**Abstract.** Particle water and pH are predicted using meteorological observations (relative humidity (RH), temperature ( $T$ )), gas/particle composition, and thermodynamic modeling (ISORROPIA-II). A comprehensive uncertainty analysis is included, and the model is validated. We investigate mass concentrations of particle water and related particle pH for ambient fine-mode aerosols sampled in a relatively remote Alabama forest during the Southern Oxidant and Aerosol Study (SOAS) in summer and at various sites in the southeastern US during different seasons, as part of the Southeastern Center for Air Pollution and Epidemiology (SCAPE) study. Particle water and pH are closely linked; pH is a measure of the particle  $H^+$  aqueous concentration and depends on both the presence of ions and amount of particle liquid water. Levels of particle water, in turn, are determined through water uptake by both the ionic species and organic compounds. Thermodynamic calculations based on measured ion concentrations can predict both pH and liquid water but may be biased since contributions of organic species to liquid water are not considered. In this study, contributions of both the inorganic and organic fractions to aerosol liquid water were considered, and predictions were in good agreement with measured liquid water based on differences in ambient and dry light scattering coefficients (prediction vs. measurement: slope = 0.91, intercept =  $0.5 \mu\text{g m}^{-3}$ ,

$R^2 = 0.75$ ). ISORROPIA-II predictions were confirmed by good agreement between predicted and measured ammonia concentrations (slope = 1.07, intercept =  $-0.12 \mu\text{g m}^{-3}$ ,  $R^2 = 0.76$ ). Based on this study, organic species on average contributed 35 % to the total water, with a substantially higher contribution (50 %) at night. However, not including contributions of organic water had a minor effect on pH (changes pH by 0.15 to 0.23 units), suggesting that predicted pH without consideration of organic water could be sufficient for the purposes of aqueous secondary organic aerosol (SOA) chemistry. The mean pH predicted in the Alabama forest (SOAS) was  $0.94 \pm 0.59$  (median 0.93). pH diurnal trends followed liquid water and were driven mainly by variability in RH; during SOAS nighttime pH was near 1.5, while daytime pH was near 0.5. pH ranged from 0.5 to 2 in summer and 1 to 3 in the winter at other sites. The systematically low pH levels in the southeast may have important ramifications, such as significantly influencing acid-catalyzed reactions, gas–aerosol partitioning, and mobilization of redox metals and minerals. Particle ion balances or molar ratios, often used to infer pH, do not consider the dissociation state of individual ions or particle liquid water levels and do not correlate with particle pH.

## 1 Introduction

The concentration of the hydronium ion ( $H^+$ ) in aqueous aerosols, or pH, is an important aerosol property that drives many processes related to particle composition and gas–aerosol partitioning (Jang et al., 2002; Meskhidze et al., 2003; Gao et al., 2004; Iinuma et al., 2004; Tolocka et al., 2004; Edney et al., 2005; Czoschke and Jang, 2006; Kleindienst et al., 2006; Surratt et al., 2007; Eddingsaas et al., 2010; Surratt et al., 2010). Measurement of pH is highly challenging, and so indirect proxies are often used to represent particle acidity. The most common is an ion balance: the charge balance of measurable cations and anions (excluding the hydronium ion). Although correlated with an acidic (net negative balance) or alkaline (net positive balance) aerosol (Surratt et al., 2007; Tanner et al., 2009; Pathak et al., 2011; Yin et al., 2014), an ion balance cannot be used as a measure of the aerosol concentration of  $H^+$  in air (i.e., moles  $H^+$  per volume of air, denoted hereafter as  $H_{\text{air}}^+$ ). This is due to two factors: first, an ion balance assumes all ions are completely dissociated, but multiple forms are possible, depending on pH (e.g., sulfate can be in the form of  $H_2SO_4$ ,  $HSO_4^-$ , or  $SO_4^{2-}$ ); second, pH depends on the particle liquid water content (LWC), as pH is the concentration of  $H^+$  in an aqueous solution. LWC can vary considerably over the course of a day and between seasons, significantly influencing pH (Seinfeld and Pandis, 2006). Aerosol thermodynamic models, such as ISORROPIA-II (Nenes et al., 1998; Fountoukis and Nenes, 2007) and E-AIM (Clegg et al., 1998), are able to calculate LWC and particle pH – based on concentrations of various aerosol species, temperature ( $T$ ), and relative humidity (RH) – and offer a more rigorous approach to obtain aerosol pH (Pye et al., 2013). ISORROPIA-II calculates the composition and phase state of an  $NH_4^+ - SO_4^{2-} - NO_3^- - Cl^- - Na^+ - Ca^{2+} - K^+ - Mg^{2+}$ –water inorganic aerosol in thermodynamic equilibrium with water vapor and gas-phase precursors. The model has been tested with ambient data to predict acidic or basic compounds, such as  $NH_3(g)$ ,  $NH_4^+$ , and  $NO_3^-$  (Meskhidze et al., 2003; Nowak et al., 2006; Fountoukis et al., 2009; Hennigan et al., 2015).

LWC is a function of RH, particle concentration, and composition, and it is the most abundant particle-phase species in the atmosphere, at least 2–3 times the total aerosol dry mass on a global average (Pilinis et al., 1995; Liao and Seinfeld, 2005). At 90 % RH, the scattering cross section of an ammonium sulfate particle can increase by a factor of 5 or more above that of the dry particle, due to large increases in size from water uptake (Malm and Day, 2001). Because of this, LWC is the most important contributor to direct radiative cooling by aerosols (Pilinis et al., 1995), currently thought to be  $-0.45 \text{ W m}^{-2}$  ( $-0.95$  to  $+0.05 \text{ W m}^{-2}$ ) (IPCC, 2013). LWC plays a large role in secondary aerosol formation for inorganic and possibly organic species by providing a large aqueous surface for increased gas uptake and a liquid

phase where aqueous-phase chemical reactions can result in products of lower vapor pressures than the absorbed gases (Seinfeld and Pandis, 2006; Ervens et al., 2011; Nguyen et al., 2013). In the eastern USA, it has been suggested that the potential for organic gases to partition to LWC is greater than the potential to partition to particle-phase organic matter (Carlton and Turpin, 2013), and partitioning of water-soluble organic carbon (WSOC) into the particle phase becomes stronger as RH (i.e., LWC) increases (Hennigan et al., 2008). Thus LWC enhances particle scattering effects directly by increasing particle cross sections (Nemesure et al., 1995) and indirectly by promoting secondary aerosol formation (Ervens et al., 2011; Nguyen et al., 2013).

The behavior of inorganic salts under variable RH is well established both experimentally and theoretically. It is known that dry inorganic salts (or mixtures thereof) exhibit a phase change, called deliquescence, when exposed to RH above a characteristic value. During deliquescence, the dry aerosol spontaneously transforms (at least partially) into an aqueous solution (Tang, 1976; Wexler and Seinfeld, 1991; Tang and Munkelwitz, 1993). In contrast, due to its chemical complexity that evolves with atmospheric aging, the relationship of organics to LWC is not well characterized and requires a parameterized approach (Petters and Kreidenweis, 2007). Relationships between volatility, oxidation level, and hygroscopicity are not always straightforward and still remain to be fully understood (Frosch et al., 2011; Villani et al., 2013; Cerully et al., 2014; Hildebrandt Ruiz et al., 2014). Despite the abundance and importance of LWC, it is not routinely measured. Thus typically, particle total mass concentration (that includes liquid water) is often not characterized. In general, LWC is measured by perturbing the in situ RH. The loss of particle volume when RH is lowered is assumed to be solely due to evaporated water. Approaches for LWC measurements are classified into single-particle-size probes and bulk size quantification (Sorooshian et al., 2008). Single-particle-size probes provide more information, i.e., size-resolved hygroscopic growth, and usually tend to be slow due to whole size range scanning. In contrast, bulk size measurements quantify the total water amount directly. The LWC measurement presented in this paper by nephelometers is a bulk measurement.

As part of the Southern Oxidant and Aerosol Study (SOAS), we made detailed measurements of particle organic and inorganic composition (Xu et al., 2015), and aerosol hygroscopicity (Cerully et al., 2014), and indirect measurements of particle LWC. These data are used to first determine the particle water mass concentrations, which are then utilized in a thermodynamic model for predicting pH. The fine-particle LWC and pH data from this analysis are used in our other studies of secondary aerosol formation as part of SOAS and discussed in companion papers to this work (Cerully et al., 2014; Xu et al., 2015).

## 2 Data collection

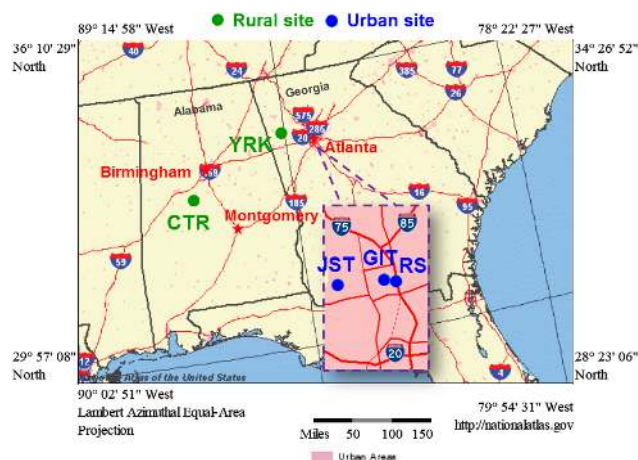

### 2.1 Measurement sites

Aerosol measurements were conducted at the Southeastern Aerosol Research and Characterization (SEARCH) Centreville site (CTR; 32.90289° N, 87.24968° W; altitude: 126 m), located in Brent, Alabama, as part of SOAS (<http://soas2013.rutgers.edu>). SOAS ground measurements were made from 1 June to 15 July in the summer of 2013. CTR is a rural site within a large forested region dominated by biogenic volatile organic compound (VOC) emissions, with minor local anthropogenic emissions and some plumes transported from other locations (coal-fired electrical generating units, urban emissions, biomass burning, mineral dust). It is representative of background conditions in the southeastern US and chosen to investigate biogenic secondary organic aerosol (SOA) formation and its interaction with anthropogenic pollution transported from other locations.

