Abstract:	Current climate change is a major threat to biodiversity. Species unable to adapt or move will face local or global extinction and this is more likely to happen to species with narrow climatic and habitat requirements and limited dispersal abilities, such as amphibians and reptiles. Biodiversity losses are likely to be greatest in global biodiversity hotspots where climate change is fast, such as the Iberian Peninsula. Here we assess the impact of climate change on 37 endemic and nearly endemic herptiles of the Iberian Peninsula by predicting species distributions for three different times into the future (2020, 2050 and 2080) using an ensemble of bioclimatic models and different combinations of species dispersal ability, emission levels and global circulation models. Our results show that species with Atlantic affinities that occur mainly in the North-western Iberian Peninsula have severely reduced future distributions. Up to 13 species may lose their entire potential distribution by 2080. Furthermore, our analysis indicates that the most critical period for the majority of these species will be the next decade. While there is considerable variability between the scenarios we believe that our results provide a robust relative evaluation of climate change impacts among different species. Future evaluation of the vulnerability of individual species to climate change should account for their adaptive capacity to climate change, including factors such as physiological climate tolerance,

25 species distribution model, vulnerability, adaptive management

**Abstract**

Current climate change is a major threat to biodiversity. Species unable to adapt or move will face local or global extinction and this is more likely to happen to species with narrow climatic and habitat requirements and limited dispersal abilities, such as amphibians and reptiles. Biodiversity losses are likely to be greatest in global biodiversity hotspots where climate change is fast, such as the Iberian Peninsula. Here we assess the impact of climate change on 37 endemic and nearly endemic herptiles of the Iberian Peninsula by predicting species distributions for three different times into the future (2020, 2050 and 2080) using an ensemble of bioclimatic models and different combinations of species dispersal ability, emission levels and global circulation models. Our results show that species with Atlantic affinities that occur mainly in the North-western Iberian Peninsula have severely reduced future distributions. Up to 13 species may lose their entire potential distribution by 2080. Furthermore, our analysis indicates that the most critical period for the majority of these species will be the next decade. While there is considerable variability between the scenarios we believe that our results provide a robust relative evaluation of climate change impacts among different species. Future evaluation of the vulnerability of individual species to climate change should account for their adaptive capacity to climate change, including factors such as physiological climate tolerance, geographical range size, local abundance, life cycle, behavioural and phenological adaptability, evolutionary potential and dispersal ability.

## 45 Introduction

46 Anthropogenic driven climate change is evident and for the next two decades a warming of at  
47 least 0.2°C per decade is projected (IPCC, 2007) with associated changes in precipitation  
48 patterns. Throughout the history of Earth, climate has changed and species have coped and  
49 adapted to these changes, but current climate change is threatening biodiversity because it is  
50 fast compared to most past changes (Thomas *et al.*, 2004). Current climate warming was  
51 considered the second most important threat to terrestrial biodiversity, only exceeded by  
52 land-use change (Sala *et al.*, 2000).

53 Climate change have been reported to affect many aspects of populations: physiology,  
54 distribution, phenology, behaviour and propensity for local extinction (Hughes, 2000,  
55 Walther *et al.*, 2002, McCarty, 2002, Root *et al.*, 2003, Parmesan, 2006). Species may be able  
56 to adapt to climatic changes via ecological (Root *et al.*, 2005) or evolutionary processes  
57 (Bradshaw *et al.*, 2006, Skelly *et al.*, 2007). However, species unable to achieve a sufficient  
58 level of adaptation will likely face local or global extinction and this is more likely to happen  
59 to species with restricted climate and habitat requirements, limited dispersal abilities and  
60 ectothermal physiology (Walther *et al.*, 2002, Thomas *et al.*, 2004, Massot *et al.*, 2008).

61 Amphibians and reptiles are considered one of the most vulnerable taxonomic groups to  
62 climate change (Gibbons *et al.*, 2000, Carey *et al.*, 2003, Araújo *et al.*, 2006, Wake, 2007).

63 Climate warming is projected to induce a) changes in abundance; b) fragmentation of suitable  
64 habitats; c) changes in the timing of life-cycle events, such as hibernation, aestivation and  
65 breeding (Blaustein *et al.*, 2001, Chadwick *et al.*, 2006) and d) the spread of agents of  
66 infectious diseases such as the chytridiomycete fungus (Pounds *et al.*, 2006, Bosch *et al.*,  
67 2007, Wake, 2007). The interaction of these impacts causes disruptions in population and  
68 metapopulations dynamics, which ultimately may lead to changes in distribution.

1  
2  
3 69 The impact of global warming on biodiversity is likely to be more severe in regions rich in  
4  
5 70 endemic species that are also predicted to be affected by dramatic climatic changes. The  
6  
7  
8 71 Mediterranean Basin is a particularly susceptible region: it is a biodiversity hotspot holding  
9  
10 72 many endemic species (Médail *et al.*, 1999, Myers *et al.*, 2000, Mittermeier *et al.* 2005) and  
11  
12 73 climate predictions for this region include a substantial rise in temperature and a drastic drop  
13  
14  
15 74 in rainfall, contributing to desertification (MIO-ECSDE, 2003). The synergistic effect of  
16  
17 75 climate change with other threats to biodiversity makes this region one of the most vulnerable  
18  
19  
20 76 in the world (Sala *et al.*, 2000).

