Abstract

In this article some qualitative and geometric aspects of non-smooth dynamical systems theory are discussed. The main aim of this article is to develop a systematic method for studying local (and global) bifurcations in non-smooth dynamical systems. Our results deal with the classification and characterization of generic codimension-2 typical singularities of planar Filippov systems as well as the presentation of the bifurcation diagrams and some dynamical consequences.

Keywords: singularity, non-smooth vector field, structural stability, bifurcation.

1 Introduction

In this article some qualitative and geometric aspects of non-smooth dynamical systems theory are discussed. Non-smooth dynamical systems is a subject that has been developed at a very fast pace in recent years and it has become certainly one of the common frontiers between Mathematics and Physics/Engineering.

The main aim of this article is to develop a systematic method to study typical local (and global) bifurcations in non-smooth dynamical systems. More concretely, we focus our attention on Filippov Systems (see [Fil88]), which are systems modelled by ordinary differential equations discontinuous along a hypersurface in the phase space. Non-smooth systems often appear as models for plenty of phenomena such as dry friction in mechanical systems or switches in electronic circuits. Moreover, it is well known that many of these models (see for instance [dBBCK08]) occur in generic two-parameter families and therefore they typically undergo generic codimension-2 bifurcations.

Many authors have contributed to the study of Filippov systems (see for instance [BL76, Fil88, Koz84]). See also [Tei09] references therein. One of the starting points for a systematic approach in the study of bifurcations in these systems was the work of M. A Teixeira [Tei77] about smooth systems in 2-dimensional manifolds with boundary. This work was generalized in [BPS01] to the study of

structurally stable Filippov systems defined in 2-dimensional manifolds with several discontinuity curves which intersect. The classification of codimension-1 local and some global bifurcations for planar systems was given in [KRG03]. Concerning higher dimensions, it is worth to mention [Tei79, Tei81, Tei90, Tei93, Tei96, Tei99, JH09] for the study of local bifurcations in $\mathbb{R}^3$ and [dBBCK08, dBBC$^+$08, KdBC$^+$06] for bifurcations of periodic orbits. Nevertheless, in dimension higher than 2 even the codimension-1 local bifurcations are not completely well understood (see [Tei90]).

In this paper we study the most remarkable codimension-2 local bifurcations for planar Filippov systems as well as exhibit their intrinsic characterizations, presenting (local) bifurcation diagrams and some dynamical consequences. It is worth to say that, since we are considering Filippov vector fields in $\mathbb{R}^2$, their discontinuity set is given by a smooth curve Σ.

It has to be remarked that, due to the discontinuities of the vector field, the usual concepts of orbit, singularity and topological equivalence can not be straightforwardly generalized to Filippov Systems. Thus, when one wants to study some features of these systems, has to decide first how to generalize these definitions from the classical smooth ones. In fact, in the literature of Filippov Systems one finds several definitions of orbit. The authors choose it adapted to their purposes, but some of them fail to be consistent for general Filippov systems (see for instance [Fil88, BPS01]). In this paper, we present definitions (based on [BPS01]) which seem to be a consistent and natural generalization of the concept of orbit, singularity and topological equivalence to planar Filippov systems. In particular, the definition of orbit preserves the existence and uniqueness property. Thus, in Section 2 we will make an introduction to planar Filippov Systems from a rigorous point of view, showing examples to justify our choices.

One of our concerns is the problem of structural stability, the most comprehensive of many different notions of stability. This problem is of obvious importance, since in practice one obtains a lot of qualitative information not only on a concrete system but also on its nearby systems. In Section 2.3, we consider both the classical notion of topological equivalence and also the notion of Σ-equivalence, which has been widely used in the setting of Filippov systems (see [KRG03, BPS01]). This last definition is more restrictive than the usual one. In Section 9, a comparative analysis between both concepts based in some models is provided.

On the other hand, even if the definition of bifurcation is based on breaking structural stability, as far as the authors know, none of the papers studying bifurcations in Filippov Systems show how to construct the homeomorphisms which lead to equivalences. Thus, in Section 3, we show how to construct some of them, focusing on the regular points and codimension-0 singularities and their normal forms.

