Acknowledgments: The authors wish to thank the GAZEL study team for help in implementing the TEMPO cohort, the TEMPO participants who made this study possible, Ms. Aude Chollet for her role in coordinating and managing TEMPO study data, as well as Ms. Jeanna-Eve Franck for her statistical consulting.

The first author obtained a postdoctoral research grant from France's national health and medical research institution, INSERM (Institut National de la santé et de la recherche médicale), in order to complete the present work, including its design and conduct, analysis and interpretation of data, and the preparation and submission of the manuscript for publication.

ABSTRACT

Purpose: Food insecurity has been found to be related to anxiety and depression; however the association with other psychiatric disorders, particularly among young adults, is not well known. We examined whether food insecurity is independently associated with four common mental health problems among a community sample of young adults in France.

Methods: Data are from the TEMPO longitudinal cohort study. In 1991, participants' parents provided information on health and family socioeconomic characteristics. In 2011, participants' (18-35 years) reported food insecurity, mental health symptoms, and socioeconomic conditions (n=1214). Mental health problems ascertained included major depressive episode, suicidal ideation, attention deficit and hyperactivity disorder, and substance abuse and/or dependence (nicotine, alcohol and cannabis). Cross-sectional associations between food insecurity and mental health problems were tested using modified Poisson regressions, weighted by inverse probability weights (IPW) of exposure. This makes food-insecure and not food-insecure participants comparable on all characteristics including socioeconomic factors and past mental health problems.

Results: 8.5% of young adults were food insecure. In IPW-controlled analyses, food insecurity was associated with increased levels of depression (RR= 2.01, 95% CI 1.01-4.02), suicidal ideation (RR= 3.23, 95% CI 1.55-6.75) and substance use problems (RR=1.68, 95% CI 1.15-2.46).

Conclusions: Food insecurity co-occurs with depression, suicidal ideation and substance use problems in young adulthood. Our findings suggest that reductions in food insecurity during this important life period may help prevent mental health problems. Policies aiming to alleviate food insecurity should also address individuals' psychiatric problems, to prevent a lifelong vicious circle of poor mental health and low socioeconomic attainment.

Keywords: Food insecurity, Mental health, Substance use, Young adulthood, Social inequalities.

INTRODUCTION

Food insecurity refers to the lack of physical or economic access to sufficient, safe, or nutritious food in order to maintain a healthy and active lifestyle [1]. Affecting 5-15% of households in developed countries[2,3], it is a situation that is thought to have worsened since the recent economic crisis [4]. In addition to the potential for adverse physical health outcomes [5], the role of food insecurity in mental ill health has been suggested [6-8]. For instance, women who experience food insecurity have an increased prevalence of mood disorders, while children have increased rates of behavioral problems [9,6]. Food insecurity has also been linked to substance use problems in adolescence[7] and suicidal ideation in adulthood [10].

Food insecurity is closely linked to socioeconomic status (SES) and can be considered a marker of extreme material deprivation [7]. Yet food insecurity is also a situation that has been shown to have distinct effects on health, notably because of high levels of stress and impaired nutrition. Research on the mental health impacts of food insecurity can therefore help gain a better understanding of the subjective experiences of those affected by food insecurity as well as guide policies which aim to prevent the onset of psychiatric disorders.

Despite high prevalence, studies regarding the health impact of food insecurity have mainly focused on high-risk populations and little work has examined young adults in community samples. Young adulthood represents an important developmental period to study food insecurity, as it is often characterized by significant changes in living and occupational situation, which may place individuals in a vulnerable position. A recent nationally representative study of adults aged 18-79 years identified an inverse relationship between age and household food insecurity, with younger adults more often reporting this problem [3]. Moreover, the onset of mental health problems is also quite frequent in young adulthood [11], and food insecurity may be a predisposing factor.

The aim of this study was to examine, among a community sample of young adults, whether there exists an independent association between food insecurity and four frequent mental health problems: depression, symptoms of inattention and hyperactivity, suicidal ideation and substance abuse and dependence. We hypothesized that, controlling for past mental health problems, parent mental health problems and past and present SES indicators, food insecurity would remain associated with psychological and substance use difficulties in young adulthood.