21  
22 77 The Iberian Peninsula, in particular, is a Mediterranean sub-region with many endemic  
23  
24  
25 78 species. The high biodiversity derives from the fact that this area was one of the major glacial  
26  
27 79 refugia in Europe during the Pleistocene (Hewitt, 1996) and a diversification centre  
28  
29  
30 80 afterwards (Gómez *et al.*, 2006, Pinho *et al.*, 2007). Biodiversity richness in this area is also  
31  
32 81 influenced by the climatic heterogeneity, since the climate transition between Atlantic and  
33  
34 82 Mediterranean allows the co-occurrence of species with African and Euro-Siberian affinities,  
35  
36  
37 83 which means that the Iberian Peninsula is a biogeographic crossroad (Spector, 2002).

38  
39  
40 84 In face of climate change challenges, conservation organizations are being asked to take  
41  
42 85 proactive measures to mitigate impacts on biodiversity. To select appropriate measures we  
43  
44  
45 86 need to be able to predict the impact of climate change on biodiversity and evaluate the  
46  
47 87 ability of biodiversity to adapt to those impacts. The combination of this information can be  
48  
49  
50 88 used to determine biodiversity vulnerability, which in turn becomes the basis for prioritizing  
51  
52 89 species and defining management strategies (Kareiva *et al.*, 2008).

53  
54 90 Species distribution models (SDMs) are frequently used to assess the impacts of climate  
55  
56  
57 91 change on species distributions (*e.g.* Araújo *et al.*, 2006). These statistical tools relate present  
58  
59  
60 92 day distributions with current environmental conditions and then use future potential climate  
93  
94 93 conditions to predict future species distributions (Pearson *et al.*, 2003). Predicting the impacts

1  
2  
3 94 of climate change on species is a challenging task because SDMs include parameters with  
4  
5 95 many sources of uncertainty (Webster *et al.*, 2002) mostly related to: a) the statistical tool  
6  
7  
8 96 used for modelling species distributions; b) the global circulation models used to predict  
9  
10 97 future climate conditions (Thuiller, 2004, Pearson *et al.*, 2006, Beaumont *et al.*, 2008); and c)  
11  
12 98 uncertainty derived from scale effects (Seo *et al.*, 2009). Recently, advances in SDMs have  
13  
14  
15 99 made it possible to significantly reduce prediction uncertainties. For example, several robust  
16  
17 100 statistical modelling methods have been developed to predict species distributions (see Elith  
18  
19 101 *et al.*, 2006 for review), while advanced methodologies in ensemble forecasting allow us to  
20  
21 102 overcome the problem of variability in predictions made by different modelling techniques or  
22  
23 103 different global circulation models (Pearson *et al.*, 2006, Araújo *et al.*, 2007, Marmion *et al.*,  
24  
25 104 2009). Additionally, climate predictions have been improved at smaller spatial scales  
26  
27 105 (Hijmans *et al.*, 2005).

31  
32 106 In this study, we will evaluate potential impacts of climate change on the distribution of  
33  
34 107 amphibians and reptiles in the Iberian Peninsula. We focus on endemic and nearly endemic  
35  
36 108 species, the later defined as species that have approximately more than two thirds of their  
37  
38 109 entire range in the Iberian Peninsula. We then use information about species adaptability and  
39  
40 110 vulnerability to make conservation recommendations.

43  
44 111 Araújo *et al.* (2006) identified the Iberian Peninsula as one of the areas in Europe where  
45  
46 112 amphibians and reptiles are likely to undergo major contractions in their ranges. Therefore, a  
47  
48 113 detailed analysis of the Iberian Peninsula at a scale appropriate for establishing management  
49  
50 114 strategies is urgently needed. We complement Araújo *et al.*'s (2006) European-wide research  
51  
52 115 by providing a more detailed analysis of the impact of climate change on amphibian and  
53  
54 116 reptile's distribution within the Iberian Peninsula. In particular, we used the most recent  
55  
56 117 distribution data which are geographically more detailed than the one used in Araújo *et al.*  
57  
58 118 (2006) (10x10 km in opposition to 50x50km) and incorporate recent taxonomic discoveries,  
59  
60

1  
2  
3 119 that significantly increases the number of endemics (21 species vs. 12 species). Additionally,  
4  
5 120 we project species ranges to three times in the future (2020, 2050, 2080 instead of 2050  
6  
7  
8 121 only), which may assist conservation decision making in terms of prioritizing the allocation  
9  
10 122 of conservation funds through time.

11  
12 123 We provide specific recommendations to conservation practitioners for enhancing the  
13  
14 124 probability of species persistence by answering the following questions: In the Iberian  
15  
16 125 Peninsula, which endemic and nearly endemic amphibian and reptile species are predicted to  
17  
18 126 lose and gain suitable habitat in the future? For species predicted to lose suitable habitat, is  
19  
20 127 the loss rate constant throughout time or are there more critical periods? Which areas will be  
21  
22 128 more impacted by species loss? Which species should be under priority conservation action?  
23  
24 129 Which conservation measures are most likely to increase the probability of species  
25  
26 130 persistence?  
27  
28  
29  
30  
31  
32  
33

## 34 132 **Methods**

### 35 36 37 133 *Study area*

38  
39 134 The study region is the continental Iberian Peninsula, situated in the extreme southwest of  
40  
41 135 Europe (bounded by 9°32' to 3°20'E and 35°56' to 43°55'N). With an area of 582 860 km<sup>2</sup>, it  
42  
43 136 includes the continental territories of Portugal and Spain. It is bordered to the south and east  
44  
45 137 by the Mediterranean Sea and to the north and west by the Atlantic Ocean. The Pyrenees and  
46  
47 138 the Strait of Gibraltar separate most of the region from the remainder of Europe and Africa,  
48  
49 139 respectively (Figure 1). The dominant climate type of the region is Mediterranean, but the  
50  
51 140 north and northwest of the Iberian Peninsula and the major mountain systems are  
52  
53 141 characterised by an Atlantic climate.  
54  
55  
56  
57  
58  
59  
60