The codimension-1 local and global bifurcations were studied in [Fil88, KRG03]. Thus, we use these works as a basis from which our study is developed. Nevertheless, in Section 4, we give some remarks on these previous works. First, concerning local bifurcations, we give necessary generic non-degeneracy conditions needed to define the bifurcations and their codimension. The results in [KRG03] were achieved mainly from certain normal forms. However, some of those conditions were not explicitly stated there. Regarding the codimension-1 global bifurcations, we propose a systematic approach from the point of view of separatrix connections following the ideas in [Tei77]. The authors think that this new approach, being more systematic, helps more to understand the full classification of global bifurcations and sharpens some results obtained in [KRG03].

Section 5 is devoted to establish a preliminary classification of the codimension-2 singularities. In Sections 6, 7, 8, 9, 10, 11, 12, 13 and 14 the most interesting cases, as well as their bifurcation diagrams, are presented. All the local and global codimension-1 bifurcations which appear in their unfoldings are also described. It is worth to mention that in this study we detect several rich phenomena which are not present in any codimension-1 singularity and are genuinely non-smooth.

For instance, in Section 9 we show a singularity whose bifurcation diagram differs whether one considers topological or Σ-equivalence. On the other hand, in Section 10 we encounter a codimension-2 singularity whose unfolding presents some of the classical sliding bifurcations of periodic orbits (see [dBBCK08]).

Finally, in Sections 11 and 12, we detect codimension-2 singularities whose unfoldings present infinitely many branches of codimension-1 global bifurcations emerging from the codimension-2 singularities.

2 Preliminaries on Filippov Systems

2.1 Orbits and singularities

The basic notions of Dynamical Systems can not be translated directly to Filippov Systems due to the presence of discontinuities, but they have to be reformulated. Of course, the first step in order to clarify the study of this kind of systems is to establish the notion of orbit and singularity.

In this section, we state these basic notions. Basically, we will follow in spirit the approach done in [BPS01]. Nevertheless, we will not consider Filippov vector fields with several discontinuity curves which intersect in vertices as was done in that paper, and then we will not need to consider their approach in its full generality.

On the other hand, it has to be recalled that in [BPS01], the authors only study generic Filippov vector fields, in such a way that they avoid some *particular* behaviors which have positive codimension. For this reason, their definitions turn out to be simpler but can not be directly generalized to a wider class of systems. Throughout this section, some of these non-generic examples will be shown in order to justify our choices in the definitions of orbit and singularity.

First, we state here some general assumptions and we fix some notation. Since we study Filippov systems locally, we deal with germs of vector fields and functions and we do not distinguish them from any of their representatives.

We also assume that discontinuities only appear in a differentiable submanifold Σ, which can be given as $\Sigma = f^{-1}(0) \cap U$ for certain germ of a $\mathcal{C}^r$ function f (with $r > 1$) which has 0 as a regular value. Then, the curve Σ splits U in two open sets

$$\Sigma^+ = \{(x, y) \in U : f(x, y) > 0\} \text{ and } \Sigma^- = \{(x, y) \in U : f(x, y) < 0\}.$$

In this paper, the germs of discontinuous vector fields we consider are of the form

$$Z(x, y) = \begin{cases} X(x, y), \ (x, y) \in \Sigma^+ \\ Y(x, y), \ (x, y) \in \Sigma^-. \end{cases} \tag{1}$$

For simplicity, we consider only germs of vector fields in a neighborhood of $(0, 0)$.

We denote $Z = (X, Y)$ in order to clarify which are the components of the vector field. Furthermore we assume that they are $\mathcal{C}^r$ for $r > 1$ in $\overline{\Sigma^+}$ and $\overline{\Sigma^-}$ respectively. In this assumption we are using the standard convention that for a function defined in a non-open domain D, being class $\mathcal{C}^r$ means that it can be extended to a $\mathcal{C}^r$ function defined on an open set containing D, and the same applies to vector fields.

We call $\mathcal{Z}^r$ to the space of vector fields of this type. It can be taken as $\mathcal{Z}^r = \mathfrak{X}^r \times \mathfrak{X}^r$ and therefore we consider it with the product $\mathcal{C}^r$ topology.

