression of President Juan Manuel Santos) grew much faster than the rest of the economy, while the manufacturing sector registered a negative rate of growth. These are classic symptoms of the well-known “Dutch disease,” but our purpose here is not to establish whether or not the Dutch disease exists, but rather to shed some light on the financial viability of several, simultaneous dynamics: (1) the existence of a traditional Dutch disease being due to a large increase in mining exports and a significant exchange rate appreciation; (2) a massive increase in foreign direct investment, particularly in the mining sector; (3) a rather passive monetary policy, aimed at increasing purchasing power via exchange rate appreciation; (4) and more recently, a large distribution of dividends from Colombia to the rest of the world and the accumulation of mounting financial liabilities. The paper shows that these dynamics constitute a potential danger for the stability of the Colombian economy. Some policy recommendations are also discussed.

Keywords: Colombia; Dutch disease; Balance of payments

1. COLOMBIA: A BONANZA FOR INTERNATIONAL INVESTORS?

Since 2011, CIVETS¹ has stood out as the new buzz word circulating among financial operators and possibly as a form of dogma in the near future. In the jargon of financial markets, this term is nothing but the acronym for six developing countries on which international investors should speculate, in search of high (and safe?) returns.

Most observers believe that recent macroeconomic data fully confirm optimistic perspectives on Colombia. In 2013, The Economist Intelligence Unit (EIU 2013, 8) portrayed Colombia as a “[...] success story [which] is now one of the most open and most business-friendly countries in Latin America [...and in which] new opportunities are opening up for foreign investors, particularly in hydrocarbons and mining, construction, and electricity, and there is free-trade access to the US market.”

Park Madison Partners (PMP), a New York–based business leader in the real estate sector, acknowledges Colombian achievements as being due to “sound” macroeconomic management of the economy. According to PMP, fiscal discipline and a successful inflation-targeting monetary policy have contributed towards creating a stable macroeconomic environment together with persistently positive growth rates, even in the wake of the most recent worldwide financial crisis;² see figure 1 (left-hand side). PMP further notes that Colombian monetary authorities have wisely decided not to obstruct any market-driven appreciation of the Colombian peso, in order to reassure foreign investors regarding the political commitment to avoid market distortions and policy-induced exchange rate risks.³ Thanks to such policies Colombia is now characterized by “a vibrant and developing capital market [...and the above] attractive fundamentals also create significant opportunities in real estate” (PMP 2013, 12). The increasing balance of payments surpluses (figure 1, right-hand side) and mounting capital inflows would seem to confirm Colombia’s bright future.

¹ CIVETS stands for Colombia, Indonesia, Vietnam, Egypt, Turkey, and South Africa.

² In the last decade, Colombian per capita income grew at rates that are certainly not comparable to the fastest-growing Asian economies. Still, despite an inevitable slowdown from 2007 to 2009, Colombian per capita gross national income grew annually at an average of 5.3% between 2004 and 2013.

³ Following Coelho and Gallagher (2013), Colombia temporarily introduced some capital controls in order to tame booming capital inflows and reduce pressures on real exchange rate appreciation from May 2007 to October 2008. These measures, however, have proved to be too mild to reach their targets and thus have been lifted since then.

Figure 1. Annual Real GDP Growth (left) and Balance of Payments Surplus (right)

Source: DANE

The above reports and recent analyses by the Colombian government⁴ create the impression of a perfectly sound economy enjoying high and stable growth. In this paper, we argue that such seemingly good performances hide more disturbing processes. On the one hand, past and prospective macroeconomic records have largely depended on—and indeed will continue to hinge upon—the increasing exploitation of Colombian natural resources, as well as high commodity prices on international markets. On the other hand, and perhaps more fundamentally, a dangerous process is currently unfolding within the Colombian economy, i.e., a dependence on foreign capital inflow to support a surprisingly high current account deficit.⁵ We believe these facts may pose serious challenges to Colombian development in the near future.

International and domestic institutions have shared some of the above concerns. OECD (2013), for instance, explicitly points out the *relative*, and at times absolute, contraction of the non-resource-based tradable good sector with respect to the energy and mining industry. In a working paper published by the central bank, Ojeda, Parra-Polonia, and Vargas (2014) elaborate on a dynamic stochastic general equilibrium (DSGE) model to assess the effects of a natural resource boom in the context of a three-sector small open economy. Both analyses share the description of structural (sectoral) changes in the Colombian economy, which follow the lines of a standard Dutch disease phenomenon. In a nutshell, the expansion of the

⁴ See Ministry of Finance and Public Credit (2014a), “An Outlook of the Colombian Economy,” freely available for download at <http://www.minhacienda.gov.co/HomeMinhacienda/saladeprensa/Presentaciones>.

⁵ Increasing exploitation of domestic natural resources and high commodity prices are usually associated with long-lasting current account surpluses; see Ojeda, Parra-Polonia, and Vargas (2014), for example.

energy sector and the ensuing foreign revenue windfall first raise domestic expenditures and lead to a *real* exchange rate appreciation. This, in turn, makes domestic manufacturing less profitable and less attractive for investment, thus reducing the size of the sector. The two papers conclude with similar policy implications. For example, they advise for countercyclical fiscal policies in order to cut expenditures and soften real exchange rate appreciation. The focus of this paper is different. We do not want to establish whether there is Dutch disease in Colombia or not. Rather, we claim that, on top of the long-run dynamics traditionally associated with a Dutch disease (i.e., deindustrialization, exchange rate appreciation, trade balance surplus, etc.), Colombia's experience of unsustainable medium- to long-run financial dynamics related to the Dutch disease impacts on the balance of payments. For this reason, we will concentrate our analysis on the dynamics observed in the balance of payments components, namely the trade balance, the net factor payments, and the foreign direct investment (FDI) flows.