### 143 *Species and distribution data*

1  
2  
3 144 Distribution data for 37 endemic and nearly endemic species (15 amphibians and 22 reptiles)  
4  
5 145 were collected from the most recent herpetological atlases of Portugal (Loureiro *et al.*, 2008)  
6  
7  
8 146 and Spain (Pleguezuelos *et al.*, 2002), which are referenced to the UTM grid of 10x10 km.  
9  
10 147 Taxonomy was defined according to the most recent revision of the taxonomic list in  
11  
12 148 Carretero *et al.* (2009). We excluded from our analysis records from the Portuguese atlas for  
13  
14 149 *Triturus marmoratus* because that data does not distinguish between *Triturus marmoratus*  
15  
16 150 and *T. pygmaeus*. We followed the same method for Portuguese records of *Pelodytes*  
17  
18 151 *punctatus* because they represent two species: *Pelodytes punctatus* and *P. ibericus*. Our data  
19  
20 152 contained only two records of *Iberolacerta martinezricai* so we were unable to develop a  
21  
22 153 plausible predictive model.  
23  
24  
25  
26  
27  
28  
29

### 30 *Climate data*

31  
32  
33 156 Current bioclimatic data were downloaded from WorldClim database (Hijmans *et al.*, 2005)  
34  
35 157 which is a set of global climate layers generated through interpolation of climate data from  
36  
37 158 weather stations. We used nine variables that were not tightly correlated with each other  
38  
39 159 (with a Pearson correlation coefficient between them lower than 0.75): temperature  
40  
41 160 seasonality, maximum temperature of warmest month, minimum temperature of coldest  
42  
43 161 month, temperature annual range, annual precipitation, precipitation of wettest month,  
44  
45 162 precipitation of driest month, precipitation seasonality and altitude. All variables were  
46  
47 163 downloaded in a 2.5 arc-minute resolution. We converted these data to match with the same  
48  
49 164 grid format as the species distribution data by averaging the variable's values inside each grid  
50  
51 165 cell.  
52  
53  
54  
55

56  
57 166 We used future climate data for three Global Circulation Models (GCM) (CCCMA,  
58  
59 167 HADCM3 and CSIRO) and two IPCC 3rd assessment storylines (A2 and B2). The IPCC  
60  
168 storylines describe the relationships between the forces driving greenhouse gas and aerosol

1  
2  
3 169 emissions such as demographic, social, economic, technological, and environmental  
4  
5 170 developments (IPCC-TGICA, 2007). The two storylines used for this study assume  
6  
7  
8 171 regionally oriented economic growth, with population and economic growth being higher in  
9  
10 172 A2 than B2. Future climate data were downloaded from WorldClim, for three different future  
11  
12 173 years (2020, 2050 and 2080) creating six storyline-GCM combinations for each future year.  
14  
15 174 We downloaded monthly averages of maximum and minimum temperatures and total  
16  
17 175 precipitation and calculated the bioclimatic variables according to the same methodology  
18  
19 176 used to calculate them for current climate conditions (Hijmans *et al.*, 2005).  
20  
21  
22  
23 177  
24  
25  
26 178 ***Species distributions: current predictions and future projections***  
27  
28 179 We used a set of nine modelling techniques to predict the distribution of each of the 37  
29  
30 180 species in four different times (current, 2020, 2050 and 2080): Maximum Entropy (MXT),  
31  
32 181 Generalised Linear Models (GLM), Generalised Additive Models (GAM), Classification  
33  
34 182 Tree Analysis (CTE), Artificial Neural Networks (ANN), Generalised Boosting Model  
35  
36 183 (GBM), Breiman and Cutler's random forest for classification and regression (RF), Mixture  
37  
38 184 Discriminant Analysis (MDS) and Multiple Adaptive Regression Splines (MARS).  
39  
40  
41  
42  
43 185 To produce Maximum Entropy models we used Maxent software (Phillips *et al.*, 2004).  
44  
45 186 Maxent estimates the range of a species with the constraint that the expected value of each  
46  
47 187 variable (or its transform and/or interactions) should match its empirical average, *i.e.* the  
48  
49 188 average value for a set of sample points taken from the species-target distribution (Phillips *et*  
50  
51 189 *al.*, 2006, Phillips *et al.*, 2008). We used the default “auto features” option, logistic output,  
52  
53 190 the recommended default values for the convergence threshold ( $10^{-5}$ ) and the maximum  
54  
55 191 number of iterations (500).  
56  
57  
58  
59  
60

1  
2  
3 192 The remaining eight models were built within BIOMOD (Thuiller *et al.*, 2009) . BIOMOD is  
4  
5 193 a collection of functions running within the R software v. 2.8.1 (R Development Core Team  
6  
7 194 2008) for ensemble forecasting of species distributions and a summary of model statistics is  
8  
9 195 described in Thuiller *et al.*, (2009). The majority of model-techniques requires data about  
10  
11 196 presences and absences, thus we determined pseudo-absences for each species by using the  
12  
13 197 “random strategy” in BIOMOD. The number of selected pseudo-absences for each species  
14  
15 198 was equal to the number of its occurrences, whenever possible. In cases where the number of  
16  
17 199 locations where species was not recorded was less than the number of occurrences, we  
18  
19 200 selected all non-occurrences as pseudo-absences. All models were produced using default  
20  
21 201 BIOMOD parameters where possible (Thuiller *et al.*, 2009). Further parameters were as  
22  
23 202 following: GLMs were generated using quadratic terms and a stepwise procedure with the  
24  
25 203 AIC criteria. GAMs were generated with a spline function with 4 degrees of smoothing.  
26  
27 204 ANNs were produced with two cross-validations. BIOMOD allows evaluation of model  
28  
29 205 performance on different data split runs and then allows using 100% of the data to make a  
30  
31 206 final calibration of the models for prediction. Thus we randomly assigned 80% of occurrence  
32  
33 207 data to train the model with the remaining 20% for testing. Each model was run ten times to  
34  
35 208 avoid bias resulting from randomly splitting the data into training and testing.  
36  
37  
38  
39  
40  
41  
42  
43

