We investigate the ultraslow motion of polychromatic Bessel beams in unbounded, nondispersive media. Control over the group velocity is exercised by means of the angular dispersion of pulsed Bessel beams of invariant transverse spatial frequency, which spontaneously emerge from near-field generators. Temporal dynamics in transients and resonances over homogeneous delay lines (dielectric slabs) are also examined.

Society of America

1. INTRODUCTION

The speed of a light pulse propagating in an optical medium may vary significantly depending on the dispersion in the refractive index n and ranges from subluminal to superluminal, and even negative, velocities. Ultraslow wave propagation refers to group velocities much smaller than c or, equivalently, to group indices $n_g = n + \omega \partial_\omega n$ exceeding by far unity, which requires strong chromatic dispersion $\partial_\omega n$. Strong absorption under such conditions, however, brings severe limitations in the experimental observation of slow light, which has led to pursuit of quantum interference effects such as electromagnetically induced transparency or coherent population oscillations

Reduction of the group velocity was achieved much earlier in optical resonances. Structural dispersion in metallic hollow waveguides, or optical fibers, induces chromatic dispersion that allows for both subluminal and superluminal modes of propagation. Flatband regions of ultraslow propagation are found in the vicinity of bandgaps where, at the edges, modes with zero group velocity should exist. Slow-wave structure assemblies for use in traveling-wave tubes benefit from this phenomenon

Evidence of slow light phenomena in photonic crystals and their use in delay lines for optical buffering, dispersion compensation, and for enhanced light-matter interactions in nanophotonic circuits, have been described more recently.

In a rather different context undistorted wave transmission in free space with polychromatic Bessel beams has attracted considerable attention in recent years

Potential applications may be found in different research areas, e.g., remote sensing, high resolution imaging, impulse radar, plasma physics, directed energy transfer, and secure communications

In the absence of a medium or a structure it is the plane-wave angular dispersion that is at

work in the control of the wave shape and its velocity

Most of the research has been focused on superluminal diffraction-free solutions of the wave equation and on undistorted pulse beam propagation in dispersive dielectric media. Although subluminal localized pulses have been reported previously, the characteristic features of pulsed Bessel beams (PBBs) with group velocity approaching zero have not been examined at length

We investigate in this paper slow-wave propagation of ultrashort PBBs in nondispersive bulk media, and free space as a particular case. Within the vast variety of non-diffracting PBBs presenting subluminal group velocity, we have focused on those with constant transverse spatial frequency, exhibiting therefore a high-pass semi-infinite band. Near the band edge we encounter proper conditions for ultraslow wave propagation. Far-field synthesis of PBBs usually relies on complex approaches such as dynamic aperturing. Alternatively, near-field generation of such wave packets is commonly performed by direct pulse-plane-wave diffraction with radial gratings or annular arrays. The characteristic periodic modulation of these diffractive optical elements allows the imprinting of a given spatial frequency, which is independent upon frequency, onto the wavefield. Also, the fundamental modes of surface-emitting semiconductor laser structures is of this kind. Finally, excitation of stable PBBs driven by nonlinearities represents an attractive route

In this paper, pulse dynamics (in particular, transit times and pulse stretching) of PBBs traveling within nondispersive homogeneous material systems are thoroughly examined for applications such as all-optical transmission delay lines and resonant cavity confinement. We present analytical and numerical results of PBBs propagating at group indices ranging from 8 in glass microlines of 20 μm for few-cycle wave packets, up to $n_g=1000$ for resonant

optical 20 ns long pulses in a plane-parallel cavity of a length of 10 mm.

2. PULSED BESSEL BEAMS

PBBs are coherent superpositions of monochromatic Bessel beams $A(\omega, z)J_m(k_{\perp}r)\exp(im\phi)\exp(-i\omega t)$ of different frequencies ω , where (r, ϕ) are polar coordinates in a plane perpendicular to the propagation direction z , $J_m(\cdot)$ is the Bessel function of the m th order, $A(\omega, z) = A(\omega)\exp[ik_z(\omega)z]$, and

$$k_z(\omega) = [k^2(\omega) - k_{\perp}^2]^{1/2}, \quad (1)$$

is the axial wavenumber. The transverse wavenumber $k_{\perp} > 0$ is taken to be independent of frequency for PBBs, which makes them factorized in time and space, with an identical Bessel profile at any temporal slice of the pulse, as we will see in Figs. 3 and 5.