The astonishing expansion of the energy and mining industry in Colombia mostly relies on FDI targeting the sector. The object of this paper is to check whether such a boom might give rise to financial fragility (boom-and-bust cycles) and a deterioration of growth prospects. The fundamental mechanics of what we are suggesting are as follows. A large FDI inflow leads to balance of payments surpluses and, in a flexible exchange rate regime, to *nominal* (and real) appreciation of the domestic currency. At first, such an appreciation jeopardizes Colombian manufacturing's competitiveness and exports, thus inducing considerable manufactured goods trade deficits and some deindustrialization.⁶ On top of this, the appreciation of the nominal exchange rate attracts short-term portfolio investments, and thus further appreciation, further deindustrialization, and mounting foreign debt. Eventually, the repatriation of profits accruing to foreign investors in the energy sector (as well as the growing manufacturing trade deficit) leads to a deterioration in the current account such that the overall balance of payments may turn negative. The "boom" turns into a "bust" and, without the central bank's interventions, the exchange rate depreciates. Such medium-run cyclical dynamics may be detrimental to long-run growth because it is likely to reduce (both

⁶ Goda and Torres (2013) perform an econometric analysis in order to test the existence of any effects of FDI on Colombian real exchange rate and, in turn, on manufacturing development. Their sample coverage runs from 1996 (first quarter) to 2012 (first quarter). On the one hand, they conclude that "net FDI and net other inflows are the main drivers of the post-2003 capital inflow appreciation effect in Colombia" (Goda and Torres 2013, 16). On the other hand, they find that real exchange rate appreciation explains most of the deindustrialization episode currently underway in Colombia.

directly and indirectly) the share of manufacturing in total GDP and manufacturing constitutes, *à la* Kaldor, the ultimate source of labor productivity growth and long-run development. Our purpose, and let us assert this point, is thus to establish whether this Colombian pattern of growth is macroeconomically viable and sustainable in the medium to long run.

Section 2 briefly outlines the abundant literature on Dutch disease, to make it clearer what we are (and what we are not) discussing. Section 3 provides evidence supporting the idea that Colombia is currently experiencing a deindustrialization process. Section 4 continues the analysis by observing some interesting macroeconomic features of the current Colombian pattern of growth. In particular, we look at changes in the sectoral destination of FDI and at the decoupling in the dynamics of the current account and trade balance. Section 5 recapitulates our findings and describes briefly the risks associated with such a pattern. To emphasize these risks and make them more evident, we provide a scenario analysis, assessing the financial stability of the processes currently unfolding in the Colombian economy. We conclude discussing some policy options.

2. DUTCH DISEASE IN A NUTSHELL

Dutch disease is a well-known issue in the field of development economics. According to the original contribution by Corden and Neary (1982), it refers to the structural consequences of a change in the sectoral composition of an economy, i.e., the relative and absolute reduction in the manufacturing sector's participation in GDP, due to a boom in the use of domestic natural resources. The traditional literature on this topic describes the Dutch disease as a real-side phenomenon, taking place through real-side mechanisms. In particular, a shock such as a sudden technological innovation in the energy sector,⁷ the discovery of new natural resource endowments, and/or rising international prices of primary commodities, tends to raise domestic expenditures and alter domestic relative prices against the non-tradable

⁷ Corden and Neary (1982) assume a Hicks-neutral technological progress to take place in the energy sector, raising both labor and capital productivity in that sector. Similar results could also be obtained if an increase of primary commodities' prices is assumed and the country under consideration is a net exporter of primary energy commodities, or if there is an increase in the endowment of the natural resource input specific to the energy sector.

sector. Such a real exchange rate appreciation in turn reduces the viability and profitability of the manufacturing sector. In a general equilibrium framework, while both the energy and services sectors may expand, the manufacturing sector producing non-tradable goods will shrink.

While it is worth studying such structural changes on their own, they are even more important if they entail consequences on the long-run growth potential of the economy. Indeed, several studies interpret the Dutch disease as the main source of a natural resource curse, i.e., the general disappointing economic performance of natural resource-rich countries compared to natural resource-poor economies (see Sachs and Warner 1995, 2001). In this regard, the core point of the Dutch disease–natural resource curse nexus lies in the growth-enhancing properties generally attributed to manufacturing, with respect to the energy sector and services (see Sachs and Warner 1995, 1999; Ros 2001; Chang 2010), so that the real wage, the profit rate, and labor productivity growth may be simultaneously higher in a sufficiently large manufacturing-based economy with respect to countries specializing in non-manufacturing and non-tradable sectors (Ros 2001; Botta 2010).⁸

Regardless of the specific mechanisms at work and their theoretical or empirical character, all these analyses share the common aspect of being real-side studies without a well-defined macroeconomic framework based on national accounting. In a way, they follow the original contribution of Corden and Neary (1982, 825) by “ignoring the monetary implications” of natural resource booms and the ensuing structural changes, i.e., the effects such events may trigger on the external balance and financial solidity of the economies under observation. Sachs and Warner (1995, 1999), for instance, assume the current account of the balance of payments to be always in equilibrium thanks to natural resource “manna” counterbalancing trade deficits arising from increased imports of tradable goods. Gylfason, Herbertsson, and Zoega (1999) assume an exogenous trade surplus in order to meet interest payments on a given and constant stock of foreign debt. When capital movements and financial transactions are considered (see Mansoorian 1991), they are formalized in a perfect foresight infinite horizon framework, in which international borrowing and accumulation of foreign debt today are repaid through expanding manufacturing productions, increasing domestic savings, and

⁸ Torvik (2001) allows for different results by allowing for “learning by doing” to take place in the non-tradable sector as well, and technological spill-over running both ways (from manufacturing to services and vice versa).

rising current account surpluses tomorrow.⁹ Accordingly, in these models, boom-and-bust cycles linked to mounting foreign debts are ignored by assumption, even though they may represent relevant ways in which natural resource booms may influence long-run economic dynamics (Manzano and Rigobon 2001).