44 209 To evaluate the performance of individual models from each technique, we calculated the  
45  
46 210 area under the receiver operating characteristic curve (AUC) (Zweig *et al.*, 1993, Fielding *et*  
47  
48 211 *al.*, 1997). For each of the 37 species we produced nine models for the current time and  
49  
50 212 climate (with different modelling techniques) and 54 models (combination of nine modelling  
51  
52 213 techniques, three GCM and two storylines) for each of the three times in the future (2020,  
53  
54 214 2050 and 2080), in a total of 171 models per species.  
55  
56  
57

58 215 For each year in the future (2020, 2050 and 2080) we calculated an ensemble forecast for  
59  
60 216 current time and for each IPCC scenario for the future (A2, and B2). For this purpose, we

217 used weighted average consensus method based on AUC values, because this method is  
 218 considered to significantly improve the predictive accuracy of single models (Marmion *et al.*,  
 219 2009). Thus, AUCs values of each model technique were assigned the weights of the  
 220 weighted average in order to enhance contributions of those models with higher model  
 221 performance values (equation 1).

222

$$WA_i = \frac{\sum_m (AUC_m \times p_{mi})}{\sum_m AUC_m} \quad (\text{equation 1})$$

224 where  $i$  is the index of the grid cell,  $m$  is the model technique and  $p$  is the probability of  
 225 occurrence of the species (according to model  $m$  in grid cell  $i$ ).

226 To investigate if species ranges were predicted to contract or expand, we needed to convert  
 227 the consensus forecasted probabilities of occurrence in each year to a binary value of  
 228 predicted presence/absence. For each model technique, we calculated the threshold of the  
 229 receiver operating characteristic curve that maximizes both correctly predicted presences and  
 230 absences, relative to the evaluation data (Liu *et al.*, 2005). Subsequently, we determined a  
 231 consensus threshold (CT) by calculating the weighted average threshold, assigning the AUC  
 232 value of each model as a weight (equation 2).

233

$$CT = \frac{\sum_m (AUC_m \times t_m)}{\sum_m AUC_m} \quad (\text{equation 2})$$

235 where  $m$  is the model technique and  $t_m$  is the optimised threshold of model  $m$ .

236 Potential range shifts of each species and time period were measured under two extreme  
 237 dispersion scenarios: unlimited dispersal (scenario D), assuming that species can disperse to

1  
2  
3 238 any grid cell with suitable habitat, and no dispersal (scenario ND), assuming that species are  
4  
5 239 not capable to disperse even if suitable habitat is available. To predict species presence under  
6  
7  
8 240 the D scenario, we transformed the consensus probability value in each grid cell into 0 if it  
9  
10 241 was lower than CT and to 1 if it was equal to or higher than CT. To predict species presences  
11  
12 242 under the ND scenario, we transformed predicted presences to absences in grid cells where  
13  
14  
15 243 species is not presently predicted to occur. We evaluated the degree of uncertainty of  
16  
17 244 projections for each year and scenario by calculating the standard deviation of predicted  
18  
19 245 occurrence of species by grid cell.

20  
21  
22 246 Subsequently, we calculated predicted species richness in each grid cell for the three future  
23  
24  
25 247 periods. Future species richness was estimated by summing the number of species predicted  
26  
27 248 to occur in each grid cell under each of the storylines and the dispersion scenarios. Species  
28  
29 249 turnover (T) is the dissimilarity index between the present and future species composition of  
30  
31 250 a given area. It accounts both for species gain and losses and its relation to the overall number  
32  
33 251 of species occurring in the grid cell in present and future. Thus, a turnover value of 0  
34  
35 252 indicates that the predicted assemblage in the future would be the same as the current  
36  
37 253 assemblage, whereas a turnover value of 100 indicates that the assemblage would be  
38  
39 254 completely different under climate change. To determine it, we first calculated the number of  
40  
41 255 species lost (L), *i.e.*, the number of species predicted to lose suitable habitat in each grid cell,  
42  
43 256 and the species gain (G), *i.e.*, the number of species predicted to gain suitable habitat in each  
44  
45 257 grid cell. Percentage of species turnover by grid cell was then calculated according to  
46  
47 258 equation 3.

52  
53  
54 259 
$$T = 100 \times \frac{L + G}{SR + G},$$
 (equation 3)  
55  
56  
57

58 260 where SR is the current predicted species richness.  
59  
60  
261

## 262 **Results**

263 Model predictions within different modelling techniques, GCMs, and storylines showed high  
264 variability in the projection of range shifts, with most species being projected to both lose and  
265 gain suitable habitat, depending on the scenario (supplementary material A.1 and A.2).  
266 However, when analysing the ensemble model results (Tables 1 and 2), we found that 46% of  
267 the species are consistently predicted to have a smaller distribution in both storylines (9  
268 amphibian species and 8 reptile species), 28% of the species are consistently predicted to  
269 have a larger distribution (3 amphibian species and 8 reptile species) and the remaining  
270 species show increases and decreases depending in the time period and storyline. For  
271 example *Algyroides marchi* is predicted to have a smaller distribution until 2050 and then  
272 increase its distribution by 2080, while, *Alytes cisternasii* and *Lissotriton boscai* are predicted  
273 to have a larger distribution until 2020 and then have a smaller distribution.