METHODS

Data were drawn from the French TEMPO (Trajectoires Épidémiologiques en Population) cohort. As part of the GAZEL epidemiological study, a longitudinal follow-up of 20 624 employees of France's national gas and electrical company, parents provided, in 1991, information on child health and family socioeconomic characteristics. This initial sample of 2498 children (4-16 years) was selected to represent children in France in terms of key socio-demographic characteristics. In 2009, these youths were invited for a follow-up (TEMPO cohort). In 2011, 1214 young adults aged 18-35 years described their mental health symptoms and living conditions, including food insecurity experiences, in a telephone interview. As compared to young adults of the same age in France, participants in 2011 were slightly more likely to live with a partner, to have attended postsecondary education and hold a managerial job. However, the rate of lifetime unemployment was comparable to the general population [12]. Ethics approval was obtained from France's national committees for data protection [12].

It is important to note that various conceptualizations for what constitutes young adulthood exist [11,13], and several scholars agree that setting limits for developmental periods in terms of age range is somewhat arbitrary [13,14]. Following other researchers [15,16], we define young adulthood as extending from the late teens to the mid-thirties.

Measures

Independent Variable

Food insecurity was ascertained using three questions, modified from the Cornell-Radimer Hunger Scale [17] and the USDA 10-item questionnaire [18]: Over the past 12 months, have you had financial difficulties in: 1) Eating adequately (you had to reduce portions or number of meals)?; 2) Eating balanced meals?; and 3) Eating varied meals (you had to eat the same thing several times)? For each item, participants answered “yes” or “no”. These items have previously been used in population studies [19,20]. As in prior studies, participants reporting at least one affirmative response were classified as having experienced food insecurity (=1) vs. not (=0).

Dependent Variables

Past-year depression was measured using the Mini-International Neuropsychiatric Interview. Participants responded *yes* or *no* to 14 items, and were categorized as having experienced a major depressive episode (=1) or not (=0) in the past year if they responded “yes” to at least 5 symptoms items, in addition to one measure ascertaining whether symptoms caused impairment. Symptoms of inattention and hyperactivity were measured using the Adult Attention Deficit Hyperactivity Disorder (ADHD) Self-Report Scale 6-item screener. Each item was scored on a range from *never* (=0) to *very often* (=4) and then categorized as representing, or not, a symptom of ADHD (cut-off values varied by item, from “sometimes” to “often” responses)[21]. Symptoms were summed for a score ranging from 0 to 6. A categorical variable was created with 0= 0-3 symptoms and 1= 4-6 symptoms, corresponding to a symptom level approaching clinical diagnosis.

The following question, drawn from the *Monitoring the Future Study*, was used to assess suicidal ideation: “Have you thought of suicide in the preceding 12 months?”[22] Participants were categorized as having had suicidal thoughts (=1) vs. not (=0).

Substance use problems were defined as the presence of at least one of the following over the past 12 months: 1) Tobacco dependence; 2) Alcohol abuse and/or dependence or 3) Cannabis abuse and/or dependence. Participants who responded yes to smoking at least one cigarette per day were screened for nicotine dependence using the 5-item Fagerström Test for Nicotine Dependence (FTND)[23]. As per test authors' guidelines, all items were summed, yielding a score of 0 to 10. Participants with a score greater than 2 were considered nicotine dependent and categorized as dependent (= 1) vs. not (=0). Alcohol abuse and/or dependence was assessed using the French version of the Alcohol Use Disorders Identification Test (AUDIT), a 10-item questionnaire developed by the World Health Organization to match DSM-IV criteria, and validated against clinical diagnosis [24,12]. All 10 items were summed, yielding a score ranging from 0 to 20. Following published guidelines, a score ≥ 8 in men and ≥ 7 in women was considered indicative of alcohol abuse or dependence (=1) vs. no abuse or dependence (=0) [24]. Cannabis abuse or dependence was assessed with the 8-item Cannabis Abuse Screening Test (CAST)[25]. The items included: "Do you smoke cannabis in the morning before going to school or work?", "Do you smoke cannabis when alone?", "Do you find it difficult to spend a day without smoking cannabis?", "Have you driven a car or a motor bike after smoking cannabis?", "Have you had memory problems after using cannabis?". Total scores ranged from 0 to 8. As recommended by test authors', cannabis abuse or dependence was defined as a score ≥ 2 (=1, vs. no abuse/dependence= 0) [25,26].