Our contribution aims to fill this gap. In this sense, it draws illumination and insight from two previous works by Dutt (1997) and Taylor (2004). Dutt (1997) emphasizes that incoming FDI may induce detrimental effects on the catching-up process of developing economies, depending on the productive sector targeted by FDI. Taylor (2004, chapter 12) describes the cyclical boom-and-bust dynamics, which are possibly set in motion by temporary capital inflows in developing economies. Our paper represents an attempt to put these two perspectives together in order to assess the macroeconomic instability and external vulnerability possibly originating from the FDI-induced Colombian Dutch disease.¹⁰

3. STRUCTURAL CHANGE AND SECTORAL DYNAMICS IN COLOMBIA

Colombia has already gone through various episodes of deindustrialization.¹¹ On top of the current sharp decline in the manufacturing sector's share in real value added, a similar trend also emerged from 1990 to 1999. The Colombian deindustrialization episode of the 1990s was most likely due to the radical switch in economic policy that Colombia went through during that period. The reform process, centered on trade liberalization, is deemed to have harshly hit Colombian industry, manufacturing in particular, which had been traditionally supported by a protectionist trade regime (Ocampo 1994). Colombian manufacturing output share eventually reached a minimum in 1999. The deep economic downturn that affected

⁹ Different conclusions with respect to the standard "Dutch disease" literature can be obtained when inter-temporal optimization and consumption smoothing is allowed through financial market mechanisms. Mansoorian (1991), for instance, finds that a real depreciation and an expanding manufacturing sector could emerge in the long run as the optimal response to overborrowing, real exchange rate appreciation, and deindustrialization in the short run. These conclusions reinforce those provided by Bruno and Sachs (1982, 858), who stress that "optimizing far-sight households (and government) will not consume all current oil revenues, but will rather save in anticipation of the future decline [...] to the extent that the current revenues overstate the 'perpetuity equivalent' of oil earnings, a focus on current production levels overstates the resource allocation consequences of the oil sector."

¹⁰ Considering the interplay between financial and real factors in the analysis of Dutch disease is not completely new. See, for instance, Blecker and Seccareccia (2008).

¹¹ The debate on Colombian deindustrialization dates back to at least 1986, see Kamas (1986).

Colombia in that year was as a result of the fall-out from financial crises in other emerging countries contributing to this dynamic.

The Colombian manufacturing sector partially recovered at the beginning of the 2000s; however since 2007, the manufacturing sector's share over GDP has been shrinking again in a remarkable and consistent way. The current episode of deindustrialization (or, better, de-manufacturing) does not comprise a general or proportional decline in all the several components of the industrial sector. Indeed, the contraction of the manufacturing sector is accompanied by an increase in the energy sector's real GDP share. By the first quarter in 2014, the Colombian manufacturing accounted for less than 11% of real GDP, while the energy sector share has been constantly expanding.

Figure 2 shows the quarterly growth rate differential for the mining and manufacturing sectors with respect to GDP. We observe, first, that the volatility of the mining sector growth rate is much higher than the manufacturing one. Aside from this high volatility, there seems to be no distinct trend until mid-2007, when the mining sector starts enjoying a growth rate mostly above GDP while the opposite is true for the manufacturing sector.

Figure 2. Sectoral Quarterly Growth Rates Differential

Source: Central Bank of Colombia

We use the standard Chow test to validate the structural break that seems to emerge from the data. The data set consists of 53 quarterly observations from 2001Q1 to 2014Q1.

Unfortunately, due to a change in the methodology used by the Colombian statistical office (DANE), we cannot include previous data. Table 1 and table 2 show the estimation results for the mining and manufacturing sectors. The tests indicate that there seems to be a structural break for both series in 2007Q3. There is no clear trend before 2007Q3. The mining sector seems to grow less than GDP (1.07% below GDP, not statistically significant), while the manufacturing sector is growing at a par with GDP (0.13% above GDP, not statistically significant). By contrast, after 2007Q3, however, the trend is very clear. The mining sector experienced an average growth rate higher than overall GDP (+1.15%) while the manufacturing sector is growing at a rate lower than GDP (-0.99%).

All the above-mentioned deindustrialization episodes are consistent with the worst deindustrialization case stressed by Tregenna (2011).¹² From 1985 to 1995, Colombia is the only developing economy in which the contraction of the manufacturing sector outweighed the increase in labor intensity (a decreasing labor productivity). Sadly, these findings are confirmed for the 2007–13 period.¹³ Data reported in table 3 show that a negative variation in the manufacturing employment share in the order of 1.8 percentage points is due to the significant contraction of manufacturing participation to GDP. Such a contraction outweighs the reduction in manufacturing labor productivity. These puzzling and worrisome dynamics in Colombian manufacturing labor productivity can be partially explained by the manufacturing subsector’s dynamics. Since 2000, more disaggregated data (see DANE 2014) reveal that production of basic metallic and non-metallic goods has expanded their participation in manufacturing value added. By contrast, the manufacturing value-added share attributed to the chemical industry has decreased. The same story applies to the capital goods sector. While the former are usually classified as labor-intensive and low-skill sectors, with

¹² Tregenna (2011) identifies three possible processes leading to deindustrialization as measured by a reduction of the manufacturing employment share. First, a reduction in labor intensity (increase in labor productivity) coupled with a contraction of that sector’s output; second, a reduction in labor intensity that outweighs the expansion of sector production; finally, the contraction of sectoral activity that outweighs the increase in labor intensity (decline in labor productivity). Such processes, all giving rise to a lower manufacturing employment share, are likely to prompt different and perhaps opposite effects on overall economic records. This is also the reason why analogous trends in manufacturing employment in Asian and Latin American economies, Colombia among them, have been often associated with diverging economic performances. Whilst the former registered increasing manufacturing value-added shares and even stronger improvements in manufacturing labor productivity, most Latin American economies experienced worrisome premature reductions in manufacturing GDP shares, and dismal increases in labor productivity by international standards. Indeed,

if a decrease in manufacturing employment share is primarily accounted for by falling labor intensity of manufacturing, this calls into question the extent to which ‘deindustrialization’ is an appropriate characterization. The point is that a fall in the share of manufacturing employment that is mostly accounted for by falling labor intensity (i.e., increasing labor productivity) would not necessarily have a negative impact on growth. This is different from the case where the fall in the share of manufacturing employment is associated primarily with a decline of the manufacturing sector as a share of GDP. In such a scenario, an economy would be particularly at risk of losing out on the growth-pulling effects of manufacturing. (Tregenna 2011, 15)