Additional measurements were also made at various sampling sites in and around the metropolitan Atlanta region from May 2012 to December 2012 as part of a large health study: the Southeastern Center for Air Pollution and Epidemiology (SCAPE). A map of all five sites is shown in Fig. 1. The SCAPE measurement sites include

1. a road-side (RS) site (33.775602° N, 84.390957° W), situated within 5 m from the interstate highway (I75/85) in midtown Atlanta and chosen to capture fresh traffic emissions;
2. a near-road site (GIT site, 33.779125° N, 84.395797° W), located on the rooftop of the Ford Environmental Science and Technology (EST) building at Georgia Institute of Technology (GIT), Atlanta, roughly 30 to 40 m above ground level, 840 m from the RS site;
3. Jefferson Street (JST) (33.777501° N, 84.416667° W), a central SEARCH site representative of the Atlanta urban environment, located approximately 2000 m west of the GIT site;
4. Yorkville (YRK) (33.928528° N, 85.045483° W), the rural SEARCH pair of JST, situated in an agricultural region approximately 70 km west from the JST, GIT, and RS sites.

More information on the SEARCH sites can be found elsewhere (Hansen et al., 2003; Hansen et al., 2006). We first focus on the SOAS campaign data, where a wide range of instrumentation was deployed (<http://soas2013.rutgers.edu>) to develop a comprehensive method of predicting LWC and pH, as well as assessing their uncertainties. The approach is then applied to the SCAPE site data to provide a broader spatial and temporal assessment of PM<sub>2.5</sub> pH in the southeastern US.

**Figure 1.** Sampling sites in the southeastern USA, consisting of two rural and three urban sites.

### 2.2 Instrumentation

#### 2.2.1 PILS-IC

PM<sub>2.5</sub> or PM<sub>1</sub> (particles with aerodynamic diameters < 2.5 or 1.0 μm at ambient conditions) water-soluble ions were measured by a particle-into-liquid sampler coupled to an ion chromatograph (PILS-IC; Metrohm 761 Compact IC). Similar setups are described in previous field studies (Orsini et al., 2003; Liu et al., 2012). Metrosep A Supp-5, 150/4.0 anion column and C 4, 150/4.0 cation column (Metrohm USA, Riverside, FL) were used to separate the PILS liquid sample anions (sulfate, nitrate, chloride, oxalate, acetate, formate) and cations (ammonium, sodium, potassium, calcium, magnesium) at a 20 min duty cycle. The PILS sample ambient air flow rate was 16.8 ± 0.4 L min<sup>-1</sup>. URG (Chapel Hill, NC) cyclones were used to provide PM cut sizes of PM<sub>2.5</sub> for the first half of field study (1 June to 22 June) and PM<sub>1</sub> for the latter half (23 June to 15 July). Honeycomb acid (phosphoric acid)- and base (sodium carbonate)-coated denuders removed interfering gases before entering the PILS. The sample inlet was ~ 7 m above ground level and ~ 4 m long. The sampling line was insulated inside the trailer (typical indoor *T* was 25 °C) and less than 1 m in length to minimize possible changes in aerosol composition prior to measurement. Periodic 1 h blank measurements were made every day by placing a HEPA filter (Pall Corp.) on the cyclone inlet. All data were blank-corrected. The PILS IC was only deployed for the SOAS study.

#### 2.2.2 AMS

A high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS, Aerodyne Research Inc., hereafter referred to as “AMS”) provided real-time, quantitative measurements of the non-refractory components of submicron aerosols (DeCarlo et al., 2006; Canagaratna et al., 2007). In brief, par-

ticles were first dried ( $\text{RH} < 20\%$ ) and then immediately sampled through an aerodynamic lens into the high vacuum region of the mass spectrometer, then transmitted into a detection chamber where particles impact on a hot surface ( $600\text{ }^\circ\text{C}$ ). Non-refractory species are flash-vaporized and then ionized by  $70\text{ eV}$  electron impact ionization. The generated ions are extracted into the time-of-flight mass spectrometer. Further details on the AMS setup and data processing can be found in Xu et al. (2015).

### 2.2.3 CCNc

The particle hygroscopic parameter,  $\kappa$  (Petters and Kreidenweis, 2007), used to infer the hygroscopic properties (liquid water associated with organics), was obtained from size-resolved CCN measurements from a Droplet Measurement Technologies continuous-flow streamwise thermal gradient cloud condensation nuclei counter (CFSTGC, referred to hereafter as CCNc) (Roberts and Nenes, 2005; Lance et al., 2006). The CCNc exposes aerosols to a known supersaturation and then counts the activated particles that grow rapidly to droplet size. Köhler theory can be used to parameterize the water-phase properties (here, expressed by  $\kappa$ ; Petters and Kreidenweis, 2007) of the organic aerosol, based on the size of particles that form CCN and their composition. A URG (Chapel Hill, NC)  $\text{PM}_1$  cyclone was installed for both AMS and CCNc. The details of the CCNc setup and data analysis procedure can be found in Cerully et al. (2014).

### 2.2.4 Ambient vs. dry nephelometers

$\text{PM}_{2.5}$  (URG cyclones) aerosol light scattering coefficients ( $\sigma_{\text{sp}}$ ) were measured online with two different nephelometers (Radiance Research M903) to infer LWC. Both were operated at nominally  $3\text{ L min}^{-1}$ . Particle dry scattering was measured with a nephelometer located in the air-conditioned sampling trailer operated with a nafion dryer upstream that maintained an RH of  $32 \pm 2\%$  (study mean  $\pm$  SD,  $n = 12\,464$  based on 5 min averages). The other was situated in a small white three-sided wooden shelter (one side covered by a loose tarp) located a distance away from all buildings to provide a scattering measurement at ambient  $T$  and RH. Both  $\text{PM}_{2.5}$  cut cyclones were located in ambient conditions, and both nephelometers were calibrated by  $\text{CO}_2$  prior to the SOAS field campaign. Typical uncertainty is 3% for scattering coefficients (Mitchell et al., 2009). In addition, the nephelometer RH sensors were calibrated by placing the sensors in a closed container above aqueous saturated salt solutions that had reached equilibrium (measurements made in a thermally insulated container after a period of a few hours). Solution temperatures were monitored. Details on the calibration results are provided in the Supplement Sect. 1. Recorded RH was corrected by the calibration results.

The deployment status of the above instruments at the SOAS and SCAPE sites are summarized in Table 1.

### 2.3 Determining LWC from nephelometers

Particle water was inferred from the ratio of ambient and dry  $\text{PM}_{2.5}$  scattering coefficients ( $\sigma_{\text{sp}}$ ) measured by the two nephelometers (defined here as aerosol hygroscopic growth factor,  $f(\text{RH}) = \sigma_{\text{sp}(\text{ambient})}/\sigma_{\text{sp}(\text{dry})}$ , where  $\sigma_{\text{sp}(\text{ambient})}$  and  $\sigma_{\text{sp}(\text{dry})}$  are particle scattering coefficients at ambient and dry RH conditions, respectively) following the method developed by other investigators (Carrico et al., 1998; Kotchenruther and Hobbs, 1998; Carrico et al., 2000; Malm and Day, 2001; Sheridan et al., 2002; Magi and Hobbs, 2003; Kim et al., 2006). A difference between ambient and dry scattering coefficients is assumed to be caused solely by loss of water. Detailed derivations are provided in the Supplement.  $f(\text{RH})$  is related to the particle scattering efficiencies ( $Q_s$ ) and average particle diameter ( $\overline{D_p}$ ) by

$$\overline{D_{p,\text{ambient}}} = \overline{D_{p,\text{dry}}} \sqrt{f(\text{RH}) \overline{Q_{s,\text{dry}}} / \overline{Q_{s,\text{ambient}}}}. \quad (1)$$

$\overline{Q_{s,\text{ambient}}}$ ,  $\overline{D_{p,\text{ambient}}}$  are the average scattering efficiency and average particle diameter under ambient conditions, while  $\overline{Q_{s,\text{dry}}}$ ,  $\overline{D_{p,\text{dry}}}$  represent dry conditions. The method is based on fine-particle light scattering being mostly due to particles in the accumulation mode and can be related to scattering efficiencies and the diameter of average surface, for both ambient and dry particle size distributions. Assuming that  $\overline{Q_{s,\text{ambient}}} = \overline{Q_{s,\text{dry}}}$  (see Supplement Sect. 2 for justification and uncertainty analysis), it follows then that

$$\overline{D_{p,\text{ambient}}} = \overline{D_{p,\text{dry}}} \sqrt{f(\text{RH})}. \quad (2)$$

Since the LWC is equal to the difference between ambient and dry particle volume, we get

$$f(\text{RH})_{\text{water}} = \left[ f(\text{RH})^{1.5} - 1 \right] m_p \rho_w / \rho_p, \quad (3)$$

where  $m_p$  and  $\rho_p$  are dry particle mass and density, respectively;  $\rho_w$  is water density (constant  $1\text{ g cm}^{-3}$  is applied). For SOAS, dry  $\text{PM}_{2.5}$  mass concentrations were measured continuously by a TEOM (tapered element oscillating microbalance, 1400a, Thermo Fisher Scientific Inc., operated by Atmospheric Research & Analysis Inc., referred to hereafter as ARA). Particle density,  $\rho_p$ , was computed from the particle composition, including AMS total organics, ammonium, and sulfate, which accounted for 90% of the measured  $\text{PM}_{2.5}$  (TEOM) dry mass (SOAS study mean). A typical organic density  $1.4\text{ g cm}^{-3}$  is assumed (Turpin and Lim, 2001; King et al., 2007; Engelhart et al., 2008; Kuwata et al., 2012; Cerully et al., 2014), and the density of ammonium sulfate is assumed to be  $1.77\text{ g cm}^{-3}$  (Sloane et al., 1991; Stein et al., 1994).  $\rho_p$  was calculated to be  $1.49 \pm 0.04\text{ g cm}^{-3}$

**Table 1.** Deployment status of instruments at various sites. All the listed instruments or probes were operated at CTR for SOAS.