Here we investigate the dispersion effects on the pulse propagation driven by the transversal localization of the PBB, so that the refractive index n is assumed to be independent of frequency for simplicity, or the propagation constant $k(\omega) = \omega n/c$ linear with frequency. From Eq. (1) the axial wavenumber k_z vanishes at the cutoff frequency $\omega_c = k_{\perp}c/n$, taking real positive values $0 < k_z < k$ for $\omega > \omega_c$. The spectrum $A(\omega)$ is usually assumed to vanish for $\omega \leq \omega_c$.

For quasi-monochromatic radiation of carrier frequency ω_0 , the group velocity $v_g = 1/k'_{z0}$ along the z direction (the prime stands for derivation with respect to ω , and the subscript 0 for evaluation at ω_0) results to be

$$v_g = \frac{c}{n} \left[1 - \left(\frac{\omega_c}{\omega_0} \right)^2 \right]^{1/2}, \quad (2)$$

which is subluminal (lower than c/n). On the contrary, the phase velocity $v_p = \omega_0/k_{z0}$ is found to be superluminal, and related to the group velocity by $v_p v_g = (c/n)^2$. Figure 1 shows the dispersion curve [Eq. (1)] in the plane $\omega-k_z$, where the relation $v_g < v_p$ is evidenced geometrically. Furthermore the slope of the dispersion curve approaching zero in the vicinity of ω_c evidences that PBBs can propagate at arbitrarily small group velocities. The speeds of the wave packet can be equivalently expressed in terms of

Fig. 1. (Color online) Typical $\omega-k_z$ diagram with a cutoff frequency of $\omega_c = 3.14 \text{ fs}^{-1}$ and $n=1$. Bandgap induced by angular dispersion is filled in color. The slope of the curve at any point (ω, k_z) of the curve (or group velocity) is smaller than the quotient between ω and k_z (phase velocity).

the effective refractive index $n_{\text{eff}} = c/v_p$ and of the group index $n_g = c/v_g$, related by $n_{\text{eff}} n_g = n^2$ for PBBs. The group index is inversely proportional to the group velocity, and directly proportional to the phase velocity for PBBs. Value $n_g \gg n$ refers to the ultraslow propagation regime.

3. ULTRAHIGH GROUP-INDEX REGIME

In the vicinity of the band edge ($\omega \rightarrow \omega_c, k_z \rightarrow 0$), the group velocity tends to zero, and hence the group index tends to infinity. PBBs in this ultraslow regime approach a nearly frozen pulse with a diffraction-free Bessel transversal profile. The dispersion relation in this regime can be approached by the parabola

$$\omega = \omega_c \left(1 + \frac{1}{2} \frac{k_z^2}{k_{\perp}^2} \right) = \omega_c + \frac{c^2}{2\omega_c n^2} k_z^2, \quad (3)$$

which holds for a sufficiently low axial wavenumber $k_z \ll k_{\perp} = \omega_c n/c$, or sufficiently small frequency shift $\omega - \omega_c$ from the cut of frequency. It follows from Eq. (3) that in this regime v_g is proportional to the axial wavenumber k_{z0} , and thus is proportional to the squared root of the shift $\delta\omega = \omega_0 - \omega_c$ of the carrier frequency from the cutoff frequency ω_c .

The proximity of slow-PBBs spectra to the band edge strongly influences the practicable pulse durations. If the spectrum is located about ω_0 and must vanish for $\omega < \omega_c$, then the half-bandwidth σ must satisfy $\sigma < \delta\omega$. From Eq. (3), $\delta\omega \approx (n^2/2n_g^2)\omega_0$, from which the fractional bandwidth $\Gamma \equiv 2\sigma/\omega_0$ must satisfy $\Gamma < n^2/n_g^2$. Since $n_g \gg n$ in the ultraslow regime, ultraslow PBB are inherently quasi-monochromatic ($\Gamma \ll 1$). The number of cycles is roughly estimated by $N = \Gamma^{-1}$ (for a transform-limited pulse), which increases as the square root of the group index.