The first step is to define rigorously $\varphi_Z(t, p)$ for any $p \in U$. In other words, in order to establish the dynamics given by the Filippov vector field $Z = (X, Y)$ in U, first step is to define the local trajectory through a point $p \in U$. To this end, we need to distinguish whether this point belongs to Σ^+, Σ^- or Σ. Since we are dealing with autonomous systems we will use trajectory and orbit indistinctly.

For the first two regions, the local trajectory is defined by the vector fields X and Y as usual. In order to extend its definition to Σ we split it in three parts depending whether the vector fields point towards Σ or not:

1. Crossing Region: $\Sigma^c = \{p \in \Sigma : Xf(p) \cdot Yf(p) > 0\}$
2. Sliding Region: $\Sigma^s = \{p \in \Sigma : Xf(p) < 0, Yf(p) > 0\}$
3. Escaping Region: $\Sigma^e = \{p \in \Sigma : Xf(p) > 0, Yf(p) < 0\}$

where $Xf(p) = X(p) \cdot \text{grad} f(p)$ is the Lie derivative of f with respect to the vector field X at p.

These three regions are relatively open in Σ and can have several connected components. Therefore, their definitions exclude the so called *tangency points*, that is, points where one of the two vector fields is tangent to Σ, which can be characterized by $p \in \Sigma$ such that $Xf(p) = 0$ or $Yf(p) = 0$. These points,

which are on the boundary of the regions Σ^c, Σ^s and Σ^e, will be carefully studied later. We recall that the tangency points include the case $X(p) = 0$ or $Y(p) = 0$, that is, when one of the two vector fields has a critical point at Σ.

Remark 2.1. *Throughout this article we assume that the tangency points are isolated in Σ. This happens when one studies low codimension bifurcations in planar Filippov Systems, but in more degenerate systems (of infinite codimension) could exist a continuum of tangency points.*

For the sake of simplicity, the definition of orbit that is stated in this section only apply to Filippov systems with isolated singularities.

We define the orbit through a point p in Σ^c, Σ^s and Σ^e. In Σ^c, since both vector fields point towards the same direction, it is enough to match the orbits of X and Y through that point.

In Σ^s and Σ^e, the definition of local orbit is given by the Filippov convention. We consider the vector field Z_s which is the linear convex combination of X and Y tangent to Σ, that is

$$Z_s(p) = \frac{1}{Yf(p) - Xf(p)} F_Z(p) = \frac{1}{Yf(p) - Xf(p)} \left(Yf(p)X(p) - Xf(p)Y(p)\right) \tag{2}$$

This vector field is called *sliding vector field* independently whether it is defined in the sliding or escaping region, and for $p \in \Sigma^s \cup \Sigma^e$ the local orbit of p is given by this vector field (and therefore is contained in Σ^s or Σ^e). All of this is summarized in next definition.

Definition 2.2. *The local trajectory (or orbital solution) of a Filippov vector field of the form* (1) *through a point p is defined as follows:*

- *For $p \in \Sigma^{\pm}$ such that $X(p) \neq 0$ and $Y(p) \neq 0$ respectively, the trajectory is given by $\varphi_Z(t,p) = \varphi_X(t,p)$ and $\varphi_Z(t,p) = \varphi_Y(t,p)$ respectively, for $t \in I_p \subset \mathbb{R}$.*
- *For $p \in \Sigma^c$ such that $Xf(p), Yf(p) > 0$ and taking the origin of time at p, the trajectory is defined as $\varphi_Z(t,p) = \varphi_Y(t,p)$ for $t \in I_p \cap \{t < 0\}$ and $\varphi_Z(t,p) = \varphi_X(t,p)$ for $t \in I_p \cap \{t > 0\}$. For the case $Xf(p), Yf(p) < 0$ the definition is the same reversing time.*
- *For $p \in \Sigma^e \cup \Sigma^s$ such that $Z_s(p) \neq 0$, $\varphi_Z(t,p) = \varphi_{Z_s}(t,p)$ for $t \in I_p \subset \mathbb{R}$, where Z_s is the sliding vector field in* (2).
- *For $p \in \partial\Sigma^c \cup \partial\Sigma^s \cup \partial\Sigma^e$ such that the definitions of trajectories for points in Σ in both sides of p can be extended to p and coincide, the orbit through p is this limiting orbit. We will call these points* regular tangency points.
- *For any other point $\varphi_Z(t,p) = p$ for all $t \in \mathbb{R}$. In this set are included the tangency points which are not regular and which will be called* singular tangency points