274 Several species are predicted to lose a significant fraction of their current range (Figure 2)  
275 and 10 species are predicted to lose their entire suitable distribution at some time in both  
276 storylines. Three other species are predicted to lose all suitable range in one of the storylines  
277 only (Table 3). Surprisingly 5 to 10 of the 13 species that are predicted to lose all their  
278 suitable distribution lose it by 2020 (Table 3). Additionally, 9 of these species are also  
279 threatened by other causes, and currently considered “critically endangered”, “endangered” or  
280 “vulnerable”, in Portuguese or Spanish red data books (Tables 1 and 2).

281 If we assume that species have no ability to disperse, 34 species are predicted to contract their  
282 distribution and 10 species are predicted to completely lose their entire distribution in both  
283 storylines.

284 It is noteworthy that for species predicted to have a smaller distribution in the future, both the  
285 magnitude of contraction and the rate of contraction differ between species (Figure 3). While  
286 for most contracting species, the rate of range contraction is greater now (until 2020), for

1  
2  
3 287 some species there is almost a constant rate of predicted distribution loss (*e.g. Rana iberica*),  
4  
5 288 while for a minority of species the period of greatest contraction is later (*e.g. Psammodromus*  
6  
7 289 *algius*).

8  
9  
10 290 Predicted patterns of species richness are substantially different between the two dispersion  
11  
12 291 scenarios, but higher species richness was commonly predicted in south-western Iberian  
13  
14 292 Peninsula, the Central System mountain range and Morena Mountains (Figures 4 and 5).  
15  
16 293 Major species gain, in the unlimited dispersion scenario, was predicted for the central  
17  
18 294 plateaus, the central-western coast of the Iberian Peninsula, and the Cantabrian Mountains  
19  
20 295 (Figure.6). Major loss of species ranges is predicted for the Atlantic climate regions, mostly  
21  
22 296 along the northwest of the Iberian Peninsula and the main mountain ranges, such as the  
23  
24 297 Central System and the Morena Mountains (Figure. 6). Spatial patterns of predicted species  
25  
26 298 richness are similar in both storylines, although storyline B2 predicted slightly higher species  
27  
28 299 losses for 2020 and storyline A2 predicted higher species loss for 2080 (Figures 4 and 5).

36  
37

## 38 301 **Discussion**

### 39 302 *Main findings and relation with previous projections*

40  
41 303 Our results suggest that climate change might have serious impacts on the distribution  
42  
43 304 patterns of the endemic and nearly endemic amphibians and reptiles of the Iberian Peninsula,  
44  
45 305 particularly for species with Atlantic climate affinities such as *Chioglossa lusitanica*, *Rana*  
46  
47 306 *iberica* and *Vipera seoanei* and particularly high altitude species with Atlantic climate  
48  
49 307 affinities such as, *Rana pyrenaica*, *Iberolacerta monticola*, *I. aranica*, *I. aurelioi*, and *I.*  
50  
51 308 *bonnali*. It is also possible that other species may be more affected by climate change than  
52  
53 309 predicted by the models, such as *Iberolacerta cyreni*. This species is an endemic with a  
54  
55 310 current range restricted to the Gredos Mountains in Spain. However, the ensemble model for  
56  
57  
58  
59  
60

1  
2  
3 311 this species predicted a current range much larger than probably the one where the species  
4  
5 312 actually occurs. This indicates that predicted future range may also be overestimated. On the  
6  
7  
8 313 other side, models for *Pelodytes ibericus*, *Triturus marmoratus* and *T. pygmaeus* were built  
9  
10 314 only based on Spanish records, although they also occur in Portugal. This methodological  
11  
12 315 caveat may have conducted to an under estimation of current and future ranges of those  
13  
14  
15 316 species.

16  
17 317 Our analysis indicates that the most critical period for the majority of these species will be the  
18  
19 318 next decade. This result emphasises the need for immediate conservation action in the Iberian  
20  
21 319 Peninsula to ameliorate the impact of climate change.

22  
23  
24 320 Previous macroscale studies have called attention to the vulnerability of biodiversity in the  
25  
26 321 Mediterranean basin. This region was considered one of the most vulnerable in the world  
27  
28 322 (Sala *et al.*, 2000) and one of the biodiversity hotspots likely to undergo major losses due to  
29  
30 323 climate change, along with the Cape Floristic Region, the Caribbean, Indo-Burma, Southwest  
31  
32 324 Australia, and the Tropical Andes (Malcolm *et al.*, 2006). The Iberian Peninsula is considered  
33  
34 325 the Mediterranean sub-region most likely to be affected by future climate change (EEA,  
35  
36 326 2004). Our analysis confirm the vulnerability of species occurring in the Iberian Peninsula to  
37  
38 327 climate change, but curiously, species with Atlantic climate affinities were predicted to be  
39  
40 328 more affected by climate change then the Mediterranean ones. The Atlantic climate region is  
41  
42 329 much more restricted in the Iberian Peninsula then the Mediterranean. Due to predicted drops  
43  
44 330 in precipitation and temperature raise it is likely that the all Iberia became dominated by a  
45  
46 331 Mediterranean climate. Thus, it seems logical that Atlantic species become more affected by  
47  
48 332 climate change then the Mediterranean ones. Climate change impacts on Atlantic species was  
49  
50 333 exacerbated by the region being a peninsula so dispersal out of the region to other Atlantic  
51  
52 334 climate regions is restricted. Similar patterns should be found in other Mediterranean  
53  
54 335 Peninsulas that present different climatic types (*e.g.* the Italian Peninsula and the Balkans).