Variables used to Estimate Food Insecurity Propensity Score

Participants' 1) childhood and family background and 2) social, economic and living situation characteristics, potentially related to both food insecurity and mental health outcomes, were controlled for using the propensity score technique.

Participants' Childhood and Family Background Variables

Low family income (1989 and 2002) categorized families who were below (vs. above) the French median income level in 1989 and/or 2002 (approximately 2000 euros monthly). Parent alcohol

abuse or dependence (1992-2011) as well as depression (1989-2011) were reported by parents and TEMPO participants (2009 and 2011) and considered present if reported by either source. Mean parent Body Mass Index was calculated from 15 self-report data points from 1997- 2011. Childhood violence and neglect, as well as past behavioral problems were reported by participants in 2011. Early internalizing and externalizing symptoms and thought problems were reported by parents in 1991 using the Child Behavior Checklist [27]. T-scores above the 85th percentile were considered high.

Participants' Social, Economic and Living situation

In 2011, participants reported the following in their household (over the past 12 months): Age and sex, pregnancy/birth, single-parent status, stable job vs. short-term contracts, lifetime unemployment, overdrawn bank account, financial aid, financial difficulties paying for rent/medical care, main activity (paid work, student, looking for work, without work/not looking), educational level (0=postsecondary; 1=high school; 2= no diploma), occupational grade and income level category. Poverty status was defined according to French guidelines, using the modified-OECD method. Social network size was classified using the French version of the Berkman-Syme Social Network Index [28]. Early smoking and cannabis initiation were categorized respectively as <13 years and <15 years. Finally, a sum of eight negative life events was included, based on the following items: Over the past 12 months, have you: Had a miscarriage or a voluntary termination of pregnancy?; Separated from your partner?; Had someone close to you suffer from a serious illness or pass away?; Been the victim of another's violent behaviors?; Been robbed, or something that belonged to you was ruined or stolen?; Been insulted or verbally harassed? Been unjustly and repeatedly criticized by someone (for ex: due to your physical appearance, dress, ideas, and opinions)? Received malicious calls, texts, and letters or internet messages?

Statistical Analyses

Analyses were conducted using SAS version 9.3. Given the complex nature of food insecurity and its inextricable link with socioeconomic factors, we used the propensity score (PS) method to balance characteristics of food-insecure and non-food-insecure participants. First we calculated the

propensity score, indicating the probability an individual would be food insecure in 2011 given the risk factors described above (n=1115). This was truncated slightly (for a final sample size of n=1109) at the upper end of the distribution in order to maintain overlap in propensity score values between those who had (n= 94) or had not experienced food insecurity (n=1015).

Based on propensity scores (PS) of food insecurity, we calculated inverse probability weights (IPW) using the equation $IPW = 1/PS$ for those who were food insecure and $IPW = 1/1-PS$ for those who were not [29]. These were normalized and the maximum IPW was set at the value of the 99th percentile IPW (6.97) in order to avoid including excessively high weights in subsequent analyses. The IPW method serves to approximate a random exposure allocation to the independent variable in observational data (here food insecurity) by creating a “pseudo-population” where the independent variable and covariates are not correlated [29,12]. In our analytical sample, we verified that the distribution of each risk factor among the food insecure and non-food insecure groups were made comparable after applying the IPWs.

Associations between food insecurity and each of depression, suicidal ideation, ADHD, and substance abuse were tested using modified Poisson regression models with robust error variance analyses [30] which make it possible to estimate relative risks. We chose this method over logistic regression because our study outcomes were not rare; this approach has also been shown to perform better than binomial or regular Poisson regression [30]. Additionally we studied the occurrence of at least one mental health problem. Bivariate and multivariate (IPW-weighted) analyses were performed.

A total of 6% of all values were missing. Results imputing missing data were similar to those obtained using the complete sample, which we present here.