Site	Period	PILS-IC	AMS	CCNc	Nephelometer	TEOM	RH & T
JST	May & Nov 2012	No	Yes	No	No	Yes	Yes
YRK	Jul & Dec 2012	No	Yes	No	No	Yes	Yes
GIT	Jul–Aug 2012	No	Yes	No	No	Yes	Yes
RS	Sep 2012	No	Yes	No	No	Yes	Yes
CTR	Jun–Jul 2013	Yes	Yes	Yes	Yes	Yes	Yes

( $n = 4393$ ) using mass fractions ( $\varepsilon$ ):

$$\rho_p = \frac{1}{\varepsilon(\text{NH}_4^+ + \text{SO}_4^{2-})/1.77 + \varepsilon(\text{Organics})/1.4} \quad (4)$$

The time-resolved composition data show that dry-particle density did not have a significant diurnal variability ( $\pm 2.7\%$ , SD/mean, Supplement Fig. S2). In the following we refer to the particle water calculated by this method as  $f(\text{RH})_{\text{water}}$ . The uncertainty of  $f(\text{RH})_{\text{water}}$  is estimated to be 15%, mainly caused by the calculation of  $\overline{Q_{s,\text{ambient}}}/\overline{Q_{s,\text{dry}}}$  (LWC error of 10% from assuming  $\overline{Q_{s,\text{ambient}}}/\overline{Q_{s,\text{dry}}} = 1$ ; see Supplement),  $m_p$  (10%),  $\sigma_{\text{sp}(\text{ambient})}/\sigma_{\text{sp}(\text{dry})}$  (4.2%) (uncertainty for a single  $\sigma_{\text{sp}}$  measurement is 3%; Mitchell et al., 2009), and  $\rho_p$  (2.7%). Note that LWC error depends on RH, and for SOAS average aerosol composition could increase to 21% for RH > 90% (Supplement Fig. S6).

### 3 Modeling methods: predicting LWC and pH from aerosol composition

In most studies, such as SCAPE, particle water was not measured and must be determined based on aerosol composition. Both inorganic and organic components contribute to uptake of water vapor, establishing equilibrium for the ambient RH and  $T$  conditions. Thus, LWC is controlled by meteorological conditions and also by aerosol concentration and composition. Thermodynamic models, such as ISORROPIA-II, have been extensively used to predict LWC due to inorganic aerosol components (Fountoukis and Nenes, 2007). Contributions to LWC by organic components are typically based on an aerosol hygroscopicity parameter,  $\kappa$ , which is determined by CCN data. Here we refer to particle water associated with inorganics and organics as  $W_i$  and  $W_o$ , respectively. Total particle water ( $W_i + W_o$ ) is taken as the sum of water associated with individual aerosol chemical components (sum of ions and lumped organics) based on the Zdanovskii–Stokes–Robinson (ZSR) relationship (Zdanovskii, 1936; Stokes and Robinson, 1966), with the assumption that the particles are internally mixed. The assumptions made in our analysis were discussed in Sect. 3.4.

#### 3.1 LWC from inorganic species

Particle water associated with inorganic species ( $W_i$ ) were predicted by ISORROPIA-II (Nenes et al., 1998; Fountoukis and Nenes, 2007). ISORROPIA-II calculates the composition and phase state of a  $\text{K}^+ - \text{Ca}^{2+} - \text{Mg}^{2+} - \text{NH}_4^+ - \text{Na}^+ - \text{SO}_4^{2-} - \text{NO}_3^- - \text{Cl}^-$ -water inorganic aerosol in thermodynamic equilibrium with gas-phase precursors. Chemical and meteorological data are necessary inputs. For our analysis at CTR, the inputs to ISORROPIA-II are the inorganic ions measured by the IC or AMS, RH measured by the outside nephelometer, and temperature from the SEARCH site (ARA) meteorological data.

#### 3.2 LWC from organic fraction

To determine the contributions to particle water by  $W_o$ , in SOAS the organic hygroscopicity parameter ( $\kappa_{\text{org}}$ ) was calculated based on the observed CCN activities of the organic fraction (Cerully et al., 2014). In the following analysis diurnal 3 h running averages are used in the calculation. (Diurnal plot is included in the Supplement as Fig. S7).  $W_o$  is calculated using the following equation (Petters and Kreidenweis, 2007):

$$W_o = \frac{m_{\text{org}} \rho_w}{\rho_{\text{org}}} \frac{\kappa_{\text{org}}}{(1/\text{RH} - 1)}, \quad (5)$$

where  $m_{\text{org}}$  is the organic mass concentration from AMS (Xu et al., 2015),  $\rho_w$  is water density, and a typical organic density ( $\rho_{\text{org}}$ ) of  $1.4 \text{ g cm}^{-3}$  is used (Turpin and Lim, 2001; King et al., 2007; Engelhart et al., 2008; Kuwata et al., 2012; Cerully et al., 2014).

#### 3.3 pH prediction

The thermodynamic model ISORROPIA-II (Fountoukis and Nenes, 2007) calculates the equilibrium particle hydronium ion concentration per volume air ( $\text{H}_{\text{air}}^+$ ), which along with the LWC is then used to predict particle pH. To correct for the LWC associated with the organic aerosol (not considered in ISORROPIA-II), we recalculate pH by considering  $\text{H}_{\text{air}}^+$  and total predicted water ( $W_i$  and  $W_o$ ).

The modeled concentrations are micrograms per cubic meter ( $\mu\text{g m}^{-3}$ ) air for  $\text{H}_{\text{air}}^+$  and LWC. The pH is, then,

$$\text{pH} = -\log_{10} \text{H}_{\text{aq}}^+ = -\log_{10} \frac{1000 \text{H}_{\text{air}}^+}{W_i + W_o}, \quad (6)$$

where  $\text{H}_{\text{aq}}^+$  ( $\text{mol L}^{-1}$ ) is hydronium concentration in an aqueous solution.  $\text{H}_{\text{air}}^+$  and  $W_i$  are the output of ISORROPIA-II based on input of water-soluble ions, RH, and  $T$ .  $\text{H}_{\text{aq}}^+$  is  $\text{H}_{\text{air}}^+$  divided by the LWC, and so including  $W_o$  decreases  $\text{H}_{\text{aq}}^+$  by a factor of  $W_o/(W_i + W_o)$ , relative to only considering  $W_i$ .

ISORROPIA-II has been tested in previous field campaigns where a suite of both gas and particle components were measured (Nowak et al., 2006; Fountoukis et al., 2009). The model was able to predict the equilibrium partitioning of ammonia (Nowak et al., 2006) in Atlanta and nitric acid (Fountoukis et al., 2009) in Mexico City within measurement uncertainty. For instance,  $\text{NH}_{3(\text{g})}$ ,  $\text{NH}_4^+$ ,  $\text{HNO}_{3(\text{g})}$ , and  $\text{NO}_3^-$  were within 10, 20, 80, and 20 % of measurements (Fountoukis et al., 2009). In this study, ISORROPIA-II was run in the “forward mode” for metastable aerosol. Forward mode calculates the equilibrium partitioning given the total concentration of various species (gas + particle) together with RH and  $T$  as input. Reverse mode involves predicting the thermodynamic composition based only on the aerosol composition. Here we use the forward mode with just aerosol-phase data input because it is less sensitive to measurement error than the reverse mode (Hennigan et al., 2015). The  $W_i$  prediction remains the same (reverse vs. forward: slope = 0.993, intercept =  $-0.005 \mu\text{g m}^{-3}$ , and  $R^2 = 0.99$ ) no matter which approach is used. Gas-phase input does have an important impact on the  $\text{H}_{\text{air}}^+$  calculation. ISORROPIA-II was tested with ammonia partitioning, which is discussed in more detail below. Here it is noted that we found that further constraining ISORROPIA-II with measured  $\text{NH}_{3(\text{g})}$  (You et al., 2014) resulted in a pH increase of 0.8 at CTR and that the predicted  $\text{NH}_{3(\text{g})}$  matched the measured  $\text{NH}_{3(\text{g})}$  well (slope = 1.07, intercept =  $-0.12 \mu\text{g m}^{-3}$ ,  $R^2 = 0.76$ ). This also confirms that ISORROPIA-II predicts the pH in the ambient aerosol with reasonable accuracy, as inputting the total (gas + aerosol) ammonium results in predictions that agree with those observed. This is also in agreement with findings of Hennigan et al. (2015) and Fountoukis et al. (2009), both of whom found that ISORROPIA-II reproduced the partitioning of ammonia and inorganic nitrate in Mexico City during the Megacity Initiative: Local and Global Research Observations (MILARGO) campaign.