¹³ Variations in the sectoral employment share can be decomposed into three elements: variations in the labor intensity characterizing a sector’s production (i.e., the labor-intensity effect); variations in the sectoral GDP share (i.e., the sector-share effect); variations of overall labor productivity, which obviously affect overall employment dynamics (i.e., the above labor-productivity effects). We can represent the sectoral employment share (hence its variation) according to this formula: $L_{it}/L_t = L_{it}/Y_{it} * Y_{it}/Y_t * Y_t/L_t$, L_{it} being employment level in sector i at time t , Y_{it} sectoral production at time t , and L_t and Y_t overall employment and production levels. It is worth noting that the sectoral labor intensity (or the inverse of the labor productivity) is a output-weighted average of each subsector’s labor intensities. Thus, a decrease in labor productivity does not necessarily imply using a less-efficient technology but can be the result of a change of the output shares in favor of a more labor-intensive subsector.

little scope for innovation and productivity growth, the latter are medium- and high-skill technology-intensive sectors characterized by stronger (productivity) growth opportunities.¹⁴ Overall, it seems that Colombian manufacturing is not only shrinking in relative and absolute terms, but it is concentrated in labor-intensive low-skill industries. Hence, it might be a reasonable concern that the ongoing deindustrialization process might seriously impinge on Colombian long-run development, provided that the non-traditional sophisticated tradable goods sectors still represent a fundamental source of labor productivity dynamics (Rodrik 2007; Szirmai 2012).

Table 3. Decomposition of the Manufacturing Employment Share’s Variation, 2007–13

Labor share variation	Labor-intensity variation	Sector share variation	Overall labor productivity variation
-1,8	0,8	-3,0	0,4

Source: Central Bank of Colombia, ILO (Labor Force Survey), and authors’ computations

4. REAL EXCHANGE RATE DYNAMICS, FOREIGN DIRECT INVESTMENTS, AND THE COLOMBIAN EXTERNAL ACCOUNT

The macroeconomic dynamics briefly sketched in the first sections of this paper depend on a wide range of endogenous and exogenous factors of both long- and short-run nature. In 2008 and 2009, there is no doubt that temporary circumstances linked to the worldwide “Great Recession” have negatively affected Colombian GDP growth. At a more profound level, Colombian performances are likely to be affected by some radical changes in the Colombian domestic policy framework. Since the end of the 1980s, Colombia has been experiencing a long-lasting and deep reform process. At the beginning of the 1990s, the so-called “*apertura hacia adentro*” was launched, aiming to move Colombia, and the Colombian industrial sector in particular, from a fairly protected trade regime to an open and liberalized setting. More recently, this process has continued through a long series of free trade agreements.¹⁵ Further,

¹⁴ See UNCTAD (2014), “Manufactured goods by degree of manufacturing,” freely available for download from: <http://unctadstat.unctad.org/EN/Classifications.html>.

¹⁵ United States of America (November 22, 2006), Chile (November 27, 2006), Northern Triangle (El Salvador, Guatemala, and Honduras, August 9, 2007), Canada (November 21, 2008), European Free Trade Association

since the mid-2000s the regulation of the mining and energy sectors has been subject to important modifications. In 2004, the government lifted the restrictions to foreign companies' exploitation of domestic oil resources (UNCTAD 2006). Accordingly, the monopolistic control of the oil sector by domestic firms has been removed and the national company Ecopetrol partially privatized. Such a regime shift, together with significant natural resource discoveries and high prices of primary commodities, has steered massive foreign direct investment towards Colombia.

4.1 The FDI–Exchange Rate Nexus

Most economists would interpret the recent appreciation of the Colombian peso as the main factor curtailing the profitability and viability of Colombian manufacturing. Such an appreciation would in turn be attributed to a natural resource boom raising domestic expenditures and lifting inflation, in particular the non-tradable sector inflation.

Since 2003, the Colombian real exchange rate has appreciated by 6.6% yearly on average (see figure 3).¹⁶ However, contrary to what might be expected, most of this trend comes from nominal appreciation, in the order of 6.4% yearly, rather than strong inflationary pressures. Data from international economic organizations confirm that Colombian inflation has been under control and has decreased remarkably since 2008. Since 2003 Colombia has experienced the lowest inflation rates among CIVETS countries.¹⁷ Colombian inflation has often been lower than that registered in many of its most relevant trading partners, Latin American partners in particular. According to the IMF (2014), it was below 3% in 2013 and it is expected to be around 1.9% in 2014.¹⁸

(November 25, 2011), and European Union (June 26, 2012). Source: Organization of American State's Foreign Trade Information System, <http://www.sice.oas.org>.

¹⁶ In figure 3, according to UNCTAD data, upward trends in the nominal and real effective exchange rate indexes stand for appreciations. Depreciations are represented by downward-sloping sections in exchange rates dynamics.

¹⁷ According to data provided by the IMF (2014), from 2003 to 2012, Colombia has experienced average inflation rates significantly lower than those observed in other emerging economies such as Brazil (1.6 percentage point less), India (2.6), South Africa (0.8), and Turkey (5.7).

¹⁸ See IMF World Economic Outlook (April 2014). Data freely available from: <http://www.imf.org>.

Figure 3. Colombian Effective Real and Nominal Exchange Rate (index number)

Source: UNCTAD Datastat

Of course, it could be said that nominal and real appreciation of the Colombian peso might come from Colombian trade and current account surpluses, but data relating to Colombian external accounts show that this is not the case. Since 2001, Colombia has experienced a persistent, although modest, trade deficit only replaced by a mild surplus in 2011. Yet, the Colombian current account has remained in deficit, and it has surprisingly worsened and diverged from an improving trade account. It is now in the order of more than 3% of GDP.