1  
2  
3 336 Our results are consistent with those found by Araújo *et al.* (2006), in the sense that climate  
4  
5 337 change is predicted to cause a major contraction in the distribution of a considerable number  
6  
7  
8 338 of amphibian and reptile species in the Iberian Peninsula. However, our results revealed that  
9  
10 339 major losses for endemic and nearly endemic species will occur in substantially different  
11  
12 340 areas than the ones predicted by Araújo *et al.* (2006) for the all amphibians and reptiles. We  
13  
14  
15 341 predict that the north-west of the region, the Central System and the Morena Mountains will  
16  
17 342 lose many species in contrast to their results where there is expected to be species gain. The  
18  
19 343 reasons for this difference may be our focus on endemic and nearly endemic species rather  
20  
21 344 than all species, but it could also be differences in spatial scale or methods used to construct  
22  
23 345 the ensemble models. Dissimilarities in areas predicted to gain species may also be related to  
24  
25 346 the colonization of non endemic or nearly endemic species and non Iberian species not  
26  
27 347 included in our analysis. These divergent results highlight the importance of finer-scale  
28  
29 348 analyses for areas identified as vulnerable in broader continental-scale studies.  
30  
31  
32  
33

34 349  
35  
36 350 Interestingly, a previous study of climate change threats to plant diversity in Europe (Thuiller  
37  
38 351 *et al.*, 2005) also identified the Iberian Peninsula as one of the European regions likely to  
39  
40 352 undergo major species loss. Garzón *et al.* (2008) identified the north and northwest of the  
41  
42 353 Iberian Peninsula and the main mountain ranges, as the Iberian areas likely to have the  
43  
44 354 highest tree species loss, which is partially coincident with our results. Thus, if changes in  
45  
46 355 vegetation communities are also predicted, it means that amphibians and reptiles will face a  
47  
48 356 synergistic impact of climate and habitat change, which ultimately will also be coupled with  
49  
50 357 the impact of changes in biotic interactions resulting from changes in the community of  
51  
52 358 species. These results also suggest that the impacts of climate change on species ranges might  
53  
54 359 be similar across different biodiversity groups that occur in the same area, which calls for the  
55  
56 360 need to evaluate possible climate change impacts on those groups.  
57  
58  
59  
60

361

362 ***From predicted impacts (models) to vulnerability***

363 Our dramatic predictions should be interpreted with caution given all the uncertainties in the  
364 process: the statistical methods used for modelling species distributions, the global circulation  
365 models used to predict future climate conditions (*e.g.* Araújo *et al.*, 2007, Beaumont *et al.*,  
366 2008), the scale of the analysis (Seo *et al.*, 2009), and specific dispersal abilities. Additionally  
367 species distribution models disregard important biological parameters that ultimately are the  
368 determinants of species capability to adapt to climate change.

369 Different modelling techniques, GCM and storylines provided fairly different results for the  
370 number of predicted occurrences of a species. The ensemble methodology allows us to  
371 distinguish the strongest signal emerging from the noise associated with different model  
372 outputs but it is not immune from uncertainty. Taking uncertainty into account, for example  
373 by using as an uncertainty measure the standard deviation of the total number of occurrences  
374 predicted by the different models for each species (appendix 1A and A2), the most likely  
375 impact of climate change will be on species whose ranges are predicted to contract more  
376 (relatively to their current extent), or to become more restricted (considering their future  
377 absolute extent) with less uncertainty. For example, analysing only the year 2020 projections  
378 for storyline A2, species that fulfil both criteria are *Discoglossus galganoi* (considering the  
379 species whose ranges are predicted to contract more) and *Iberolacerta aranica*, (considering  
380 the species whose ranges are predicted to become more restricted or disappear).

381 The scale of analysis may also be a relevant limitation in determining the impact of climate  
382 change, because the scale used does not account for microhabitat variability within sites. This  
383 constraint is quite relevant in the case of amphibians and reptiles because they might find  
384 suitable habitat, for instance, in small ponds, water tanks, below stones or underground  
385 (Kearney *et al.*, 2009). Also, the scale of the analysis probably obscures altitudinal

1  
2  
3 386 microclimatic gradients which might allow species to move towards future suitable habitats  
4  
5  
6 387 without the need to disperse long distances.  
7

8  
9 388 Specific dispersal abilities may strongly determine the impacts of climate change on the  
10  
11 389 future distribution of species. However, given that this parameter is difficult to determine for  
12  
13 390 every species, we predicted future distributions under the assumptions of maximal and  
14  
15 391 minimal possible dispersal ability for each species. We recognize that both of these  
16  
17 392 assumptions are unrealistic, but they allow us to predict the largest and smallest possible  
18  
19 393 future ranges. A more realistic prediction would probably be somewhere in the middle of  
20  
21 394 these two extremes, but we cannot make an exact prediction with high level of certainty.  
22  
23  
24

25 395 Assuming these limitations we do not argue that species predicted to completely lose their  
26  
27 396 distribution under our analysis will go extinct. Rather, we consider that the degree, the  
28  
29 397 certainty and the time of predicted range contractions provides a relative measure of the  
30  
31 398 magnitude of the impact of climate change on each species. Ultimately, the vulnerability of a  
32  
33 399 species to a given impact will depend also on the species resistance, *i.e.* the ability of a  
34  
35 400 species to withstand an environmental perturbation, and resilience, *i.e.* the ability of a species  
36  
37 401 to adapt and recover from a perturbation (Isaac *et al.*, 2008, Williams *et al.*, 2008, ). Thus,  
38  
39 402 prioritizing species for management actions would require a further analysis of the specific  
40  
41 403 factors that determine resistance and resilience. In general, the species traits that are predicted  
42  
43 404 to promote species resistance to climate change are physiologic climatic tolerance (Calosi *et*  
44  
45 405 *al.*, 2008), geographical range size and local abundance.  
46  
47  
48  
49  
50