### 3.4 Assumptions

In the following analysis we use bulk properties and do not consider variability in parameters with particle size. Particulate organic and inorganic species are assumed to be internally mixed in the liquid phase due to the high RH ( $74 \pm 16\%$ ) typical of this study and because a large frac-

**Figure 2.** Comparisons of  $\text{PM}_1$  AMS sulfate, ammonium to  $\text{PM}_1$  and  $\text{PM}_{2.5}$  PILS-IC (i.e., complete SOAS study) and predicted  $W_i$ . Orthogonal distance regression (ODR) fits were applied.

tion of the ambient aerosol organic component is from isoprene SOA (Xu et al., 2015), which are liquids at  $\text{RH} \geq 60\%$  (Song et al., 2015). Particle liquid-phase separations are not considered, although they have been measured in bulk extracts of aerosols from the southeast (You et al., 2012). It is reported that liquid–liquid phase separation can occur when the O:C ratio of the organic material is  $\leq 0.5$ . More experiments showed that it is possible to have phase separation for  $\text{O}:\text{C} \leq 0.7$ , but not for  $\text{O}:\text{C} \geq 0.8$  (Bertram et al., 2011; Song et al., 2012; You et al., 2013). SOAS average  $\text{O}:\text{C} = 0.75 (\pm 0.12)$  is in the transition between these two regimes. According to Fig. 2 in Bertram et al. (2011), at RH typically  $> 60\%$  and organic:sulfate mass ratio  $> 1$ , it is not possible to have phase separation, which is the case for our sampling sites. Based on our basic assumption of no liquid–liquid phase separation, pH is considered to be homogeneous in a single particle. However, separated phases would likely have different pHs if liquid–liquid phase separation occurs. In that case, pH should be calculated based on the amounts of water and  $\text{H}_{\text{air}}^+$  in each phase. Gas–particle phase partitioning will change accordingly, due to these separated phases. There are models that are set up to calculate these thermodynamics (e.g., AIOMFAC), but none is yet able to address the compositional complexity of ambient SOA (Zuend et al., 2010; Zuend and Seinfeld, 2012). Although it is often true that non-ideal interactions between organic and inorganic species exist, good agreement between measured particle water and ammonia partitioning to predictions using the bulk properties (discussed below) suggests these assumptions are reasonable.

## 4 Results

### 4.1 Overall summary of meteorology and PM composition at SOAS and SCAPE sites

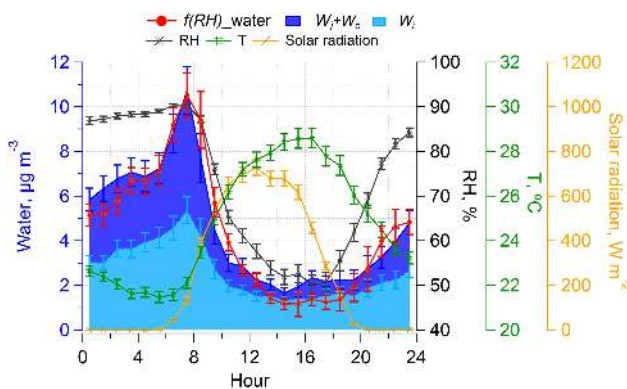

For the SOAS study period, mean  $T$  and RH were  $25 \pm 3^\circ$  and  $74 \pm 16\%$  (mean  $\pm$  SD), respectively. This resulted in a  $f(\text{RH})_{\text{water}}$  level of  $4.5 \pm 3.8 \mu\text{g m}^{-3}$ , with a maximum value of  $28.4 \mu\text{g m}^{-3}$ . In comparison, SOAS mean dry  $\text{PM}_{2.5}$  mass was  $7.7 \pm 4.6 \mu\text{g m}^{-3}$ , implying that the fine aerosols were roughly composed of 37 % water, on average. Mean  $T$  and RH for SCAPE sites are listed in Table 3. Summer  $T$

means were all above 21°, including CTR. RH means were all high (> 60 %) for summer and winter, which is typical for the southeastern US.

Of the sites in the southeastern US discussed in this paper, CTR was the least influenced by anthropogenic emissions having the lowest black carbon (BC) concentrations (measured by a MAAP, Thermo Scientific, model 5012). At CTR, the mean BC =  $0.3 \pm 0.2 \mu\text{g m}^{-3}$  ( $\pm$ SD), whereas mean BC concentrations at the other rural site (YRK) was  $0.4 \mu\text{g m}^{-3}$ . The representative Atlanta site (JST) BC was on average  $0.7 \mu\text{g m}^{-3}$ , and higher for sites closer to roadways:  $1.0 \mu\text{g m}^{-3}$  (GIT) and  $2.0 \mu\text{g m}^{-3}$  (RS).

A more comprehensive suite of ions will provide a better prediction of  $W_i$ . However, in the southeastern USA, inorganic ions are currently dominated by sulfate and ammonium. During SOAS, the PILS-IC provided a more comprehensive and accurate measurement of water-soluble ions than AMS, which measured only non-refractory sulfate, ammonium, nitrate, and chloride. Refractory but water-soluble ions, such as sodium and associated chloride, and crustal elements including calcium, potassium, and magnesium were present in  $\text{PM}_{10}$ , but in very low concentrations. Contributions of these ions are more important in  $\text{PM}_{2.5}$  than for  $\text{PM}_{10}$ , which tend to reduce aerosol acidity. For instance,  $\text{Na}^+$  has a significantly higher mean in  $\text{PM}_{2.5}$  at  $0.056 \mu\text{g m}^{-3}$  (first half of SOAS study) than  $0.001 \mu\text{g m}^{-3}$  in  $\text{PM}_{10}$  (second half of SOAS study). Four 1-day-long dust events (12, 13, 16, and 21 June) in the SOAS data set have been excluded from this analysis as assumptions relating to internal mixing of  $\text{PM}_{2.5}$  components are less valid in these cases. Excluding these days, the mean  $\text{Na}^+$  in  $\text{PM}_{2.5}$  drops to  $0.024 \mu\text{g m}^{-3}$ .

If the fraction of the refractory ions (e.g.,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ) is negligible compared to the  $\text{SO}_4$  (note that  $\text{SO}_4$  stands for sulfate in all its possible forms, from free to completely dissociated),  $\text{NH}_4^+$ , and  $\text{NO}_3^-$ , the AMS data sufficiently constrain particle composition for thermodynamic calculations; this apparently is the case for most of the time in the southeast (Supplement Sect. 4). For  $\text{PM}_{10}$   $\text{SO}_4$  and  $\text{NH}_4^+$ , AMS and PILS-IC were in good agreement ( $\text{SO}_4$  slopes within 20 %,  $R^2 = 0.90$ ;  $\text{NH}_4^+$  within 1 %,  $R^2 = 0.81$ ). Similar agreement was also found for AMS  $\text{PM}_{10}$   $\text{SO}_4$  and  $\text{NH}_4^+$  versus PILS-IC  $\text{PM}_{2.5}$   $\text{SO}_4$  and  $\text{NH}_4^+$  (see Fig. 2 for comparison of complete data set). These data indicate little  $\text{SO}_4$  and  $\text{NH}_4^+$  between the 1.0 and  $2.5 \mu\text{m}$  size range ( $\text{PM}_{2.5}$ – $\text{PM}_{10}$ ). Because of the agreement between these dominant ions, ISORROPIA-II predicted  $W_i$  for all ions measured with the PILS-IC throughout the study (includes both  $\text{PM}_{10}$  and  $\text{PM}_{2.5}$ ) agreed with  $W_i$  based on AMS inorganic species (i.e., only ammonium and sulfate) having an orthogonal slope of 1.18 (Fig. 2c).

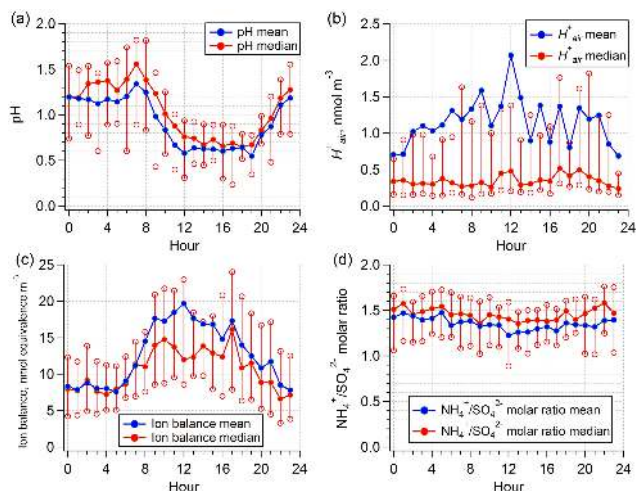

**Figure 3.** CTR (SOAS) diurnal profiles of predicted and measured water, measured RH,  $T$ , and solar radiation. Median hourly averages are shown, and standard errors are plotted as error bars.

## 4.2 Results from the SOAS Centreville site

### 4.2.1 LWC, pH, and ion balances at Centreville

The diurnal variation of LWC contributed by  $W_i$  and  $W_o$ , along with total measured water, ambient  $T$ , RH, and solar radiation at CTR is shown in Fig. 3. Predicted and measured LWC trends were in good overall agreement, although the largest discrepancy was observed during the daytime, when the LWC level was low and more difficult to measure and accurately predict. Nighttime RH median values were between 85 and 90 % and resulted in significant water uptake that reached a peak just after sunrise near 07:30 (local time). The dramatic peak in LWC starting at roughly 05:00 and reaching a maximum between 07:30 and 08:00 is likely due to RH increasing above 90 %, at which point uptake of water rapidly increases with increasing RH. The similar rapid hygroscopic growth before sunrise was also observed here at GIT, RS, and JST (November) (Fig. 11). After sunrise, rising temperatures led to a rapid drop in RH, resulting in rapid loss of particle water. LWC reached lowest levels ( $\sim 2 \mu\text{g m}^{-3}$ ) in the afternoon, only 20 % of the peak value.  $W_o$  varied more than  $W_i$  diurnally;  $W_o$  max / min ratio was 13.1, compared to 4.1 for  $W_i$ .