Remark 2.3. *In the case of $p \in \Sigma^s \cup \Sigma^e$, there have been stated different definitions of $\varphi_Z(t,p)$ (see for instance [KRG03]), since besides the orbit given by Z_s, there are two trajectories (of X and Y) which arrive to p in finite (positive or negative) time. Defining the orbits through these points as $\varphi_{Z_s}(t,p)$ we have followed the approach in [BPS01] since two main features of classical Dynamical Systems persist: every point belongs to a unique orbit and the phase space is the disjoint union of all the orbits. We consider that the orbit $\varphi_Z(t,p)$ for $p \in \Sigma^s \cup \Sigma^e$ is the trajectory given by the sliding vector field, and we will consider that the orbits of X and Y arrive at this point relatively open. With this choice Σ^s and Σ^e are locally invariant curves.*

Remark 2.4. *The points $p \in \Sigma^s \cup \Sigma^e$ which satisfy $Z_s(p) = 0$, that is, the critical points of the sliding vector field, will be called* pseudo-equilibria *of Z following [KRG03] (called singular equilibria in [BPS01]). Observe that in these points the vector fields X and Y must be collinear.*

Moreover, we will call stable pseudonode to any point $p \in \Sigma^s$ such that $Z_s'(p) < 0$, unstable pseudonode to any point $p \in \Sigma^e$ such that $Z_s'(p) > 0$ and pseudosaddle to any point $p \in \Sigma^s$ such that $Z_s'(p) > 0$ or $p \in \Sigma^e$ such that $Z_s'(p) < 0$.

Definition 2.5. *The singularities of a Filippov vector field* (1) *are:*

- $p \in \Sigma^{\pm}$ *such that* $X(p) = 0$ *and* $Y(p) = 0$ *respectively.*
- $p \in \Sigma^s \cup \Sigma^e$ *such that* p *is a pseudoequilibria, that is* $Z_s(p) = 0$
- $p \in \partial\Sigma^c \cup \partial\Sigma^s \cup \partial\Sigma^e$*, that is the (regular and singular) tangency points.*

Let us observe that in Filippov systems there exist singularities which have an orbit such that $\varphi_Z(t,p) \neq p$ (see Definition 2.2). For this reason, we will classify the singularities as:

- Distinguished singularities: points p such that $\varphi_Z(t,p) = p$.
- Non-distinguished singularities: points $p \in \Sigma$ which are regular tangency points and then their local trajectory is homeomorphic to $\mathbb{R}$.

Even if the chosen definition of orbit leads to the uniqueness property, a point $p \in \Sigma$ may belong to the closure of several other orbits. To take into account this fact, we use the following definition from [BPS01] which will be also used throughout the paper.

Definition 2.6. *Given an orbit* $\gamma(t) \in \Sigma^+ \cup \Sigma^-$ *and a point* $p \in \Sigma$*, we say that* p *is a departing point of* γ *if* $\lim_{t\to 0^+} \gamma(t) = p$ *and that it is an arrival point of* γ *if* $\lim_{t\to 0^-} \gamma(t) = p$*. We call to these orbits departing and arrival orbits of the point* p*.*

Let us observe that according to definition 2.2 the orbit through a point $p \in \Sigma^c$ is the union of the point and their departing and arrival orbits.

In the rest of this section, we will give some examples of tangency points, which in most of the cases were not considered in [BPS01], to show how Definitions 2.2 and 2.6 apply to them.