51  
52 406 Overall, reptiles are usually considered more resistant to global warming effects than  
53  
54 407 amphibians because they have evolved a set of adaptations to water scarcity, such as eggs  
55  
56 408 with calcareous shells (while amphibian eggs are enclosed by simple gelatinous membranes),  
57  
58 409 and the excretion of metabolic wastes in the form of urea or uric acid, which is an adaptation  
59  
60 410 to retain body-water (Gibbons *et al.*, 2000). Additionally, most reptiles are not dependent on

1  
2  
3 411 water for reproduction. Although more specific climatic tolerances might be difficult to  
4  
5 412 determine, they may be inferred by morphological traits or by the complete climatic envelope  
6  
7  
8 413 of species. Also, the climatic envelope of phylogenetic related species might provide some  
9  
10 414 clues, if one considers niche conservatism (Hawkins *et al.*, 2007). For example, species  
11  
12 415 belonging to clades that evolved under warm environments may be more tolerant to global  
13  
14  
15 416 warming.

16  
17  
18 417 Species with restricted ranges are relatively more vulnerable to climate change because  
19  
20 418 contractions of their small range will not be balanced elsewhere. From this point of view,  
21  
22 419 species with very restricted distributions predicted to completely lose suitable habitat in the  
23  
24  
25 420 Iberian Peninsula such as *Iberolacerta aranica*, *I. aurelioi*, and *Rana pyrenaica* may be more  
26  
27 421 impacted by climate change than more widespread Iberian species such as *Lissotriton boscai*  
28  
29  
30 422 or *Chalcides bedriagai*.

31  
32  
33 423 Demographic parameters are also important factors in determining resistance to climate  
34  
35 424 change (Keith *et al.*, 2008). Species with restricted ranges but with high local abundance may  
36  
37 425 have more chances to adapt because genetic variation and potential response to selection  
38  
39 426 pressures are positively correlated with population size. Thus, biological traits that regulate  
40  
41 427 abundance, such as reproductive rates, age of female sexual maturity and life span length are  
42  
43  
44 428 also relevant. *Discoglossus galganoi* and *Podarcis bocagei* are species predicted to  
45  
46 429 completely lose their range in the Iberian Peninsula but have high abundance and  
47  
48  
49 430 reproductive rate, and consequently will probably be less impacted by climate change than  
50  
51 431 the others will.

52  
53  
54 432 The adaptive capacity (or plasticity) of a species describes the intrinsic ability of a species to  
55  
56 433 adapt to changing conditions. Species might be able to adjust their behaviour and phenology  
57  
58 434 by switching periods of daily activity, aestivation and hibernation towards more favourable  
59  
60 435 climatic conditions (Parmesan, 2007). Species might also be able to evolve traits that allow

1  
2  
3 436 them to adapt to different climatic conditions (Harte *et al.*, 2004, Bradshaw *et al.*, 2006).  
4  
5 437 Adaptation ability may be species-specific, however, the current knowledge is insufficient to  
6  
7  
8 438 determine which species are more able to adapt and further studies and monitoring are  
9  
10 439 required to fully understand it.

11  
12  
13 440 Species might also adapt to novel climate conditions by dispersing to other areas (Thuiller,  
14  
15 441 2004, Massot *et al.*, 2008). Dispersion ability has been identified as one of the most decisive  
16  
17  
18 442 parameters in determining species resilience to climate change as species with greater  
19  
20 443 dispersion ability may be able to track climate transitions. However this parameter is also one  
21  
22 444 of the most difficult to determine. A growing body of literature proposes a vast collection of  
23  
24  
25 445 complex models to predict dispersion ability (reviewed by Thuiller *et al.*, 2008) but these  
26  
27 446 require detailed data on an array of ecological processes that usually are unavailable for large  
28  
29  
30 447 numbers of species.

31  
32  
33 448 A preliminary analysis of the model results and previous considerations indicate that species  
34  
35 449 requiring more conservation attention under a climate warming perspective may be *Rana*  
36  
37 450 *pyrenaica*, *Rana iberica* and *Calotriton asper* , within the amphibians, and *Iberolacerta*  
38  
39 451 *aranica*, *Iberolacerta aurelioi*, *Iberolacerta bonnali* and *Iberolacerta monticola* within the  
40  
41  
42 452 reptiles. However, this does not mean that these are the most vulnerable species to extinction,  
43  
44 453 because this evaluation is only based on vulnerability to climate change, and does not account  
45  
46  
47 454 for other threats or the interaction of climate change with other threats (Brook *et al.*, 2008).  
48  
49 455 Particularly, climate change is likely to induce further habitat changes and fragmentation (due  
50  
51 456 to shifts in plant species distribution and an increase in fire incidence) and the spread of  
52  
53  
54 457 agents of infectious diseases such as the chytridiomycete fungus which is already across the  
55  
56 458 Iberian Peninsula (Garner *et al.*, 2005). These factors are already considered the primary  
57  
58  
59 459 threats to amphibians and reptiles, along with pollution, invasive species, road kills and  
60  
460 genetic depression.