At CTR, the aerosol was highly acidic, with predicted mean pH =  $0.94 \pm 0.59$  ( $\pm$ SD). The minimum and maximum pH were  $-0.94$  and  $2.23$ , respectively, and pH varied by approximately 1 on average throughout the day (Fig. 4a); that is, the  $\text{H}_{\text{air}}^+ / \text{LWC}$  ratio increased by a factor of 10 from night to day. LWC max / min ratio was 5, whereas  $\text{H}_{\text{air}}^+$  diurnal variation was significantly less (Fig. 4b), indicating that the diurnal pattern in pH was mainly driven by particle water dilution. This is further demonstrated in Fig. 4d, which shows the diurnal variation in the  $\text{NH}_4^+ / \text{SO}_4^{2-}$  molar ratio (the main ions driving pH), with only slightly lower ratios during the day. The study mean ( $\pm$ SD)  $\text{NH}_4^+ / \text{SO}_4^{2-}$  molar ratio was  $1.4$  ( $\pm 0.5$ ). As LWC is mainly controlled by RH and tem-

**Figure 4.** CTR (SOAS) diurnal patterns of calculated pH based on total predicted water ( $W_i + W_o$ ) (a),  $H_{\text{air}}^+$  predicted by ISORROPIA-II (b), ion balance (c), and  $\text{NH}_4^+/\text{SO}_4^{2-}$  molar ratio (d). Mean and median values are shown, together with 25 and 75 % quantiles marked as non-filled circles.

perature, the pH diurnal variation was thus largely driven by meteorological conditions, not aerosol composition.

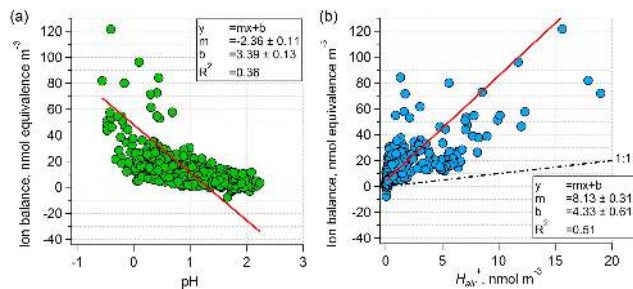

In part because of the diurnal variation of LWC, a simple ion balance or  $\text{NH}_4^+/\text{SO}_4^{2-}$  molar ratio or per-volume-air concentration of aerosol hydronium ion ( $H_{\text{air}}^+$ ) alone cannot be used as a proxy for pH in the particle. Figure 5a shows a weak inverse correlation ( $R^2 = 0.36$ ) between ion balance and pH. An ion balance of an aerosol is usually calculated as follows (in units of nmol equivalence m<sup>-3</sup>) for a  $\text{NH}_4^+ - \text{Na}^+ - \text{SO}_4^{2-} - \text{NO}_3^- - \text{Cl}^-$  - water inorganic aerosol:

$$\text{ion balance} = \frac{[\text{SO}_4^{2-}]}{48} + \frac{[\text{NO}_3^-]}{62} + \frac{[\text{Cl}^-]}{35.5} - \frac{[\text{NH}_4^+]}{18} - \frac{[\text{Na}^+]}{23}, \quad (7)$$

where  $[\text{SO}_4^{2-}]$ ,  $[\text{NO}_3^-]$ ,  $[\text{Cl}^-]$ ,  $[\text{NH}_4^+]$ , and  $[\text{Na}^+]$  are concentrations of these ions in units of grams per cubic meter ( $\text{g m}^{-3}$ ). An ion balance is also a bad indicator of pH because it poorly predicts the aerosol concentration of  $H_{\text{air}}^+$ . An ion balance assumes all ions are completely dissociated, but multiple forms are possible, depending on pH (e.g., sulfate can be in the form of  $\text{H}_2\text{SO}_4$ ,  $\text{HSO}_4^-$ , or  $\text{SO}_4^{2-}$ ). For example, if aerosol sulfate remains in the free form of  $\text{H}_2\text{SO}_4$ , it does not add protons. Thus, an ion balance usually overestimates protons and is only moderately correlated with  $H_{\text{air}}^+$  (Fig. 5b).

#### 4.2.2 LWC uncertainty

In estimating the water uncertainty, we consider  $W_i$  and  $W_o$  separately. The uncertainty of  $W_i$  is estimated by propagat-

**Figure 5.** Comparison of ion balance to pH (a) and to  $H_{\text{air}}^+$  (b) at CTR (SOAS). An ODR fit was applied.

**Figure 6.**  $W_i$  based on artificially perturbed ion data at upper and lower uncertainty limits is compared to  $W_i$  at base level. The slopes indicate the  $W_i$  uncertainty caused by ions.

ing the measurement uncertainty of ions and RH through the ISORROPIA-II thermodynamic model by finite perturbations about the model base state. Uncertainties of ions were estimated by difference between IC ions and AMS ions, as well as PILS-IC measurement uncertainty (Table 2).  $\text{Na}^+$  is excluded because it is not measured by the AMS. PILS-IC instrumental uncertainty is estimated to be 15 % from the variability in standards (variability is calibration slopes), blanks, sample airflow rate, and liquid flow rate (one SD). The total ion uncertainties are listed in Table 2.  $\text{SO}_4$  has a higher uncertainty, at 25 %, than the rest, which are at 15 %. These combined uncertainties lead to an  $W_i$  uncertainty of 25 % (Fig. 6), which is the same as the  $\text{SO}_4$  uncertainty.  $\text{SO}_4$ , one of the most hygroscopic ions (Petters and Kreidenweis, 2007), controls  $W_i$  uptake.

For the SOAS study, the RH probe in the ambient nephelometer (Humitter 50U, VAISALA Inc.) has a stated maximum uncertainty of 5 % at  $\text{RH} = 90$  %. RH biases with respect to environment conditions can also occur due to placement of the probe. Based on RH comparisons between ARA, Rutgers (Nguyen et al., 2014), and the Georgia Tech instrumentation, a systematic bias as large as 10 % is found. Given this, we consider an RH probe factory uncertainty (5 %) as a typical value and intercomparison difference (10 %) as an

**Table 2.** Sensitivity of  $H_{\text{air}}^+$  to ions from ANISORROPIA (second row) and contribution to uncertainty. Uncertainties of inorganic ions ( $\frac{\delta_{\text{Ion}}}{\text{Ion}}$ ) are calculated based on a combination of PILS-IC instrumental relative uncertainties (IC uncertainty, referred to as  $\frac{\delta_{\text{Ion,IC}}}{\text{Ion}}$ , all estimated to be 15 %) and the difference between PILS-IC and AMS ( $\frac{\delta_{\text{Ion,IC-AMS}}}{\text{Ion}}$ , defined as the (slope – 1) in Fig. 2a and 2b) (third row), where  $\frac{\delta_{\text{Ion}}}{\text{Ion}} = \sqrt{\left(\frac{\delta_{\text{Ion,IC}}}{\text{Ion}}\right)^2 + \left(\frac{\delta_{\text{Ion,IC-AMS}}}{\text{Ion}}\right)^2}$  (fourth row). Contribution of uncertainty is the ratio of ion uncertainty over  $H_{\text{air}}^+$  uncertainty ( $\frac{\delta_{H_{\text{air}}^+}}{H_{\text{air}}^+}$ , calculated to be 14 % in Eq. 8) (fifth row).

<sup>a</sup>  $\text{Na}^+$  is not measured by AMS. <sup>b</sup>  $\left|\frac{\partial H_{\text{air}}^+}{\partial \text{NO}_3^-}\right|$  and  $\left|\frac{\partial H_{\text{air}}^+}{\partial \text{Cl}^-}\right|$  are less than 1 % of the other  $H_{\text{air}}^+$  sensitivities, and the loadings of  $\text{NO}_3^-$  and  $\text{Cl}^-$  are less than 5 % of the total inorganic ion mass. As a result, their contributions to  $H_{\text{air}}^+$  uncertainty are negligible.

extreme condition. In this analysis, RH was adjusted by  $\pm 5$  and  $\pm 10$  %, and  $W_i$  recalculated (Fig. 7). A  $\pm 5$  % perturbation in RH leads to a 91 % (slope – 1) error for 5 % perturbation above the measured value (1.05 RH) and 29 % error for a perturbation below the measured value (0.95 RH). We take 60 % as average uncertainty. Higher uncertainty is introduced with increasing RH, owing to the exponential growth of LWC with RH, and results in the asymmetric LWC uncertainty. Combining  $W_i$  uncertainty from ions (25 %) and RH (60 %), the overall uncertainty is calculated as 65 %.

The uncertainty sources for  $W_o$  are  $\kappa_{\text{org}}$ ,  $\rho_s$ ,  $m_s$ , and RH (Eq. 5). The uncertainties of these parameters are estimated to be 26 (details can be found in Supplement Sect. 3), 10, 20, and 5 % (from above), respectively. In summary, the overall uncertainty of  $W_o$  is 35 %.