In order to understand why, despite a growing current account deficit, the Colombian peso revaluated so heavily over the last ten years, it is instructive to have a look to all the different components of the Colombian balance of payments. It is crucial to emphasize that the capital account surplus more than compensated for the current account deficit. In the period 2002–13 the cumulative current account deficit amounted to US\$67 billion, whereas the capital account surplus reached more than US\$97 billion. These numbers seem to indicate that the origin of the Colombian Dutch disease is perhaps to be found in the macro sphere, the financial one in particular.

In the case of Colombia, FDI has shown some degree of volatility and instability due to exogenous economic factors (i.e., the worldwide “Great Recession”), and their links to one-shot investment opportunities. SABMiller Company’s acquisition of the local beer brand

Bavaria lies behind the erratic jump in Colombian FDI in 2005, for instance. This fact notwithstanding, Colombia has experienced a significant and apparently structural increase in incoming FDI since 2005. Indeed, before 2005 and throughout the 1990s, overall FDI in Colombia have rarely been higher than 3% of GDP (according to UNCTAD, they stood out at 4.37% of GDP only in 1997). However, they peaked up to almost 7% of Colombian GDP in 2005, and have remained systematically and remarkably above 3% of GDP since then (the only exception being in 2010). In absolute terms, from 1990 to 2004, net FDI were equal to US\$1.6 billion on a yearly average. Since 2005, they averaged US\$6.5 billion. In 2012, net FDI represented almost 100% of the positive net Colombian financial account, these same figures being far higher than 50% in 2007 and 2008.

Incoming FDI, in particular those targeting the domestic energy sector, have greatly contributed to the surplus in the Colombian capital account and overall balance of payments since 2004. Furthermore, in the last five years, increasing net foreign portfolio investment has further reinforced the macroeconomic implications, i.e, the Colombian peso's nominal and real exchange rate appreciation, of the above-mentioned FDI flows. Indeed, in the first part of the 2000s, net foreign portfolio investment in Colombia was low or even negative. A remarkable change has apparently taken place since 2007. With only the exception of 2008 (which was likely due to the worldwide consequences of the subprime financial turmoil), net foreign portfolio investment has always been positive and increasing since 2007. In 2007, it amounted to US\$1.3 billion, i.e., 0.64% of Colombian GDP. From 2011 to 2013 it surged to far more than US\$5.5 billion yearly, i.e., more than 1.5% of Colombian GDP. According to data provided by the Central Bank of Colombia, it amounted to US\$2.5 billion in the first quarter of 2014.

A type of self-reinforcing process between FDI flows, portfolio investment, and exchange rate appreciation seems thus to characterize the more recent evolution of the Colombian external account. Mounting FDI flows have provided the first move for the Colombian peso's ongoing appreciation. International investors' enthusiasm for Colombian growth opportunities and, say, exchange-rate induced capital gains, have then led to increasing net foreign short-term portfolio investment. In the light of the structural (sectoral) consequences of such macroeconomic trends and of the current account imbalances reported in next section, it would seem a straightforward progression to wonder whether such a self-feeding process may turn out to be unsustainable in the near future.

4.2 Colombian Trade and its Current Account

Figure 4 provides a closer look at the evolution of the Colombian current account and of its sub-components. Colombian structural dependence on imports of manufactured goods emerges strikingly. Despite fluctuations linked to economic cycles, the trade deficit in manufactured goods has been increasing since the beginning of the 2000s. It is now close to 10% of GDP. Obviously, these figures change radically when trade flows linked to the energy and mining sectors are taken into account. Since 2001, the overall trade account in goods and services has registered deficits no higher than 2% of GDP. Over the last four years, it has been close to balance, even though not yet positive (with the exception of 2009), thanks to the high prices of primary commodities.

Figure 4. Colombian Trade and Current Account Balances

Source: Central Bank of Colombia and authors' computations

Interestingly, before 2005, Colombian trade and current accounts showed closely similar dynamics and positively co-moved. Rising (resp. decreasing) trade deficits were associated with increasing (resp. decreasing) current account deficits. Since 2005, however, diverging trends have emerged. While the overall trade account has remained close to balance, the

current account deficit has steadily increased to above 3% of GDP. Such an apparently puzzling fact can be explained through the data portrayed in figure 5. Here we describe the dynamics of some of the above components of the current account, (net) repatriated profits linked to FDI in particular. Data are expressed as index numbers, 1995 being the base year. Both the current account deficit and manufacturing trade deficit show an upward trend. In 2013, the manufacturing trade deficit was more than four times higher than it was in 1995. What is more, net factor income shows astonishing dynamics. While they amounted to 0.29% of GDP in 1995, they stand at 2.85% of Colombian GDP in 2013 (practically the whole current account deficit). Their 2013 value is more than 30 times higher than the initial 1995 value.

5. THE MACROECONOMICS OF THE FINANCIAL DUTCH DISEASE: A SCENARIO ANALYSIS

According to the literature reviewed in section 2 and to the empirical evidence presented in sections 3 and 4, the picture we have described so far seems to suggest the existence of a strange sort of Dutch disease in Colombia. Its peculiar ingredients and the main mechanisms at work can be summarized in a few points.

First, the Colombian peso has significantly revaluated in the last decade, both in nominal and real terms. The excess world demand for Colombian pesos, however, does not come from the need to finance a rest-of-the-world current account deficit vis-à-vis Colombia. The world is not swamped by Colombian exports. On the contrary, Colombia continues to experience a structural and increasing manufacturing trade deficit. High international prices of primary commodities and an expanding energy sector have helped to bring the overall Colombian trade account back to equilibrium. Yet, the Colombian current account is negative and worsening.