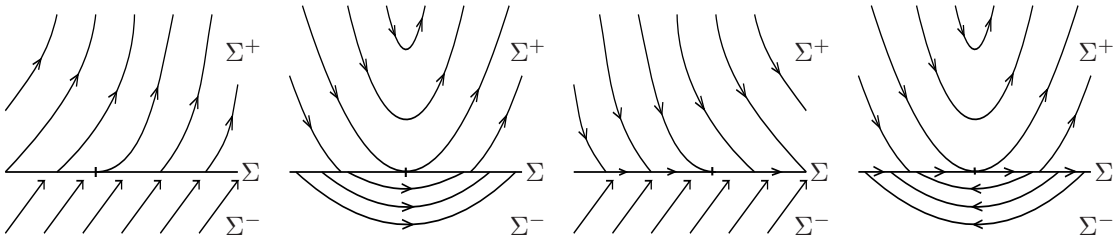

Figure 1: From left to right, phase portraits of the Filippov vector fields Z_1, Z_2, Z_3 and Z_4. These four Filippov vector fields have a regular tangency point.

First example is a regular tangency point $p \in \partial\Sigma^c$. For instance, we take $p = (0,0)$, $\Sigma = \{y = 0\}$ and

$$Z_1 = \begin{cases} X_1 = \begin{pmatrix} 1 \\ x^2 \end{pmatrix} & \text{for } y > 0 \\ Y_1 = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{for } y < 0 \end{cases}$$

(see Figure 1a). Following Definition 2.2, the orbit through p is its departing and arrival orbits as happens for points in Σ^c.

Second example of regular tangency points is ilustrated in the following model. Take $p = (0,0) \in \partial\Sigma^c \subset \Sigma = \{y = 0\}$ and

$$Z_2 = \begin{cases} X_2 = \begin{pmatrix} 1 \\ 2x \end{pmatrix} & \text{for } y > 0 \\ Y_2 = \begin{pmatrix} 2 \\ 7x \end{pmatrix} & \text{for } y < 0 \end{cases}$$

(see Figure 1b). In this case the orbit through p is $\varphi_Z(t,p) = \varphi_X(t,p)$.

For tangency points belonging to $\partial\Sigma^s$, as $p = (0,0) \in \Sigma = \{y = 0\}$ for

$$Z_3 = \begin{cases} X_3 = \begin{pmatrix} 1 \\ -x^2 \end{pmatrix} & \text{for } y > 0 \\ Y_3 = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{for } y < 0 \end{cases}$$

(see Figure 1c), we consider as their orbit the trajectory of the sliding vector field, which for Z_3 is given by $Z_s(x) = 1$, as we did for the points in Σ^s or Σ^e.

Another example of a regular tangency point $p \in \partial\Sigma^s \cup \partial\Sigma^e$, is $p = (0,0) \in \Sigma = \{y = 0\}$ for the Filippov vector field

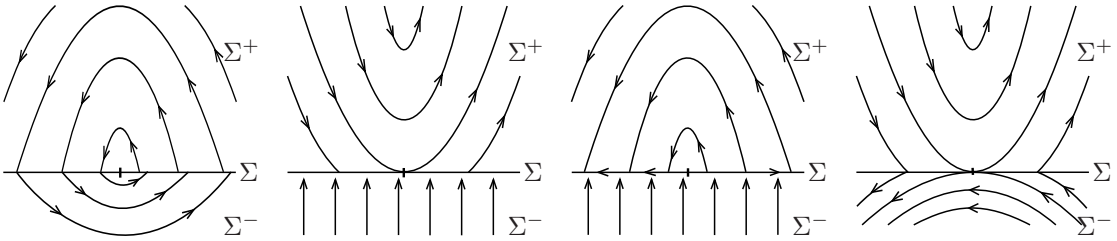
$$Z_4 = \begin{cases} X_4 = \begin{pmatrix} 1 \\ 2x \end{pmatrix} & \text{for } y > 0 \\ Y_4 = \begin{pmatrix} -2 \\ -7x \end{pmatrix} & \text{for } y < 0 \end{cases}$$

(see Figure 1d). In that case we have $\Sigma^s = \{y = 0, x < 0\}$ and $\Sigma^e = \{y = 0, x > 0\}$. In both sides of p the orbit is given by the sliding vector field $Z_s(x) = x/3x$, which can be extended to p as $Z_s(0) = 1/3$, therefore for p we have that $\varphi_Z(t,p) = \varphi_{Z_s}(t,p)$.