The total uncertainty of LWC can be expressed as a sum of  $W_i$  and  $W_o$  uncertainties, where  $\varepsilon_i$  is the mass fraction.  $\varepsilon_{W_o}$  was found to be 36 %, and  $\varepsilon_{W_i}$  was 64 %.

$$\frac{\delta_{\text{LWC}}}{\text{LWC}} = \sqrt{\left(\varepsilon_{W_i} \frac{\delta_{W_i}}{W_i}\right)^2 + \left(\varepsilon_{W_o} \frac{\delta_{W_o}}{W_o}\right)^2} \quad (8)$$

**Figure 7.**  $W_i$  based on artificially perturbed RH at upper and lower uncertainty limits compared to  $W_i$  at base level. 1.10 RH (i.e., RH increased by 10 %) is not plotted because it results in much larger  $W_i$  than the rest. Slopes and  $R^2$  indicate corresponding  $W_i$  uncertainty caused by variability (uncertainty) in RH.

Given the above,  $\frac{\delta_{\text{LWC}}}{\text{LWC}}$  is 43 %. This method of assessing predicted LWC uncertainty can be applied to SCAPE sites as well. The specific predicted LWC at SCAPE sites was calculated and is listed in Table 3.  $W_i$  uncertainty associated with

**Table 3.** Water and pH prediction for SCAPE sites. Means and SDs are listed, if not specified. Total ion concentration is counted as the sum of AMS inorganics (third row).  $\varepsilon_{W_o}$  is the mass fraction of  $W_o$  (fifth row).

ions is the same as noted above, 25 %, because it is estimated by PILS-IC and AMS differences. Similar uncertainties in  $W_i$  at the SCAPE sites are expected if RH uncertainties are similar at all sites.

### 4.2.3 pH uncertainty

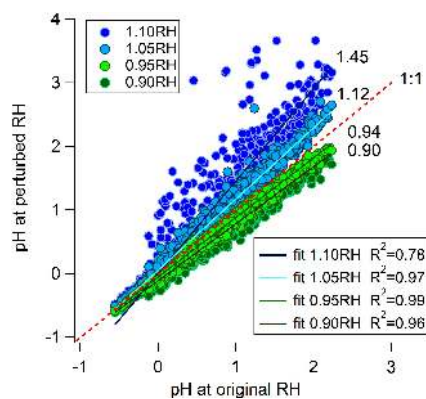

As pH is based on  $H_{\text{air}}^+$  and LWC, the uncertainty of pH can be estimated from these two parameters. We applied the adjoint model of ISORROPIA, ANISORROPIA (Capps et al., 2012), to quantify the sensitivity of predicted  $H_{\text{air}}^+$  to the input aerosol species at the conditions of the thermodynamic calculations. pH uncertainty resulting from aerosol composition is then determined by propagating the input parameter uncertainties, using ANISORROPIA sensitivities, to the corresponding  $H_{\text{air}}^+$  and pH uncertainty.

We now assess how pH of  $\text{PM}_{2.5}$  is affected by using an incomplete measurement of ionic species by comparing the pH predicted based on the more complete suite of ions measured by the PILS-IC versus the AMS, during SOAS. Sensitivities of aerosol species to  $H_{\text{air}}^+$  were calculated by ANISORROPIA with PILS-IC data and presented as partial derivatives (Table 2). Higher sensitivity values imply the inorganic ion is more important for  $H_{\text{air}}^+$ . In the SOAS study,  $H_{\text{air}}^+$  is most sensitive to  $\text{SO}_4$ , and then  $\text{NH}_4^+$ , as they were the major ions. Uncertainties of ions were estimated by the difference between IC ions and AMS ions, as well as PILS-IC measurement uncertainty. Since  $\text{Na}^+$  is not measured by AMS, we cannot estimate the difference between PILS-IC and AMS. The loadings and sensitivities of  $\text{NO}_3^-$  and  $\text{Cl}^-$  were very low, so they

are assumed not to contribute much to  $\frac{\delta_{H_{\text{air}}^+}}{H_{\text{air}}^+}$ . Given this,  $\frac{\delta_{H_{\text{air}}^+}}{H_{\text{air}}^+}$  is determined by

$$\frac{\delta_{H_{\text{air}}^+}}{H_{\text{air}}^+} = \sqrt{\left(\frac{\partial H_{\text{air}}^+}{\partial \text{SO}_4} \frac{\delta_{\text{SO}_4}}{\text{SO}_4}\right)^2 + \left(\frac{\partial H_{\text{air}}^+}{\partial \text{NH}_4^+} \frac{\delta_{\text{NH}_4^+}}{\text{NH}_4^+}\right)^2 + \left(\frac{\partial H_{\text{air}}^+}{\partial \text{Na}^+} \frac{\delta_{\text{Na}^+}}{\text{Na}^+}\right)^2} \quad (9)$$

Based on the input for Eq. (9) (Table 2),  $\frac{\delta_{H_{\text{air}}^+}}{H_{\text{air}}^+}$  is estimated as 14 %. LWC is most sensitive to RH fluctuations, so it is considered the main driver of LWC uncertainty in the pH calculation. As discussed, we artificially adjusted RH by  $\pm 5$  and  $\pm 10$  % (10 % is considered an extreme condition).  $H_{\text{air}}^+$ ,  $W_i$ ,  $W_o$ , and pH were all recalculated using 90, 95, 105, and 110 % of the actual measured RH. RH + 5 % and RH – 5 % lead to 12 and 6 % variation in pH based on orthogonal regression slopes, respectively (Fig. 8). RH – 10 % results in only 10 % variation; however, RH + 10 % results in a 45 % variation, and the coefficient of determination ( $R^2$ ) between pH calculated based on RH + 10 % and original RH drops to only 0.78, while for all other cases  $R^2 > 0.96$ . The disproportionately large effect of the positive uncertainty is caused by the exponential increase of LWC with RH, as RH reaches high levels ( $> 90$  %). Assuming the stated manufacturer uncertainty (5 %) for our RH uncertainty, pH uncertainty is estimated to be 6–12 %. We take 12 % as  $\frac{\partial \text{pH}}{\partial \text{LWC}} \delta_{\text{LWC}}$  for further calculations.

**Figure 8.** pH predictions by perturbing RH compared to pH at base level.  $W_i$ ,  $W_o$ , and  $H_{\text{air}}^+$  were recalculated based on  $\pm 5$  and  $\pm 10\%$  original RH to investigate pH uncertainty. The slopes and  $R^2$  indicate pH uncertainty caused by RH.

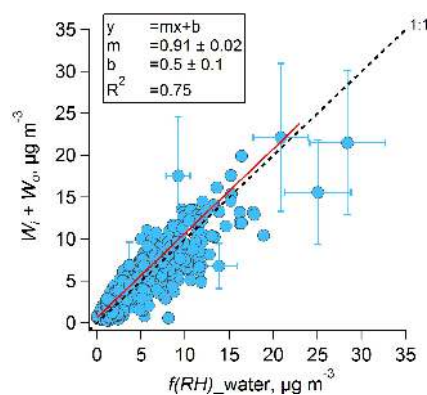

$\text{SO}_4$  was found to contribute the most to  $\frac{\delta H_{\text{air}}^+}{H_{\text{air}}^+}$ .  $\text{NH}_4^+$  and  $\text{Na}^+$  followed.  $\text{SO}_4$  and  $\text{NH}_4^+$  are the two most abundant inorganic components in aerosols and controlling aerosol acidity. Finally, the total pH uncertainty is the combination of LWC and the uncertainty associated with  $H_{\text{air}}^+$ , which is computed from the definition of pH (Eq. 6).

$$\frac{\delta_{\text{pH}}}{\text{pH}} = \sqrt{\left(\frac{\partial \text{pH}}{\partial H_{\text{air}}^+} \delta_{H_{\text{air}}^+}\right)^2 + \left(\frac{\partial \text{pH}}{\partial \text{LWC}} \delta_{\text{LWC}}\right)^2}, \quad (10)$$

where  $\frac{\partial \text{pH}}{\partial H_{\text{air}}^+}$  can be derived from Eq. (6) as

$$\frac{\partial \text{pH}}{\partial H_{\text{air}}^+} = -\frac{1}{2.303} \frac{1}{\frac{H_{\text{air}}^+}{\text{LWC}}} \frac{1}{\text{LWC}} = -\frac{1}{2.303} \frac{1}{H_{\text{air}}^+}. \quad (11)$$

From Eq. (9) and the uncertainties of  $H_{\text{air}}^+$  and LWC (Eqs. 7 and 8), we estimate the pH uncertainty for the SOAS data set to be 13% (based on the specific uncertainties considered here). pH uncertainties at SCAPE sites were also assessed via this method. As discussed above,  $\frac{\delta H_{\text{air}}^+}{H_{\text{air}}^+}$  was found to be 14% for the SOAS study, due to IC and AMS data set differences and PILS-IC instrumental uncertainty. This same uncertainty is applied to SCAPE, where no PILS-IC data were available. Because aerosol composition at all sites is similar, based on filter IC analysis (Supplement Fig. S8), similar sensitivities of  $H_{\text{air}}^+$  to ions are expected. However, actual uncertainty for each sampling period is possibly higher due to higher loadings of refractory ions at SCAPE sites due to contributions from urban emissions. Refractory ions not measured by the AMS (i.e.,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ) have a minor effect on predicting LWC but may have an important effect on pH (e.g., result in higher pH) in locations where they could substantially contribute to the overall ion balance.

**Figure 9.** Comparison between total predicted and measured water by nephelometers based on hourly averaged data at CTR (SOAS). An ODR fit was applied. Error bars for selected points are shown.