Second, Colombian peso revaluation can be explained by the dynamics of capital inflows, and among them FDI are overwhelmingly important. In the more recent period, the Colombian peso's appreciation has also been supported by positive and increasing net foreign portfolio investment aiming to exploit profit and capital gain opportunities emerging in the economy. A brief sectoral analysis also reveals that FDI are more and more directed towards the oil sector. In 2003, the real price of oil started increasing and peaked in 2008 (well above the level it had reached in the 1982, at the top of the second oil shock). Today, it is more than 150% higher than it was in 2000 (Missaglia 2012). Faced with such tremendously strong incentives, global oil companies accelerated their investment processes and oil-rich countries experienced a rapid growth of incoming FDI and an important expansion in the mining sectors. Colombia was no exception. According to a more disaggregated sectoral perspective, since 2006 FDI in the energy sector has accounted for close to 50% or more of all Colombian incoming FDI on an annual basis. Figure 6 (below) shows the quarterly FDI per sector (oil or other) from 1996Q1 to 2012Q4 (68 observations).

Figure 6. FDI in Mining and Petrol, Others, and Total

Source: DANE

The data seem to indicate a change in FDI distribution from around 2001 onwards. We ran a Chow test to check for structural breaks and estimated the average shares for different samples. Table 4 presents the results. There is a structural break in 2001Q2 where the share of FDI accruing to oil and other sector has substantially changed. Indeed, the oil sector's share on total FDI has observed a statistically significant increase.

Table 4. Estimation of FDI Share Accruing to Oil and Other Sectors

Variable	Full sample	1996Q1-2001Q2	2001Q3-2012Q4
Petrol and Mining share	0.42***(0.04)	0.12 (0.06)	0.56***(0.03)
Chow Test (2007Q3)	52.08*** (0)		

Source: Central Bank of Colombia and authors' computations

Both facts (the exchange rate revaluation and massive energy-sector-oriented FDI) contribute to shifting the Colombian productive structure away from manufacturing and to make it increasingly dependent on the exploitation of domestic natural resources.

Third, this kind of FDI generates high returns, but profits are typically expatriated. Indeed, between 2009 and 2012, the incoming flows of FDI (US\$39,306 million) have been lower than the outgoing flow of profits (US\$42,469 million), see Cabrera Galvis (2013). This fact is disturbing on a twofold level. First, before being expatriated, these profits are not taxed. Following Ocampo (2013, 15), “this reflects Colombia’s inability to take advantage of commodities’ prices boom through taxation [...] this was done in the past during the coffee price boom. This contrast is even more striking when thinking that coffee profits were captured by someone in the country. On the contrary, today’s oil profits are essentially going to foreign enterprises.”

Second, huge profit repatriation by foreign investment in the Colombian oil sector emerges as the leading force behind Colombian current account imbalances. Whilst these imbalances may easily turn out to be structural and permanent, we cannot say the same for the FDIs that have so far financed the existing external gap.

The kind of productive changes and external imbalances currently underway in Colombia cast serious doubts on its long-run growth potential and financial stability.

5.1 Possible Future Scenarios

We have already emphasized our concern about a negative link between deindustrialization and productivity dynamics. This concern will be even stronger if we consider the current reduction in manufacturing participation to the GDP to be linked to a decreasing manufacturing labor productivity. Clearly, such facts are at odds with those historically observed in developed and successful East Asian “catching-up” countries. The relative concentration of Colombian manufacturing in labor-intensive, low-skill productions may significantly downsize Colombian opportunities as to the accumulation of human capital and generation of innovation and technological spillovers on the rest of the economy. This is likely to weaken productivity dynamics and harm economic development. However, these dynamics, linked to a more traditional vision of the Dutch disease, are likely to develop at a slower pace since it involves a structural change of the composition of the economy, which typically is measured in decades rather than years.

We are concerned about the dynamics unfolding in a much shorter time frame. Persistent and large current account imbalances have often been perceived as destabilizing factors,

potentially leading to exchange rate crises and financial turmoil in developing countries. Colombia is no exception and the data presented in section 4 leads one to ask whether the current Colombian development pattern is financially sustainable. In order to address this issue, we propose a scenario analysis¹⁹ on the possible evolution of the various components of the Colombian balance of payments. Our analysis relies on the data provided by the Colombian government as to the expected dynamics of oil prices, oil production and exports, GDP, and imports growth rates (Ministry of Finance and Public Credit 2014a).²⁰ Further, the government's expectations in terms of current account dynamics and net capital inflows and variation in foreign reserves have been published. We do not have available additional information concerning net factor payments, profit repatriation in particular, and non-oil exports. The aim of our analysis is twofold. First, we compute the required evolutions in our "unknown" variables (net factor payments or non-oil exports alternatively) in order to meet the government's expectations. Second, we simulate future possible dynamics of some relevant components of the Colombian balance of payments according to past-observed trends. We are interested in the implications of such trends, should they persist in the upcoming years, in terms of current account, capital account, and foreign reserve accumulation. In this sense, we want to test the consistency of these emerging figures with government expectations.

The right-hand side of figure 7 reproduces the government's expectations in terms of foreign capital inflows and current account. The left-hand side of figure 7 in turn portrays government projections as to oil exports and overall imports of goods and services. The government's expectations are such that a persistent current account deficit should slightly decrease from 3.6% of GDP in 2014 to around 3% of GDP in 2024. Capital account and net FDI inflows are expected to remain, on average, in the order of 4% and 3.7% of GDP, respectively (in 2014, the Colombian government expects a capital account surplus close to 5% of GDP). The capital account surplus is thus expected to fully cover current account deficits and allow Colombian foreign reserves to pile up even further.

¹⁹ The R source code and the datasets used to generate all graphs and econometric results of this paper can be found on the Antoine Godin's website.

²⁰ Unfortunately, we do not have detailed yearly values for the capital account and FDI but only averages over the time period.