Thus, with respect to the definition of orbit and regarding the local dynamics, one concludes that the regular tangency points, which are non-distinguished singularities, can be tackled as regular points in Σ.

The rest of the tangency points are distinguished singularities and then their orbit is just themselves. This definition matches with the one that is done in [BPS01] since the generic tangencies that are studied in that work are all distinguished singularities.

In the set of singular tangency points, which are distinguished singularities, several different behaviors appear, but basically they can be classified in four groups.



(a) (b) (c) (d)

Figure 2: From left to right, phase portraits of the Filippov vector fields Z_5, Z_6^+, Z_6^- and Z_7. This four Filippov vector fields have a singular tangency point.

The first one, are the points which do not have any departing nor arrival trajectories in such a way that they behave analogously to a classical focus. As a model we can consider $\Sigma = \{y = 0\}$ and

$$Z_5 = \begin{cases} X_5 = \begin{pmatrix} 1 \\ -2x \end{pmatrix} & \text{for } y > 0 \\ Y_5 = \begin{pmatrix} -1 \\ -x + x^2 \end{pmatrix} & \text{for } y < 0 \end{cases}$$

(see Figure 2a) in which $p = (0,0)$ behaves as a classical focus.

The second kind of singular tangency points are the points which are in $\partial\Sigma^c \cap \partial\Sigma^s$ or $\partial\Sigma^c \cap \partial\Sigma^e$. The behavior around these points is genuinely non-smooth in the sense that it has not an analogue smooth behavior. A model for this case is, for instance, $p = (0,0) \in \Sigma = \{y = 0\}$ for

$$Z_6^{\pm} = \begin{cases} X_6^{\pm} = \begin{pmatrix} \pm 1 \\ x \end{pmatrix} & \text{for } y > 0 \\ Y_6 = \begin{pmatrix} 0 \\ 1 \end{pmatrix} & \text{for } y < 0 \end{cases}$$

(see Figure 2b and c). Since $p \in \partial\Sigma^s \cap \Sigma^c$, for points in Σ on the left of p their orbit is given by Z_s, whereas for points on the right of p the orbit is given by the arrival and departing orbits of the point, which are trajectories of X and Y, since these points belong to Σ^c. Therefore, the definition of orbit on both sides do not coincide and then this point is a singular tangency point. As it is seen in [BPS01] and it will be recalled in Section 3, generic tangency points belong to this set.

The third kind of singular tangency points are points in $\partial\Sigma^c$ which are departing or arrival points of several different trajectories of X and Y. As in the second case, the behavior of these systems does not have an analogous smooth one. Since different trajectories of X and Y depart (or arrive) from this point, we do not have uniqueness of solutions, and therefore the only choice which can be done in order to preserve uniqueness of solutions is to consider the single point as a whole orbit. Examples of this kind of systems are $p = (0,0) \in \Sigma = \{y = 0\}$ for

$$Z_7 = \begin{cases} X_7 = \begin{pmatrix} 1 \\ x \end{pmatrix} & \text{for } y > 0 \\ Y_7 = \begin{pmatrix} -1 \\ x \end{pmatrix} & \text{for } y < 0 \end{cases}$$

(see Figure 2d).

The last kind of singular tangency points corresponds to the case $X(p) = 0$ or $Y(p) = 0$.

Once we have defined the local trajectory through a point, we can state rigorously the definition of orbit. Depending on the point it can be a regular orbit, a singular orbit or a distinguished singularity.

Definition 2.7. *A regular orbit of Z is a piecewise smooth curve γ such that:*

1. *$\gamma \cap \Sigma^{\pm}$ is a trajectory of X and Y respectively,*
2. *The intersection $\gamma \cap \Sigma$ consists only of crossing points and regular tangency points in $\partial\Sigma^c$,*
3. *γ is maximal with respect to these conditions.*

Definition 2.8. *A sliding orbit of Z is a smooth curve $\gamma \subset \overline{\Sigma^s} \cup \overline{\Sigma^e}$ such that it is a maximal trajectory of Z_s.*

In [BPS01], the sliding orbit is called singular orbit.