In supplementary analyses, substance use outcomes (nicotine, alcohol and cannabis abuse/dependence) were examined individually. Additionally, we performed subgroup analyses,

testing whether associations between food insecurity and mental health varied according to participants' sex and age group (< vs. ≥ 30 years).

RESULTS

Characteristics of the TEMPO sample according to food insecurity status are shown in

Table 1.

Table 1. Sociodemographic characteristics of sample (n=1109)

			Food insecure (n= 94)		Not food insecure (n=1015)		p-value	
			n	%	n	%	x ² test ^a	Missing

Each mental health and substance use problem analyzed was associated with food insecurity in bivariate analyses, with relative risks (RR) in the range of 2 to 3 (Table 2). In multivariate analyses, the RRs decreased, with the exception of the association between food insecurity and suicidal ideation, wherein the association became stronger (IPW weighted RR= 3.23, 95% CI=1.55; 6.75).

Outcome	Bivariate				Multivariate ^a			
	RR	CI		p-value	RR	CI		p-value
Depression (n= 72)	2.88	1.82	4.55	<.0001	2.01	1.01	4.02	0.0478
Suicidal ideation (n=51)	2.04	1.7	2.47	<.0001	3.23	1.55	6.75	0.0018
ADHD (n=71)	2.61	1.64	4.16	<.0001	1.75	0.84	3.67	0.1371
Substance Use (n=207)	2.36	1.83	3.05	<.0001	1.68	1.15	2.46	0.0078
≥ 1 problem (n=317)	3.00	1.75	5.14	<.0001	1.69	1.27	2.25	0.003

^aWeighted by inverse probability weight truncated at 99th percentile.

When analyzing substance use outcomes separately, all bivariate associations between food insecurity and substance use were statistically significant (Table 3). In multivariate analyses, these RRs were reduced but remained statistically significant for alcohol abuse/dependence: (RR=1.71, 95% CI 1.01-2.89) and cannabis abuse/dependence (RR=2.58, 95% CI 1.31-5.05) (Table 3).

Outcome	Bivariate				Multivariate ^a			
	RR	CI		p-value	RR	CI		p-value
Smoking (n=77)	2.65	1.66	4.22	<.0001	1.38	0.69	2.77	0.3639
Alcohol (n=122)	2.07	1.01	2.89	0.0002	1.71	1.01	2.89	0.0445
Cannabis (n=59)	2.81	1.31	5.05	0.0002	2.58	1.31	5.05	0.0059

^aWeighted by inverse probability weight truncated at 99th percentile.

When analyses were conducted separately by sex, multivariate associations with food insecurity were significant among males only: depression (RR= 2.99, 95% CI 1.08; 8.25 for males vs. 1.42, 95% CI 0.60; 3.39 among females); suicidal ideation (RR=5.73, 95% CI 1.99; 17.82 for males vs. 1.82, 95% CI 0.64; 5.18 for females).

Additional analyses separating participants (< 30 years of age vs. >= 30 years of age) revealed that food insecurity was associated with suicide (RR=4.4, 95% CI 1.61; 12.35) and cannabis abuse/dependence within the younger group (RR=2.98, 95% CI 1.14; 7.80). Within the older group, food insecurity was associated with depression (RR=2.87, 95% CI 1.29; 6.35).

DISCUSSION

In our study based on a community sample of young adults, we found that food insecurity increases the risk of suicidal ideation, depression and substance use, even when controlling the analysis for characteristics that make food insecure and non-food insecure youths different, including indicators of socioeconomic status (SES). This study adds to the current literature on health and social risks that young adults are exposed to and suggests that this demographic group deserves attention from researchers and health professionals.

When properly specified, IPWs adjust for confounding by creating a pseudo-population wherein all individuals have the same probability of being exposed and unexposed [29]. Weighting the analyses by our calculated IPWs led to a decrease in the relative risks for the association between food insecurity and each of depression, ADHD and substance use problems (as compared to bivariate associations), indicating part of the true association between food insecurity and these problems is likely due to common underlying social and economic factors. However, the value of the relative risk for the association between food insecurity and suicidal ideation increased when confounding was minimized by IP weighting, suggesting the true association between food insecurity and suicidal ideation is not confounded by these factors.