#### 4.2.4 Model validation: prediction of liquid water

Several LWC measurements were made at CTR during SOAS. In addition to  $f(\text{RH})_{\text{water}}$  ( $4.5 \pm 3.8 \mu\text{g m}^{-3}$ ), particle water was quantified with a semi-volatile differential mobility analyzer (SVDMA). With this method, a SOAS study mean particle water concentration of  $4.3 \pm 3.7 \mu\text{g m}^{-3}$  ( $\pm \text{SD}$ ) was obtained (Nguyen et al., 2014). The orthogonal regression between these two measurements (SVDMA water vs.  $f(\text{RH})_{\text{water}}$ ) has slope = 0.91, intercept =  $-0.0 \mu\text{g m}^{-3}$ , and  $R^2 = 0.35$ . Differences could be caused by differences in size-resolved composition (particle composition beyond  $\text{PM}_{10}$  that contributes LWC; SVDMA scans up to  $1.1 \mu\text{m}$ , while  $f(\text{RH})_{\text{water}}$  is based on  $\text{PM}_{2.5}$ ), instrument sample heating (i.e., the degree to which the instrument was close to ambient conditions, especially when ambient RH was high, and most sensitive to slight  $T$  differences), and differences in RH probe calibrations.

CTR-predicted total LWC ( $W_i + W_o$ ) was  $5.1 \pm 3.8 \mu\text{g m}^{-3}$  and agreed well with  $f(\text{RH})_{\text{water}}$ . The total predicted water was highly correlated and on average within 10% of the measured water, with slope = 0.91, intercept =  $0.5 \mu\text{g m}^{-3}$ , and  $R^2 = 0.75$  (see Fig. 9). Since excluding refractory ions (Sect. 4.1) and not considering gas-phase species in the ISORROPIA-II calculations do not significantly affect the LWC prediction, its comparison across sites is less uncertain than pH.

#### 4.2.5 Model validation: prediction of pH

ISORROPIA-II calculations of pH at CTR for the SOAS study were evaluated by comparing measured and predicted  $\text{NH}_3(\text{g})$ . Although  $\text{NH}_4^+$  and  $\text{NH}_3(\text{g})$ , along with other aerosol components, are input into the model, comparing ambient  $\text{NH}_4^+$  and  $\text{NH}_3(\text{g})$  to model predictions is not a circular analysis. For each observed data point, the model calculates total ammonia from the  $\text{NH}_4^+$  and  $\text{NH}_3(\text{g})$  input, and then calcu-

**Figure 10.** CTR (SOAS) time series of hourly averaged measured  $\text{NH}_3(\text{g})$ , predicted  $\text{NH}_3(\text{g})$ ,  $\text{NH}_3(\text{g})$  fraction (i.e., measured  $\text{NH}_3(\text{g}) / (\text{NH}_3(\text{g}) + \text{NH}_4^+)$ ), and precipitation.

lates the gas–particle ammonia partitioning assuming equilibrium. There are also other various assumptions/limitations associated with the model. Figure 10 shows the SOAS study time series of measured and predicted  $\text{NH}_3(\text{g})$  and the fraction of ammonia in the gas phase ( $\text{NH}_3(\text{g}) / (\text{NH}_3(\text{g}) + \text{NH}_4^+)$ ). Measured and predicted  $\text{NH}_3(\text{g})$  are in good agreement. Periods when almost all ammonia was in the gas phase (ratio near 1) are related to precipitation events (10, 24, 28 June; 3, 4 July) when aerosol concentrations were very low. Not including these events, the study mean ( $\pm\text{SD}$ ) fraction ammonia in the gas phase was 0.41 ( $\pm 0.16$ ) (median value is also 0.41). These results provide confidence in ISORROPIA-II calculations of particle pH and demonstrate the utility of including both measurements of particle and gas phases in these types of studies.

When gas data are not available, pH predictions are not as accurate (Hennigan et al., 2015). Running ISORROPIA-II in the forward mode, but with only aerosol concentrations as input, may result in a bias in predicted pH due to repartitioning of ammonia in the model. In the southeast, where pH is largely driven by  $\text{SO}_4$  and  $\text{NH}_4^+$ , the aerosol  $\text{NH}_4^+$  input will be partitioned in the model between gas and particle phases to establish equilibrium. Sulfate repartitioning does not occur since it is non-volatile. Thus,  $\text{NH}_4^+$  will be lost from the particle and a lower pH predicted. At CTR ammonia partitioning has been included in all model runs, but no  $\text{NH}_3(\text{g})$  was available for SCAPE. Assuming the average  $\text{NH}_3(\text{g}) / \text{NH}_4^+$  ratio from CTR applies to all SCAPE sites to estimate  $\text{NH}_3(\text{g})$ , along with measured particle composition at each site, we got pH increases ranging from 0.87 to 1.38. In the following, all pHs reported for SCAPE are corrected for this bias (i.e., pHs are increased by 1 to simplify the correction). Note that ammonia partitioning does not significantly affect the LWC prediction ( $W_i$  predicted without  $\text{NH}_3(\text{g})$  vs.  $W_i$  predicted with  $\text{NH}_3(\text{g})$ : slope = 1.00, intercept =  $-0.01 \mu\text{g m}^{-3}$ ,  $R^2 = 0.98$ ).

### 4.3 LWC and pH at other sites in the southeast (SCAPE sites)

#### 4.3.1 Seasonal trends

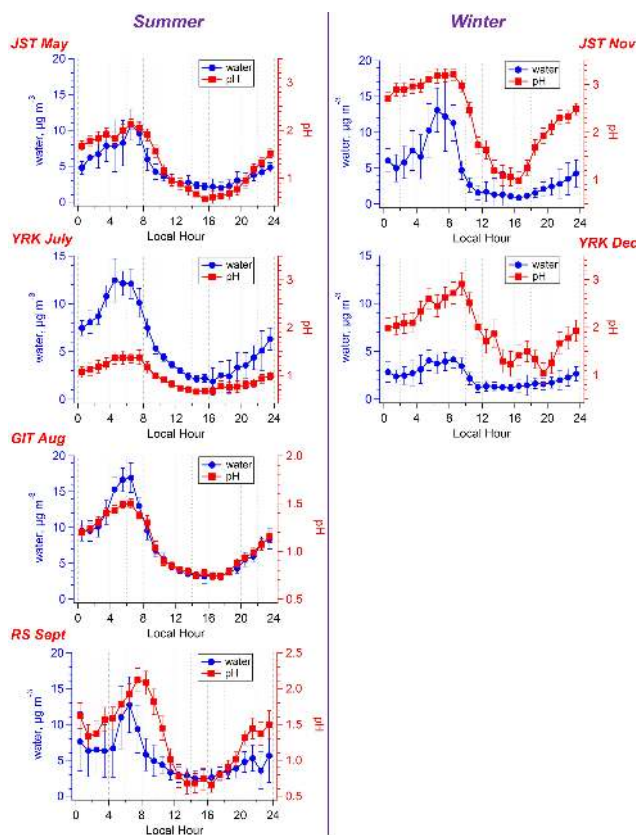

The methods developed and verified at CTR are now applied to the SCAPE study, where fewer species were measured. LWC predictions at all SCAPE sites are shown in Table 3, providing insights on seasonal trends of LWC in the southeast. The overall summer LWC mean was  $5.0 \mu\text{g m}^{-3}$  and winter mean  $2.2 \mu\text{g m}^{-3}$ .

At the SCAPE sites – JST, YRK, GIT, and RS – summer mean pHs were between 1 and 1.3, similar to CTR (mean of 0.94). In winter the pHs (mean between 1.8 and 2.2) were higher by  $\sim 1$  unit. Although LWC was higher in summer, which tends to dilute  $\text{H}_{\text{air}}^+$  and increase pH, summer pH was lower due to higher ion (i.e., sulfate) concentrations (Table 3). Similar diurnal pH patterns were seen at all sites in all seasons and follow the diurnal variations of particle water (Fig. 11). Overall the pH in the southeast is very low, between 1 and 2 (mean), in both rural and urban environments. pH values in summer at various sites were similar (1 to 1.3), suggesting a fairly homogeneous distribution of acidity due to spatially uniform sulfate in the southeastern US (Zhang et al., 2012). In winter the diurnal range in pH was roughly 2 units, while the diurnal range in summer was smaller, with pH varying by roughly 1.

Recall that, at CTR, 10 % RH uncertainty can result in a pH prediction error of up to 45 % due to the high RHs observed during the study. We estimated pH uncertainty from  $W_i$  and  $W_o$  by +10 % RH for each SCAPE site. As Table 3 shows, the pH uncertainty associated with RH is much lower in winter (only 1–3 %) than summer (20–40 %), although RH averages were similar, e.g., JST in May ( $67 \pm 19\%$ ) and November ( $63 \pm 19\%$ ), with even higher RH in winter at YRK. Total pH uncertainty at all SCAPE sites is calculated by the same method as CTR. Table 3 shows that higher RH and  $T$  result in larger pH uncertainty. In summer, pH uncertainty is mainly caused by RH, while in winter it can be attributed mostly to uncertainty in ion concentrations.

#### 4.3.2 The role of $W_o$

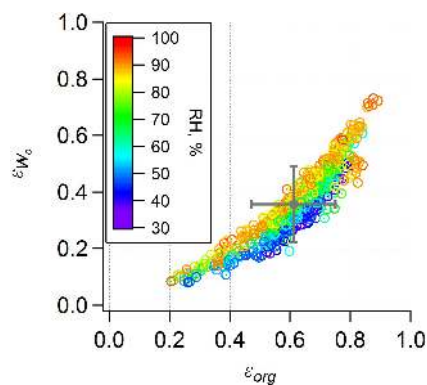

$W_o$  was significant, accounting for on average 29–39 % of the total  $\text{PM}_{2.5}$  particle water for all our sites (Fig. 12 and Table 3). Note that  $W_o$  at SCAPE sites was calculated by in situ AMS measurements at each SCAPE site and the mean  $\kappa_{\text{org}}$  (0.126) measured at CTR, due to lack of CCNc. Note that  $\varepsilon_{W_o}$  could be higher or lower at each site depending on the type of organics presented and the related  $\kappa_{\text{org}}$ . Figure 12 shows that  $W_o$  is related to the organic mass fraction.  $W_o$  is comparable to  $W_i$  at night. In contrast, it was only 33 % of  $W_i$  during the daytime (Fig. 3). The significant fraction, even during daytime, indicates organic aerosol components will have a considerable contribution to aerosol radiative forcing.