Figure 7. Government Trade Flow Forecasts and Expectations on Current and Capital Account, and Net FDI

Source: Ministry of Finance and Public Credit (2014b), Central Bank of Colombia, and authors' computations

5.2 Current Account Dynamics

In the left-hand side of figure 8, we show the current dynamics of Colombian net factor payments. Consistently with figure 6, it has become astonishingly negative in the last decade mainly due to an enormous increase in FDI profit repatriation. We assume three possible scenarios as to the future net factor payments (NFP) evolution. First, we assume it maintains a constant nominal value, equal to its 2013 level, throughout the next ten years (dashed line). Second, we assume NFP to move at the same pace as the Colombian nominal GDP, i.e., the NFP-GDP ratio is constant (dotted line). Finally, we project possible increases in NFP Colombian outflows using an Hodrick-Prescott (HP) filter trend (dashed-dotted line). On the right-hand side of figure 8, we plot the required increase in Colombian non-oil exports in order to meet government's current account expectations, following equation (1), where CA is the current account, X_{Oil} and X_{NonOil} are exports of oil and non-oil, respectively, M is imports, and NFP is net factor payments.

$$CA = X_{Oil} + X_{NonOil} - M + NFP \quad (1)$$

As shown by equation (1), once CA , X_{Oil} , and M are known, either X_{NonOil} or NFP still need to be fixed in order to determine all variables. In this first exercise, we define three different dynamics for NFP and determine the consistent dynamics for the non-oil exports required, such as those shown in equation (1). What emerges clearly is the enormous increase of non-oil exports (as a percentage of GDP) that should take place starting in 2020 in order to bring

the trade balance under control and maintain the overall current account deficit around 3% of GDP by the end of 2024.

Figure 8. NFP (different scenarios) and Required Non-oil Exports to Meet Government’s Current Account Target

Source: Ministry of Finance and Public Credit (2014b), Central Bank of Colombia, and authors’ computations

Figure 9 presents the results of the contrasting exercise. Here we make two different hypotheses on the possible future evolution of Colombian non-oil exports and determine the value for net factor payments. First, we assume them to grow on par with GDP (dashed line in figure 9, left-hand side). Alternatively, we assume non-oil exports to grow according to its trend, as calculated through the HP filter applied to annual data from 1995 to 2013 (dotted line). On the right-hand side of figure 9, we show the implications of the aforementioned scenarios on NFP dynamics in order to meet the government’s current account target. What emerges is that NFP will remain reasonably negative for some years ahead. Nonetheless from 2020 onwards, the increasing gap between total imports and oil exports, and the ensuing widening overall trade deficit (in goods and services), together with an expected reduction in the current account deficit, implies that NFP will switch from negative to positive values. Needless to say, such a scenario appears at the very least unrealistic. This is even more so if it is linked to the government’s expectations regarding persistently positive net FDI over the next ten years.

Figure 9. Non-oil Exports (different scenarios) and Required NFP to Meet Government’s Current Account Target

Source: Ministry of Finance and Public Credit (2014b), Central Bank of Colombia, and authors’ computations

Figures 8 and 9 describe “implicit” dynamics in non-oil Colombian exports or, alternatively, in NFP consistent with governmental targets on the overall current account balance. Let us now modify our perspective and assume that the Colombian current account is endogenous and determined by the prevailing trends in their several components. According to the different scenarios we assume, the Colombian current account may actually assume values quite separate from government expectations.

5.3 Capital Account and Current Account Reconciliation

Given the doubts shed on the government-forecasted value of the current account, we pursue our analysis by computing our own forecasts for the current account. We follow equation (1) and keep the government-forecasted values for oil exports and imports but use two different hypotheses for the value of non-oil exports and net factor payments. The left-hand side of figure 10 (below) portrays the dynamics of the current account for these three scenarios. Government-expected current account dynamics (dashed line) remain in stark contrast to alternative records that would emerge in the case where non-oil exports and NFP grow at the same pace as Colombian GDP (dotted line) or, even worse, if they grew according to past trends (dash-dotted line). In these two cases, it becomes strikingly clear that the effective Colombian current account deficit may eventually turn out to be much deeper than expected. The right-hand side of figure 10 determines the needed dynamics of the capital account in order to maintain the Colombian foreign reserve as constant (keeping the current exchange rate constant), according to the various scenarios for the current account dynamics. Should the government’s expectation be confirmed, decreasing net positive capital inflows (as a ratio of GDP) would be more than enough to match the current account deficit and ensure stable

Colombian foreign reserves (small dashed line). In the last decade, Colombia has experienced a remarkable surge in net capital inflows. Things change radically if we assume that the Colombian current account will be the result of non-oil exports and net factor payments moving on par with GDP (dash-dotted line) or, even worse, following past HP trends (long dash line). In both scenarios, Colombia would need constantly growing and indeed mounting capital account surpluses in order to cover the huge current account imbalances.

Figure 10. Current Account and Capital Account under Different Scenarios

Source: Ministry of Finance and Public Credit (2014b), Central Bank of Colombia, and authors' computations

5.4 Foreign Reserves Dynamics

The last exercise we ran was to determine the impact of the various scenarios at hand on the accumulation of foreign reserves, assuming a constant exchange rate. We assume two trends for each account of the balance of payment accounts, thus implying four different scenarios, on top of the governmental forecasts. Table 5 summarizes the various hypothesis made for each scenario.

Table 5. Scenario Description

<i>Scenario</i>	<i>Current Account Hypothesis</i>	<i>Capital Account Hypothesis</i>
1	<i>NFP</i> and <i>X_{NonOil}</i> GDP-based	Government forecasts
2	<i>NFP</i> and <i>X_{NonOil}</i> HP-filter trend	Government forecasts
3	<i>NFP</i> and <i>X_{NonOil}</i> GDP-based	HP-filter trend
4	<i>NFP</i> and <i>X_{NonOil}</i> HP-filter trend	HP-filter trend

The possible increase, or stabilization, of Colombian foreign reserves basically requires foreign net capital inflows to move according to observed dynamics in the current account. If the Colombian current account deficit effectively follows the expected trajectory, decreasing net capital inflows (as a percentage of GDP), in line with government expectations (3.4% of GDP yearly from 2014 to 2015), will ensure a slight increase in foreign reserves (small dashed line). Things improve when foreign capital inflows follow their HP-filter trend (scenario 3 and 4). In such a case, a large capital account surplus will materialize and allow Colombian foreign reserves to increase at the outset, even in the event that non-oil exports and, above all, NFP move at par with GDP (scenario 3). However, in this scenario, the balance of payment surplus turns negative from 2018 onwards and the reserve stock starts decreasing and reaches zero in 2023. In the case of the HP-filter trend of the current account (scenario 4) foreign reserves will actually increase until 2020, where they reach almost US\$83 billion.