Definition 2.9. *A distinguished singularity is a point p such that $\varphi_Z(t,p) = p$. They can be classified as:*

- *$p \in \Sigma^{\pm}$ such that $X(p) = 0$ and $Y(p) = 0$ respectively.*
- *$p \in \Sigma^s \cup \Sigma^e$ such that $Z_s(p) = 0$, namely a pseudoequilibria.*
- *$p \in \partial\Sigma^c \cup \partial\Sigma^s \cup \partial\Sigma^e$ such that it is a singular tangency point.*

As we have said, these definitions lead to two features (already present in [BPS01]) that make this approach suitable in the study of the structural stability and generic bifurcations: firstly, uniqueness of solutions, that is, any $p \in U$ belongs to only one orbit, and secondly, any neighborhood U of p is decomposed into disjoint union of orbits.

2.2 Separatrices, periodic orbits and cycles

In this section, we generalize the concepts of separatrix and periodic orbit for planar Filippov Systems. For the case of separatrices we follow closely [BPS01, Tei77].

Definition 2.10 ([BPS01])**.** *An unstable separatrix is either*

- *A regular orbit such that its α-limit set is a regular saddle point $p \in \overline{\Sigma^+}$ of X or $p \in \overline{\Sigma^-}$ of Y. We denote it by $W^u(p)$.*
- *A regular orbit which departs from a distinguished singularity $p \in \Sigma$. We denote it by $W^u_\pm(p)$, where the subscript $\pm$ means that it leaves p from $\Sigma^\pm$ respectively.*

We remark that in the first case, as it is well known in smooth systems, the orbit lying in the separatrix only reaches p in infinite time whereas in the second case, it may reach the singularity in finite time.

Stable separatrices $W^s(p)$ and $W^s_\pm(p)$ are defined analogously. If a separatrix is simultaneously stable and unstable it is a *separatrix connection*.

Remark 2.11. *We point out that a pseudonode $p \in \Sigma^s$ does have separatrices which are given by the two regular orbits which arrive at it. Recall that the points in these separatrices hit the pseudonode in finite time, whereas all the other points in Σ^+ and Σ^- close to the pseudonode, first hit Σ^s in finite time, and then spend infinite time in the sliding region tending to the pseudonode.*

Regarding the generalization of the concept of periodic orbit in Filippov systems we have to deal with different cases. The first one is the *regular periodic orbit*.

Definition 2.12. *A regular periodic orbit is a regular orbit $\varphi(t,p)$,which therefore belongs to $\Sigma^+ \cup \Sigma^- \cup \overline{\Sigma^c}$ and satisfies $\varphi(t+T,p) = \varphi(t,p)$ for some $T > 0$.*

The second case is the singular periodic orbit. This case appears when Σ is homeomorphic to $\mathcal{S}^1$ and $\Sigma = \Sigma^s$ or $\Sigma = \Sigma^e$ in such a way that the sliding vector field does not have critical points. In that case, the whole Σ is a periodic orbit. This case does not appear in this article since in it we only study planar Filippov systems locally and then Σ is always homeomorphic to an open segment.

From Definitions 2.7 and 2.8, it is clear that there can not exist periodic orbits which involve at the same time points in $\Sigma^+ \cup \Sigma^-$ and points in $\Sigma^s \cup \Sigma^e$ (that is, periodic orbits which are a combination of *regular motion* and *sliding motion*) since an orbit can not intersect both sets. Thus, we will define cycles to deal with *periodic motion* which involves at the same time sliding and regular motion.

Definition 2.13. *A periodic cycle is a finite set of orbits $\gamma_1, \dots \gamma_n$ such that the arrival point of γ_i is the departing point of γ_{i+1} and the arrival point of γ_n is the departing point of γ_1.*

We define the period of the cycle as the sum of the times that are spent to reach the arrival points from the departing points of the same orbit.

In [KRG03] the regular periodic orbits are classified between *standard periodic orbits* if they stay in $\Sigma^+ \cup \Sigma^-$ and *crossing periodic orbits* if they intersect $\overline{\Sigma^c}$. On the other hand they call *sliding periodic orbits* to cycles.