Although ultraslow PBBs are narrowband, the waveform may be distorted noteworthy upon propagation due to the strong dispersive character of the group index near the band edge. Figure 2 shows fast growth of group index and group-index dispersion [c times group-velocity dispersion (GVD)] collectively as ω_0 approaches ω_c . After traveling a distance L , the wave packet arrives with a time delay $T = L/v_g = (L/c)n_g$ varying for different spectral components of the field, and therefore causing pulse deformation if L is large enough. Of particular relevance is the dispersion length L_D , or propagation distance at which the pulse becomes significantly distorted due to group-index dispersion. A significant distortion is ex-

Fig. 2. Group index n_g (solid curve) and group-index dispersion $n_g'' = k''_{z0}c$ (dashed curve) for $\omega_c = 3.14 \text{ fs}^{-1}$ in vacuum.

pected to occur when the intraband delay $\Delta T = T(\omega_0 + \sigma) - T(\omega_0)$ is similar to the pulse duration $\tau = 2/\sigma$, which yields the usual expression $L_D = \tau^2/2|k''_{z0}|$ for the dispersion length. For ultraslow PBBs, Eq. (3) implies that $k_z k'_z = \omega_c n^2/c^2$ and $k_z k''_z = -k'_z{}^2$, which gives

$$k''_{z0} = -\frac{\omega_c^2 n_g^3}{\omega_0^3 n^2 c} \approx -\frac{n_g^3}{\omega_0 n^2 c}, \quad (4)$$

and a dispersion length

$$L_D = \frac{4\lambda_0 n^2}{\pi \Gamma^2 n_g^3}, \quad (5)$$

where $\lambda_0 = 2\pi c/\omega_0$ is the vacuum carrier wavelength. For the shortest PBB with given group index n_g ($\Gamma = n^2/n_g^2$), the dispersion length becomes $L_D = 4\pi^{-1}\lambda_0 n_g n^{-2}$, which is proportional to the group index and exceeds the carrier wavelength in several orders of magnitude.

In Sections 4 and 5 we take advantage of these basic properties of ultraslow PBBs for the design of light delay and storage devices without the need for any dispersive material medium or waveguiding structure. A commitment between group-velocity reduction and pulse duration may lead a simple dielectric slab (e.g., vacuum) to act as a delay line for femtosecond pulses with moderately slow velocities, or as a resonator with extremely slow pulses of nanosecond duration.

4. FEW-CYCLE PULSE DELAY LINES

We consider a dielectric slab of width L , with the left face at $z=0$ and an index of refraction of n_2 , bounded by a dielectric cladding of refractive index $n_1 > n_2$. The PBB of monochromatic components

$$\psi_{m1}^+ = A_1^+(\omega, 0) J_m(k_\perp r) \exp(im\phi), \quad (6)$$

carrier frequency ω_0 , and transverse wavenumber k_\perp impinges normally on the left face of the slab. The time origin is taken when the envelope of the input PBB is maximum at $z=0$. The Snell law of refraction implies that the Bessel transverse wavenumber is preserved within the dielectric slab.

The pulse bandwidth is limited by the cutoff frequency $\omega_c = k_\perp c/n_2$ of the slab, since it is higher than the cutoff frequency of the cladding. The axial wavenumbers $k_{zj}(\omega) = (n_j^2 \omega^2/c^2 - k_\perp^2)^{1/2}$ ($j=1$ in the cladding at $z < 0$, $j=2$ in the slab, and $j=3$ at $z > L$, with $n_3 = n_1$) will be real and positive if the bandwidth of the input PBB satisfies $\sigma < \delta\omega = \omega_0 - \omega_c$. Within the j domain, solutions of the wave equation are expressed as a superposition of the forward-propagating wave of spectrum

$$A_j^+(\omega, z) = A_j^+(\omega, 0) \exp(ik_{zj}z), \quad (7)$$

and the backpropagating wave of spectrum

$$A_j^-(\omega, z) = A_j^-(\omega, 0) \exp(-ik_{zj}z). \quad (8)$$

For simplicity in the boundary conditions, we consider PBBs whose axial electric field vanishes. In this case, the boundary conditions require continuity of the wave field and its normal derivative at interfaces $z=0$ and L . If a single wave packet impinges on the dielectric slab from

the left side (i.e., $A_3^- = 0$), the electric field may be expressed at any observation distance in terms of the spectrum $A_1^+(\omega, 0)$ of the incident field at $z=0$. In particular, the transmitted field at the output plane $z=L$ is seen to be given by

$$\psi_{m3} = \frac{A_1^+(\omega, 0) T_1 T_2 \exp(ik_{z2}L)}{1 - R^2 \exp(i2k_{z2}L)} J_m(k_\perp r) \exp(im\phi), \quad (9)$$

where

$$T_1 = \frac{2k_{z1}}{k_{z2} + k_{z1}}, \quad (10a)$$

$$T_2 = \frac{2k_{z2}}{k_{z2} + k_{z1}}, \quad (10b)$$

$$R = \frac{k_{z2} - k_{z1}}{k_{z2} + k_{z1}}. \quad (10c)$$

The set of equations (10) corresponds to the well-known Fresnel formulas for s -polarized states, where the difference $k_{z2} - k_{z1}$ is referred to as the impedance mismatch at the slab-cladding interfaces.