Low SES is a fundamental cause of ill health [31,32], limiting an individual's resources and increasing vulnerability to a disproportionate number of risk factors [32,33]. The chronic stress associated with living in poverty has repeatedly been shown to have detrimental effects on mental health through various potential pathways [34-36]. As a proxy for extreme low SES and material deprivation, food insecurity may affect mental health through some of the same pathways hypothesized for low SES more generally. However, we identified associations between food insecurity and each of depression, suicidal ideation and substance use while taking several aspects of SES into account. This suggests food insecurity may be independently linked to these outcomes during young adulthood, in line with some of the current literature among adolescents [7] and adults [10].

Several past studies have revealed associations between food insecurity and depression [37,8,38]. A 3-year longitudinal study by Heflin and colleagues [37] identified that among low-income women receiving welfare, food insufficiency increased the likelihood of reporting clinically significant major depression, while controlling for depression risk factors and time-invariant traits affecting both food insufficiency and mental health. Fewer studies have examined the association between food insecurity and suicidal ideation or substance use problems. Our results concur with Alaimo and colleagues [38], who identified a significant association between food insecurity and adolescent thoughts of death (OR=2.0) and desire to die (OR= 3.4), as well as Davison et al. [10] who found that suicidal ideation was significantly associated with moderate (OR = 1.3) and severe (OR = 1.8) food insecurity among Canadian adults. However, when subgroup analyses were performed by sex, our results differed from the aforementioned study by Alaimo and colleagues [38], who identified female adolescents as being more likely than male adolescents to have had both suicidal and depressive symptoms. We identified a significant association between food insecurity and each of depression and suicidal ideation among male, but not female, young adults. The differences found may be due to the differing measures of suicidal risk or the different age range of our samples (Alaimo et al. studied adolescents, while we studied young adults).

In addition, we identified different associations by age group. Within the younger group (younger than 30 years), there was a significant association between food insecurity and both suicidal ideation and cannabis use/dependence, while within the older group, the link with depression was significant. With regards to cannabis, this finding is in line with the fact that use is more frequent at younger ages[39] and may represent a more common outcome for those younger individuals living in precarious situations. With regards to depression and suicidal ideation, past studies have identified associations with food insecurity among both adolescents and adults, [37,8,38,7] however differences by age have rarely been systematically examined. Given this, and the fact that our tests were exploratory and not formal tests of interaction, further studies would be required to identify which factors may be specific to adolescence, young adulthood, and adulthood, as well as whether these are specific to men or women.

To our knowledge, we are the first to report the association between food insecurity and young adults' substance use problems such as alcohol or cannabis addiction. Research shows that abuse of these two psychoactive products is increasingly a concern among youths in many countries, particularly as some youths do not desist from such addictive behaviors upon adopting adult social roles. Our study suggests that food insecurity may contribute to a lasting vicious circle of addiction and social exclusion.

Mechanisms underlying the potential association between food insecurity and mental health problems have thus far centered on stress and nutrition. In qualitative research studies with individuals experiencing financial hardship and food insecurity, these situations are described as extremely stressful, frustrating, and depressing [40]. They take a toll on an individual's dignity and sense of self-worth [40]. Individuals may internalize the societal stigma associated with the situation of not being able to provide adequate nutrition for themselves, or in particular, their children[41] and this may contribute to the stress pathways linking food insecurity with poor mental health.

With regards to nutrition, it has been demonstrated that individuals experiencing food insecurity must often rely on low-nutrient, calorie-dense foods [3,42,43]. A recent study of French adults [3] has identified a significantly poorer overall diet quality among food insecure individuals, with a higher consumption of sweet foods and a lower consumption of fruits, vegetables and fish. A greater risk for iron deficiency anemia among women has been found [44,45]. Reduced intake of certain nutrients, in turn, has been linked to irritability, nervousness, depression, and dementia, among others problems [37]. When calorie restriction occurs, this has been shown to increase cortisol secretion and amplify stress reactivity, which further predisposes to mental health problems [7] *citing* [46,47].