However, things may change dramatically in the case of the capital account meeting government forecasts (scenario 1 and 2). If non-oil exports and NFP grow according to GDP growth trends (scenario 1), foreign reserves start decreasing immediately and would turn negative by 2022 (dash-dotted line). Clearly, such a reduction will be even faster should NFP and non-oil exports follow their HP-filter trends (scenario 2).²¹ In such a scenario, Colombian foreign reserves will be driven close to zero by the end of 2019.

²¹ It must be emphasized that, due to the mining-sector boom, the evolution of non-primary exports over the last decade has been particularly disappointing. The share of primary exports (oil, coffee, flowers, bananas, etc.) in total exports rose from 74% in 2001 to 81% in 2012 (Consejo Privado de Competitividad 2013).

Figure 11. Expected Dynamics in Colombian Foreign Reserves Stock (different scenarios)

Source: Ministry of Finance and Public Credit (2014b), Central Bank of Colombia, and authors' computations

6. POLICY OPTIONS

What are the policy implications of these scenarios and expected dynamics in Colombian foreign reserves? In the last decade, the Colombian economy has become far more dependent on the exploitation and exports of its own natural resources in order to pay for increasing imports of capital goods. The exports of oil and related products represent (in 2012) much more than 50% of Colombian exports. According to data provided by DANE (2014), by the end of 2012, foreign imports represent more than 60% of the total supply (domestic production plus imports) of capital goods; this ratio was less than 47% in 2000. Such a deep structural change in the Colombian economy implies that the nominal exchange rate appreciation is a fundamental macroeconomic variable affecting Colombia's capability to invest, accumulate capital stock, and support economic growth. A depreciation of the exchange rate, by making imported capital goods more expensive, could easily curtail investments and growth. In order to avoid such an event taking place, available foreign

reserves play a fundamental role—they are the weapon in the hands of the central bank to defend the domestic currency. A shortage of foreign reserves might start a financial crisis.

Our analysis shows that there is no risk of such events taking place in the near future in Colombia. The right-hand side of figure 8, for instance, reveals that slightly increasing non-oil exports (as a share of GDP) will be enough to compensate for negative NFP and guarantee the Colombian current account will reach the government's target in the next two to three years. Similarly, negative NFP do not need to be immediately reduced in order to ensure an easy management of the Colombian external account and the Colombian peso. Yet, our analysis also shows that some trends characterizing Colombia since the mid-2000s are *unsustainable* in the medium to long run. Should huge profit repatriation continue in the upcoming years according to the astonishing dynamics registered so far, net positive capital inflows will not suffice, even in the best possible scenario, to preserve Colombian foreign reserves or to avoid a possible exchange rate crisis.²²

Furthermore, optimistic government forecasts rely upon a type of “capital account–current account counter-balancing” mechanism that might be suitable in terms of addressing short-term problems, but is likely to give rise to viciously unstable dynamics in the long run. In the end, this may turn out to be the main source of possible financial instability in Colombia. According to Singh (2003, 209), “FDI investment creates foreign exchange liabilities not only now but also into the future. This characteristic leads to the danger that unfettered FDI may create a time profile of foreign exchange outflows (in the form of dividends payments or profit repatriation) and inflows (i.e., fresh FDI), which may be time inconsistent.”

Thus, important current foreign capital inflows, FDI in particular, provide the country with foreign currency flows covering current account deficits and, possibly, stabilizing the exchange rate (or creating room for an exchange rate stabilization). However, they also create the basis for even higher foreign currency outlays in the upcoming years, hence the need for even stronger capital account inflow. The beneficial impact of FDI has a weak basis and may easily break down. Should capital inflow decrease due to a reduction in the natural resource sector's profitability, for example, the fundamental source of foreign currency inflow will dry

²² See Ocampo (2009) on the disruptive effects on the Colombian external account of a possible reduction in the price of primary commodities.

up while the foreign currency outflow still exists. This is the kind of risk Singh puts forward and which Colombia may face in the medium/long run.

In order to be able to tackle such possible undesirable outcomes in advance, two policy measures come to mind. They are strictly linked each other. First, Colombia should reduce its dependence on FDI as both a source of foreign currency inflow and productive investment. To clarify this point, this does not imply that Colombia should discourage FDI from taking place, in particular that which may lead to a diversification of its productive and export pattern. We are simply suggesting that FDI should represent only part, and perhaps not the most relevant part, of Colombian capital accumulation and development processes, together with productive initiatives undertaken by domestic participants. Second, and in accordance with the previous point, the Colombian government should implement policies that significantly diversify the export base. The Colombian government foresees a reduction in the production of oil starting in 2017 onwards. There is no guarantee that the dynamics of non-oil exports (including other primary commodities) will be sustainable enough to avoid a widening current account deficit from taking place, nor to pay for increased repatriation of foreign companies' profits. The expansion of the Colombian product and export space may provide the required dynamics. In the end, such a strategy would be absolutely in line with the most recent evidence on successful episodes of long-run economic development. It is the kind of goods exported that matters for growth (Hausmann, Huang, and Rodrik 2007), and product diversification characterizes a relevant part of the development process (Imbs and Wacziarg 2003; Rodrik 2007). This is even more relevant to the present case since, according to Hernandez Jimenez and Razmi (2014), Colombia is among those Latin American economies in which an improvement in the trade account, perhaps via export diversification, provides a fundamental spur to economic growth. Apparently Colombia has followed a radically different development pattern from that outlined above, which has put too much emphasis on the exploitation of domestic natural resources as its main source of economic growth (the so called "*locomotora minera-energetica*").

It might be wise for Columbia to use natural resource revenues to support a clear diversification strategy that could, at least partially, rebalance the development strategy it has followed so far.