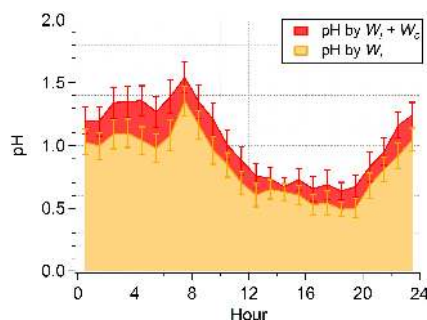

**Figure 11.** LWC and pH diurnal variation at SCAPE sites: comparison between summer and winter. Median hourly averages and standard error bars at local hour are plotted. A bias correction of 1 pH unit is applied due to not considering ammonia partitioning.

Although organics are less hygroscopic than ammonium sulfate, a large fraction of the  $PM_{2.5}$  ( $\sim 70\%$ ) was organic, making  $W_o$  contributions important. Cerully et al. (2014) showed that, of the organic factors associated with  $W_o$ , MO-OOA (more-oxidized oxygenated organic aerosol, also referred to as LVOOA: low-volatility oxygenated organic aerosol) and isoprene-OA (isoprene-derived organic aerosol) were twice as hygroscopic as LO-OOA (less-oxidized oxygenated organic aerosol, also referred to as SVOOA: semi-volatile oxygenated organic aerosol). The LWC associated with MO-OOA and isoprene-OA accounts for  $\sim 60$  and  $\sim 30\%$  of total  $W_o$  in the daytime, respectively.

The effect of particle water on pH can also be delineated. pH calculated just by  $W_i$  alone will be affected by an underestimation of particle water, resulting in a slightly lower pH (Fig. 13).  $W_o$  is on average 29 to 39 % of total water at all sites; as a result pH increases by 0.15 to 0.23 units when  $W_o$  is included. Independent of the pH range, a 29 to 39 %  $W_o$  fraction always increases pH by 0.15 to 0.23 due to the logarithmic nature of pH. The effect of  $W_o$  on pH can be simply denoted as  $\log_{10}(1 - \varepsilon_{W_o})$ . For example, when  $\varepsilon_{W_o}$  is 90 %, it shifts pH up by 1 unit. pH based on  $W_i$  is highly

**Figure 12.**  $W_o$  mass fraction ( $\varepsilon_{W_o}$ ) plotted versus organic mass fraction at CTR (SOAS). Overall study mean and standard deviation is also shown.  $\varepsilon_{Org} = 61 \pm 14\%$  and  $\varepsilon_{W_o} = 36 \pm 14\%$ .

**Figure 13.** CTR (SOAS) pH diurnal profiles based on total predicted water and  $W_i$ , respectively. Median hourly averages and standard error bars at local hour are plotted.

correlated with pH for total water ( $W_i + W_o$ ) (slope = 0.94, intercept =  $-0.14$ ,  $R^2 = 0.97$ ). This indicates that, if organic mass and  $\kappa_{org}$  are not available, ISORROPIA-II run with only ion data will give a reasonable estimate of pH, since both  $H_{air}^+$  and  $W_i$  are outputs of ISORROPIA-II, while  $W_o$  is predicted based on organic mass and  $\kappa_{org}$ . Accurate temperature and RH are still necessary inputs, especially when RH is high.

#### 4.4 Overall implications of low pH

Highly acidic aerosols throughout the southeast during all seasons will affect a variety of processes. For example, aerosol acidity strongly shifts the partitioning of  $HNO_3(g)$  to the gas phase, resulting in low nitrate aerosol levels in the southeast during summer (the higher summertime temperature also plays a secondary role). Aerosol acidity also impacts the gas–particle partitioning of semi-volatile organic acids. Note that organic acids are not considered in our model; under these acidic conditions (pH = 1) their contributions to the  $H_{air}^+$  (hence pH) are expected to be negligible. Because the  $pK_a$  ( $pK_a = -\log_{10}K_a$ , with  $K_a$  referring to acid dissociation constant) of trace organic acids is  $> 2$  (e.g.,  $pK_a$  of formic acid, one of the strongest organic acids, is 3.75;

Bacarella et al., 1955), low pH prevents dissociation of the organic acids. Since  $H^+$  is involved in aqueous-phase reactions, low pH can affect reaction rates by providing protons. Investigators have found that isoprene-OA formation is acid-catalyzed and sulfuric acid participates in the reaction as a proton donor in chamber studies (Surratt et al., 2007). However, aerosol acidity appears not to be a limiting factor for isoprene-OA formation in the southeastern USA, owing to the consistently very low pH (Karambelas et al., 2014; Xu et al., 2015). Finally, low pH can affect the solubility of trace metals (e.g., mineral dust) such as Fe and Cu, which possibly increases the toxicity of the redox metals (Ghio et al., 2012; Verma et al., 2014) and may also have a long-term effect on nutrient distributions in the region (Meskhidze et al., 2003; Meskhidze et al., 2005; Nenes et al., 2011; Ito and Xu, 2014).

## 5 Conclusions

Particle pH is important and difficult to measure directly. However, the commonly used pH proxies of ion balances and  $NH_4^+/SO_4^{2-}$  molar ratios do not necessarily correlate with pH. Therefore, predicting pH is the best method to analyze particle acidity. By combining several models we present a comprehensive prediction method to calculate pH and include an uncertainty analysis. ISORROPIA-II is applied to calculate the concentration of  $H_{air}^+$  and  $W_i$  from inorganic aerosol measurements, and CCN activity is used to predict  $W_o$ . The adjoint model of ISORROPIA, ANISORROPIA, is applied to determine sensitivities, which are used for propagating the measurement uncertainties to pH. We find that  $W_o$  should be included when predicting particle LWC when organic loadings are high (such as in the southeastern US). However, the pH prediction is not highly sensitive to  $W_o$ , unless  $W_o$  mass fraction to the total particle water is close to 1. Thus, in most cases particle pH can be predicted fairly accurately with just measurements of inorganic species and ISORROPIA-II. However, constraining ISORROPIA-II with gas-phase species, such as  $NH_3(g)$ , as done in this work (or  $HNO_3(g)$ ), is highly recommended, along with running ISORROPIA-II in the forward mode. ISORROPIA-II does not consider organic acids, but at the low pHs of this study they do not contribute protons. However, when pH approaches 7, the dissociation of organic acids cannot be neglected. Finally, the model was validated through comparing predicted to measured liquid water ( $W_i + W_o$  to  $f(RH)_{water}$ ) and predicted to measured  $NH_3(g)$  concentrations.

On average, for the SOAS and SCAPE field studies, particle water associated with the  $PM_{2.5}$  organic species ( $W_o$ ) accounted for a significant fraction of total LWC, with a mean of 35 % ( $\pm 3$  % SD) indicating the importance of organic hygroscopic properties to aqueous-phase chemistry and radiative forcing in the southeast US. Although organics are less

hygroscopic than sulfate and ammonium, the larger mass fraction of organics than inorganics promotes  $W_o$  uptake. Predicted LWC was compared to LWC determined from ambient versus dry light scattering coefficients and a TEOM measurement of dry  $PM_{2.5}$  mass. In SOAS, the sum of  $W_i$  and  $W_o$  was highly correlated and in close agreement with the measured LWC (slope = 0.91,  $R^2 = 0.75$ ). LWC showed a clear diurnal pattern, with a continuous increase at night (median of  $10 \mu g m^{-3}$  at 07:30), reaching a distinct peak when RH reached a maximum near 90 % just after sunrise during the period of lowest daily temperature, followed by a rapid decrease and lower values during the day (median of  $2 \mu g m^{-3}$  at 14:30).

In the southeastern USA, pH normally varied from 0.5 to 2 in the summer and 1 to 3 in the winter, indicating that the aerosol was highly acidic throughout the year. The minimum and maximum pH were  $-0.94$  and  $2.2$  at CTR, respectively, and varied from a nighttime average of 1.5 to daytime average of 0.6, mostly attributable to diurnal variation in RH and temperature. Mean  $NH_4^+/SO_4^{2-}$  molar ratios were  $1.4 \pm 0.5$  (SD), and roughly half the ammonia was in the gas phase ( $NH_3(g)/(NH_3(g) + NH_4^+) = 41 \pm 16$  %, mean  $\pm$  SD). pH at other sites in the southeast (SCAPE study) was estimated based on a limited data set at an estimated uncertainty of 9–49 % and a systematic bias of  $-1$  since  $NH_3(g)$  is not included in the thermodynamic model run in the forward mode. pH can still be predicted with only aerosol measurements, but an adjustment of 1 unit pH increase is recommended for the southeastern US. pH has a diurnal trend that follows LWC, higher (less acidic) at night and lower (more acidic) during the day. pH was also generally higher in the winter ( $\sim 2$ ) than summer ( $\sim 1$ ). These low pHs have significant implications for gas–aerosol partitioning, acid-catalyzed reactions including isoprene-OA formation, and trace metal mobilization.