461

462 ***From vulnerability to conservation actions***

463 Recommendations to address climate change impacts on biodiversity include a wide variety  
464 of measures, with the most popular being monitoring species (with emphasis on the  
465 physiological, behavioural and demographic response), restoring habitats and system  
466 dynamics, expanding reserve networks, performing assisted dispersal Hoegh-Guldberg *et al.*  
467 (2009), reducing other threats and increasing connectivity between suitable habitats (Heller *et*  
468 *al.*, 2009, Lawler, 2009). Probably the most important questions for management are whether  
469 species will be able to adapt to future climate conditions without the need to disperse or, if  
470 not, if they will be able to disperse. Because these questions are difficult to answer with  
471 current knowledge, novel management tools that promote flexible decision-making are  
472 emerging, such as adaptative management (Kareiva *et al.*, 2008). Following this  
473 methodology, we recommend that monitoring should be directed at the most vulnerable  
474 species identified by our research. To infer species-specific conservation measures, the  
475 monitoring parameters should include: a) physiological changes in thermal tolerances; b)  
476 phenological adjustments, such as changes in aestivation and hibernation periods along the  
477 year; c) behavioural thermoregulation changes, such as burrowing or adjustments in daily  
478 activity periods; d) quantification of dispersal rates; e) changes in population parameters,  
479 such as abundance, fertility and mortality f) incidence of infectious diseases and g) species  
480 interactions.

481 If species are not able to disperse, then management measures will be needed in order to  
482 assist local adaptation. Habitat restoration has been proposed as a proactive measure to  
483 enhance amphibian resilience to climate change. In particular, a denser network of ponds and  
484 water tanks has been recommended for amphibians (Blaustein *et al.*, 2001) in Mediterranean  
485 areas. This measure, along with a careful control of river flow and water quality may increase

1  
2  
3 486 the probability of amphibians to find suitable habitats during climate warming. Availability  
4  
5 487 of freshwater habitats will be particularly important in the regions predicted to have high  
6  
7  
8 488 species loss, the northern Iberian Peninsula and main mountain systems, but also in extreme  
9  
10 489 southern regions (Beja *et al.*, 2003).

11  
12  
13 490 Assisted colonisation has been suggested, as a measure to assist climate change adaptation  
14  
15 491 (Mueller *et al.*, 2008; Cheddadi *et al.*, 2009). This triggered intense debate (McLachlan *et al.*,  
16  
17  
18 492 2007) because translocation of species originated catastrophic impacts in many existing  
19  
20 493 cases. However, assisted dispersal is particularly relevant for amphibians and reptiles due to  
21  
22 494 their low dispersal ability, and therefore we cannot disregard this management possibility  
23  
24  
25 495 under an extreme probability of extinction scenario. However, we agree with (Hoegh-  
26  
27 496 Guldberg *et al.*, 2008) in that assisted dispersal should only be considered for a given species  
28  
29 497 if at least one of a set of assumptions is met, namely: a) the species should be in immediate  
30  
31 498 risk of extinction; b) species should have low dispersal ability and c) the species range should  
32  
33  
34 499 be highly fragmented. Moreover, those authors suggest that translocations should only be  
35  
36 500 undertaken within biogeographic regions, *i.e.*, regions that share similar species composition,  
37  
38 501 and an assessment of translocation risks should be performed previously, including ecological  
39  
40 502 and socio-economical risks. Translocation risk should subsequently be balanced against those  
41  
42 503 of extinction and safeguarded by detailed scientific understanding.  
43  
44  
45

46  
47 504 Protected areas have long been considered one of the most effective tools to conserve  
48  
49 505 biodiversity (Rodrigues *et al.*, 2004), but their effectiveness in securing species under rapid  
50  
51 506 climate change is uncertain (Araújo *et al.*, 2004). However they contribute to minimising  
52  
53 507 threats such as, habitat destruction and fragmentation, road kills and pollution, which  
54  
55 508 ultimately may assist to protect species threatened by climate warming. Therefore, it is  
56  
57 509 important to evaluate if present protected areas would be effective in securing species given  
58  
59 510 their predicted range shifts and whereas there is habitat connectivity between current and  
60

1  
2  
3 511 future species distributions. This could be achieved using reserve selection algorithms (*e.g.*  
4  
5 512 Moilanen, 2009), which allow the identification the minimum set of areas necessary to  
6  
7  
8 513 represent all species at a given target. Ultimately, the ability of species to adapt to climate  
9  
10 514 change within nature reserves will depend on the management actions undertaken in each of  
11  
12 515 them. Reserve selection algorithms may also assist in identifying areas within nature reserves  
13  
14  
15 516 where the return of the management investment will be greater for a higher number of  
16  
17 517 species.

18  
19  
20 518 If species are able to disperse to new habitats, than management actions will be needed to  
21  
22 519 facilitate dispersal, including the increase of habitat connectivity, in particular of freshwater  
23  
24  
25 520 habitats.

26  
27  
28 521 Finally, biodiversity conservation can only be successful under climate change scenarios if  
29  
30 522 socio-economical and environmental policies are integrated and if governments cooperate.  
31  
32 523 Although climate change is a global issue, there is a tendency for actions to be taken by  
33  
34 524 governments individually or by local administration, even with a common European  
35  
36 525 environmental policy. It is recommended that the Portuguese and the Spanish governments  
37  
38 526 embark on joint efforts to conserve Iberian biodiversity, particularly Iberian endemics.

Number of species predicted to gain or lose suitable habitat under different dispersion assumptions (unlimited dispersal and no dispersal) and storylines (A2 and B2), categorised by the percentage of range contraction or expansion relatively to present (x axis). Endemics and non endemics species are represented separately, with endemics representing species strictly endemic to the Iberian Peninsula and species endemic to the Pyrenean Mountains. Black columns represent species predicted to lose suitable habitat while white columns represent species predicted to gain suitable habitat.