Although we considered in this article that food insecurity may have a detrimental role on mental health, previous literature informs us that certain mental health problem symptoms also have a role in the onset of food insecurity [9,48], that a bidirectional association may exist [49], or that both food insecurity and mental health reflect preexisting common causes. Since the present study is cross-sectional, we cannot establish the causal direction between food insecurity and the presence of mental

health and substance use problems during young adulthood. Certain outcomes we analyzed were likely present earlier in the lives of these individuals. For example, substance use problems occur disproportionately among individuals with low income, as a means of coping with stressful life situations or linked to the existence of present-oriented behavior and a difficulty prioritizing longer-term health goals [50]. The presence of such problems could play a role in food insecurity, particularly due to the strain on economic resources that is incurred. As another example, an individual with prior depression symptoms may be predisposed to experiencing food insecurity due to organizational difficulties related to these symptoms, which include a lack of energy and an ability to make decisions [9].

Nonetheless, we controlled for prior mental health problems and other juvenile characteristics as much as possible, and the association we report is net of the effects of these factors. Therefore, it is likely that the experience of food insecurity influences the onset or the persistence of frequent mental health problems such as depression, suicidality and substance abuse.

Our results have several implications for public health. Policies geared towards providing income assistance to young adults who are in situations of food insecurity could help prevent mental health problems during this particular at-risk period [51]. Actions aiming to reduce the presence of food insecurity should also address individuals' potential mental health problems which may have contributed to the occurrence or persistence of food insecurity. To the extent that food insecurity has an impact on mental health problems through nutritional mechanisms, there is need to ensure access to sufficient and nutritious food during the young adulthood period. For instance, subsidized cafeterias in higher education institutions and workplaces may help some young adults access healthy, balanced and nutritious meals. Food banks may supplement the needs of the most vulnerable, although recourse to these may also play a role in the internalization of stigma and the stress that is associated with the experience of food insecurity [52]. Roncarolo and colleagues [53] distinguish between traditional (based on charity; ex: food banks) and alternative (aimed at member participation, capacity and social relationships building; ex: community gardens) interventions, the latter being possibly better in terms of nutrition, social inclusion and potentially mental health [52]. More work is needed in order to

analyze how alternative interventions (or a combination) could provide sustainable solutions to improving food security among young adults. Promising results have emerged, for example the Fresh Place initiative [54], and it is crucial to investigate whether such interventions may also show improvement in participant mental health.

The main limitations of this study include the cross-sectional design of the measurement of food insecurity and mental health as well as a short (3 item) measure of food insecurity, which does not go into detail regarding the severity of the problem for the individual and their household. To the extent that this represents an increased potential for the misclassification of individuals as being food insecure who also have high levels of mental health problems, this has the potential to overestimate our results. However, statistical analyses accounted for multiple preexisting individual and family factors and the measure we used has previously been validated and is well-suited for large community samples [19,20]. A third limitation is that TEMPO participants have a somewhat higher socioeconomic position than the general population. This would suggest the associations between food insecurity and mental health may be stronger than we report. It is also possible that self-reported substance use measures were underreported due to factors such as social desirability, however the likelihood of this may be minimized due to the low levels of stigmatization associated with the three substances examined here, particularly in France [55]. Finally it is possible that we were not able to adequately control for all confounding variables in the calculation of our propensity score and that other underlying factors may explain part of the observed relationships.

Study strengths include the use of inverse probability weights to place food-insecure and non food-insecure individuals on an equal standing in terms of a large set of confounding variables, the use of validated measures of frequent mental health and substance abuse obtained in interviews, and our ability to study food insecurity and mental among a community sample of young adults, a group that is hard to reach when not enrolled in higher education and rarely studied [13].

CONCLUSION

Our study contributes to research linking food insecurity to mental health, extending prior knowledge on this topic to young adults and adding data on substance abuse. Our findings suggest that efforts to reduce food insecurity in young adults could help prevent the presence of mental health problems. Additionally, interventions addressing the needs of individuals who are food insecure should not neglect mental health problems which can fuel a long-term circle of poverty and ill health.