A convenient interpretation of Eq. (9) is commonly given by expanding ψ_{m3} into a power series of R by use of the expression

$$[1 - R^2 \exp(i2k_{z2}L)]^{-1} = 1 + \sum_{q=1}^{\infty} R^{2q} \exp(i2qk_{z2}L). \quad (11)$$

This expansion suggests that the transmitted wave is a pulse train consisting of (1) a precursor field having the same waveform as the incident PBB $\psi_1^+(\omega, 0)$, phase delay $k_{z2}L$ and attenuation $T_1 T_2$, and (2) an infinite number of wavelets originated from $2q$ reflections at the slab interfaces at a reflectance rate R . The precursor arrives at $z=L$ at a time $T=L/v_{g2}$, where $v_{g2}=1/k'_{z2}$ (evaluated at $\omega=\omega_0$) is the group velocity of the PBB in the slab. If the impedance at the interfaces is quasi-matched ($k_{z2} \approx k_{z1}$), which corresponds to close enough refractive indices of slab and cladding, $R \approx (k_{z2} - k_{z1})(2k_{z2})^{-1}$ is close to zero and $T_1 T_2 = 1 - R^2$ approaches the unity. In this case, the precursor carries most of the energy from the incident PBB, leading to a single strong signal at the output plane.

We perform numerical simulations in order to verify the validity of this analysis. From a cladding of refraction index $n_1=1.5$, we launched on the slab of refraction index $n_2=1.48$ the azimuthal PBB of spectrum

$$\mathbf{E} = E_\phi \mathbf{u}_\phi = A_1^+(\omega, z) J_1(k_\perp r) \mathbf{u}_\phi, \quad (12)$$

about the typical optical frequency $\omega_0 = 3.14 \text{ fs}^{-1}$ and of duration $\tau = 200 \text{ fs}$. The electric field in Eq. (12) is a diffraction-free solution of the reduced wave equation $\nabla \times \nabla \times \mathbf{E} - k^2 \mathbf{E} = 0$ with zero axial components. We point out that the azimuthal unitary vector $\mathbf{u}_\phi = -\sin \phi \mathbf{x} + \cos \phi \mathbf{y}$ carries the angular dependence of the field over ϕ . Since $\Gamma = 6.37 \times 10^{-3} < n^2/n_g^2$ for PBBs, this femtosecond optical pulse can be transmitted as a PBB with a maximum group index $n_g \approx 18$. For the choice of the (rather

strong) lateral localization $k_{\perp} = 15.2 \mu\text{m}^{-1}$ ($\gg k_{z2} = 2.87 \mu\text{m}^{-1}$), the cutoff frequency results to be $\omega_c = 3.083 \text{ fs}^{-1}$, and the group index takes the moderate value $n_g = 8$. Finally, the thickness of the slab is chosen to be $L = 20 \mu\text{m}$, significantly smaller than the dispersion length $L_D = 80.64 \mu\text{m}$ in order to prevent any significant distortion of the transmitted PBB.

In Fig. 3(a) we represent the waveform of the field envelope $|E_{\phi}|^2$ at the input plane $z=0$. For convenience we used the Gaussian spectrum

$$A_1^+(\omega_0 + \Omega, 0) = (2\pi\sigma^2)^{-1/2} \exp(-\Omega^2/2\sigma^2), \quad (13)$$

since it leads to the analytical expression

$$E_{\phi}(t, r) = \exp(-i\omega_0 t) \exp(-t^2\sigma^2/2) J_1(k_{\perp} r) \quad (14)$$

for the incident wave field (if the spectral amplitude at ω_c is negligible). In Fig. 3(b) we show the transmitted field at $z=L$. The precursor arrives with a group delay of $T = 533 \text{ fs}$, a time 124 fs longer than the time taken by the PBB in traveling the same distance L within the homogeneous dielectric medium of refractive index n_1 . Due to the quasi-matched impedances, the retarded wavelets originated from reflections at the interfaces cannot be observed at the scale of the figure, as expected from the energy balance given by $R = 0.145$ (evaluated at $\omega = \omega_0$).

5. ULTRASLOW RESONANCES

We consider now the feasibility of PBBs with n_g exceeding the unity by several orders of magnitude. For sufficiently small refractive index n_2 of the dielectric slab and same cladding, the impedance mismatch at the input and output interfaces is high, and the reflectivity R may reach absolute values around the unity [see Eq. (10c)]. This attractive case leads to a leaky trapping of a extremely slow PBB within the layer through multiple reflections at $z=0$ and L . Here we better speak of a resonator of the Fabry-Pérot type sustaining ultraslow PBBs rather than of a delay line.

Fig. 3. (Color online) Instantaneous intensity $|E_{\phi}|^2$ (in arbitrary units) of the azimuthal PBB: (a) input plane ($z=0$), and (b) output pulse ($z=L$).

The round-trip group delay, or time consumed by the PBB in coming back to the input plane $z=0$ after being reflected at $z=L$, is given by $2T = 2L/v_{g2}$. For simplicity, we address our discussion to the central plane $z=L/2$, where the released PBB arrives with a delay $T/2$ and returns from a reflection on an interface with a periodic delay T . Replicas of the input beam propagating alternatively in the forward and backward directions are observed at a rate T^{-1} in the form of a genuine pulse train. However, if the pulse duration τ is sufficiently long such that $\tau > T$, the leading part of the pulse moving backwards from reflection reaches the plane $z=L/2$ in time to interfere with the rear part of the forward pulse. Overlapping will be negligible only if the resonator length is larger than the pulse coherence length, that is,

$$L > L_c = \tau v_{g2} = \frac{2\lambda_0}{\pi n_g \Gamma}. \quad (15)$$

Moreover nontotal reflection at the interfaces and dispersive distortion at each round trip causes attenuation and broadening of the replicas at distances greater than the dispersion length L_D in Eq. (5). Since L_D and L_c are related by $L_c = L_D \Gamma n_g^2 / (2n_2^2)$, and the bandwidth is limited to $\Gamma < n_2^2 / n_g^2$, the dispersion length is found to satisfy $L_D > 2L_c$. As a conclusion, a range of resonator lengths $L \in (L_c, L_D)$ exists in which overlapping and distortion are simultaneously negligible, at least for a number of round trips $\sim L_D / (2L)$. This number can be significantly high as long as $L \geq L_c$ and $\Gamma \ll n_2^2 n_g^{-2}$.

As a particular case, we consider again the azimuthal PBBs in Eq. (12) as the light signal that excites a resonant PBB when it is launched from the left side of the cladding ($n_1 = 1.5$) onto a vacuum cavity ($n_2 = 1$), a configuration that provides high reflectivity at the interfaces. For the visible carrier frequency $\omega_0 = 3.14 \text{ fs}^{-1}$, Fig. 4(a) shows the group index reachable as a function of its detuning $\delta\omega$ from the cutoff frequency. For a choice of the ultrahigh group index $n_g = 10^3$, the detuning must be $\delta\omega = 1.57 \times 10^6 \text{ fs}^{-1}$, attained by a PBB of transverse frequency $k_{\perp} = 10.5 \mu\text{m}^{-1}$, or a transversal spot size of about $0.2 \mu\text{m}$. In Fig. 4(b) we plot the dispersion length L_D and the coherence length L_c for the different possible bandwidths $\sigma < \delta\omega$ of the PBB, where $L_c < L_D$ is evidenced graphically. For instance, a pulse duration of $\tau = 20 \text{ ns}$ ($\sigma = 10^{-7} \text{ fs}^{-1}$, or $\Gamma = 6.37 \times 10^{-8}$) yields $L_c = 6 \text{ mm}$ and $L_D = 18.85 \text{ cm}$. A cav-

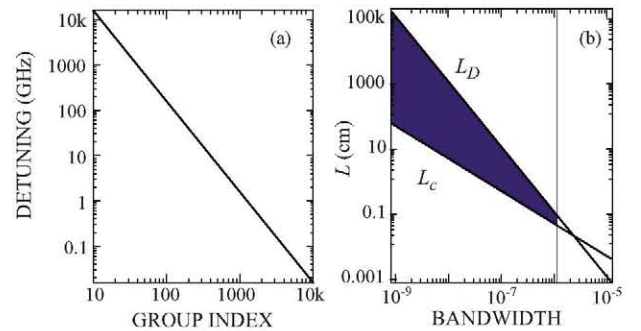

Fig. 4. (Color online) Diagrams for the synthesis of ultraslow resonant PBBs. (a) Spectral detuning $\delta\omega = \omega_0 - \omega_c$ required to attain a given group index for $\omega_0 = 3.14 \text{ fs}^{-1}$. (b) Region $L_c < L < L_D$ (in color) as for allowable relative bandwidths Γ .

ity of length $L=10$ mm, as considered below in numerical simulations, would result in nearly 10 shapely round trips without overlapping and distortion, with a period of $2T=66.7$ ns. The ultraslowness of the PBB along with the pseudoresonance provides a storage time of the order of the microsecond, to be compared with the fly time of $\sim 0.3 \times 10^{-11}$ s of light in vacuum.

In Fig. 5 we show contour plots of the intensity $|E_\phi|^2$ at the input and midplane of the resonator. The intracavity field is computed following the procedure described in Section 4 based on the continuity conditions on the interfaces, which leads to the in-plane spectra

$$A_2^+(\omega, 0) = \frac{T_1}{1 - R^2 \exp(i2k_z L)} A_1^+(\omega, 0), \quad (16a)$$

$$A_2^-(\omega, 0) = \frac{RT_1 \exp(i2k_z L)}{1 - R^2 \exp(i2k_z L)} A_1^+(\omega, 0), \quad (16b)$$

for the forward-propagating and counterpropagating components of the PBB, respectively, where $A_1^+(\omega, 0)$ is given by the Gaussian signal in Eq. (13). Figure 5(a) shows a field at the input face $z=0$ of the resonator. Only the input excitation is observable at the scale of the figure since multiple reflections are strongly attenuated. This effect originates from the negative sign of the reflection coefficient $R=-0.998$, which causes the leading part of any reflected pulse to interfere destructively with the rear part of the pulse prior to reflection. The strongly attenuated reflections are more clearly seen in Fig. 5(c) for the output face $z=L$. Attenuation is seen to be significant up

Fig. 5. (Color online) Intracavity dynamics of $|E_\phi|^2$ at different transverse planes: (a) input plane $z=0$, (b) amid-reflectors plane $z=L/2$, and (c) interface plane $z=L$.

to distances L_c from the faces of the resonator, which yields an effective cavity length of about $L-2L_c$ without attenuation. Figure 5(b) shows that the field at the central plane $z=L/2$ of the resonator is composed of a periodic sequence of nonoverlapping, nearly undistorted, and nonattenuated PBBs of period $T=33.3$ ns and an offset group delay of $T/2$. Time reversal of alternate pulses is not appreciated due to the symmetry of the Gaussian pulse.

6. CONCLUSIONS

In this paper we have established the conditions for the observation and synthesis of wave packets with ultraslow group velocity in a nondispersive medium or free space without the help of any guiding structure. In practice, laser emission from surface-emitting semiconductors carries the required angular dispersion to produce subluminal pulsed Bessel beams, which demonstrates that near-field diffraction of nonevanescing waves allows practical realizations of ultraslow wave velocities in free space. Drastic reduction of the group velocity is achieved by strong angular dispersion of the composing monochromatic Bessel beams at angles close to $\pi/2$, or, equivalently, by pseudostanding waves with transversal wavenumbers much larger than the axial wavenumber, leading additionally to strong transverse localization into a few nanometers.

The analysis of the limitations in PBB bandwidth and dispersive distortion, as imposed by the presence of the bandgap, allows us to conclude that a femtosecond optical PBB can propagate at moderate slow velocities ($n_g \sim 10$), while extremely slow group velocities ($n_g \sim 10^3$ or larger) are possible with picosecond or longer pulses.

We conclude our investigation with the analysis of non-guiding, uniform delay lines, based on lowering the refractive index with respect to the surrounding medium, which hence slow down the exciting pulsed Bessel beam. For convenience, azimuthally symmetric vector Bessel beams have been taken for the analysis and numerical simulations. The influence of the refractive index mismatch at input and output planes onto the pulse dynamics is examined. When the index mismatch is sufficiently low the dielectric slab emulates a lossless delay line usable for few-cycle femtosecond pulses. An increase of the mismatch enhances the reflectivity at the interfaces, so that the plate (vacuum in our numerical simulations) acts as an optical resonator sustaining an extremely slow PBB of nanosecond duration. Our analysis leaves an open door for the experimental demonstration and optical engineering of ultraslow wave phenomena in free space.