Besides cycles and periodic orbits, there exists another distinguished geometric object which is important when one studies topological equivalences and bifurcations in Filippov systems.

Definition 2.14. *We define* pseudocycle *as a set of orbits $\gamma_1, \dots, \gamma_n$ such that their edges, that is the arrival and departing points, of any γ_i coincide with one of the edges of γ_{i-1} and one of the edges of γ_{i+1} (and also between γ_1 and γ_n) forming a curve homeomorphic to $\mathcal{S}^1$, in such a way that in some point coincide two departing or two arrival points (see Figure 3).*

Even if this object does not have any interest in the applications, they must be preserved by topological and Σ-equivalences and therefore they must be taken into account when one studies bifurcations of planar Filippov Systems. Nevertheless, in the study of the codimension-2 local singularities we will focus our attention to the cases with more interesting dynamics, and therefore there will appear no pseudocycles.

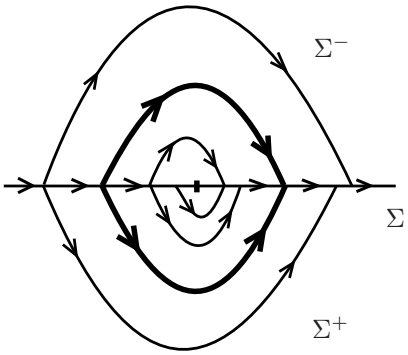


Figure 3: Example of a pseudocyle.

2.3 Topological equivalence of Filippov Systems

In this section two different notions of topological equivalence of vector fields of $\mathcal{Z}^r$ are presented. These definitions will lead to the study of the generic local behaviors and codimension-1 and 2 bifurcations. To state them we consider open sets U and V of $\mathbb{R}^2$ which intersect Σ.

The first of these concepts is what we call Σ-equivalence and is the one usually considered in the literature of Filippov systems (see the definition of orbit equivalence in [BPS01], and also [KRG03]).

Definition 2.15. *Two Filippov vector fields Z and $\tilde{Z}$ of $\mathcal{Z}^r$ with discontinuity curves Σ and $\tilde{\Sigma}$ respectively are Σ-equivalent if there exists an orientation preserving homeomorphism $h : U \to V$ which sends $\Sigma \subset U$ to $\tilde{\Sigma} \subset V$ and sends orbits of Z to orbits of $\tilde{Z}$.*

It can be easily seen that any Σ-equivalence sends regular orbits to regular orbits and distinguished singularities to distinguished singularities. Moreover, as it sends arrival and departing points to arrival and departing points, $\overline{\Sigma^c}$, $\overline{\Sigma^s}$ and $\overline{\Sigma^e}$ are preserved, and thus also sends sliding orbits to sliding orbits and preserves separatrices, separatrix connections, periodic orbits, cycles and pseudocycles.

However, it has to be pointed out that this definition seems to be too strict. In fact, in order to have Z and $\tilde{Z}$ similar qualitative behavior it is not needed the crossing region $\overline{\Sigma^c}$ to be preserved. From a topological point of view the behavior of the flow is *the same* around a point belonging to the crossing region and around a point in Σ^+ or Σ^- where the vector field is smooth. Thus, in this work, besides considering Σ-equivalence, we will consider also the classical concept of topological equivalence, which, as far as we know, it had not been applied to Filippov Systems before.

Definition 2.16. *Two Filippov vector fields Z and $\tilde{Z}$ of $\mathcal{Z}^r$ with discontinuity curves Σ and $\tilde{\Sigma}$ respectively are topological equivalent if there exists an orientation preserving homeomorphism $h : U \to V$ which sends orbits of Z to orbits of $\tilde{Z}$.*

From these definitions it is obvious that if two vector fields are Σ-equivalent, are also topologically equivalent but the reciprocal is not true (see Section 9). Analogously to Σ-equivalences, topological equivalences preserve $\overline{\Sigma^s}$ and $\overline{\Sigma^e}$. Consequently also preserve $\Sigma^+ \cup \Sigma^- \cup \overline{\Sigma^c}$ and therefore send regular orbits to regular orbits, sliding orbits to sliding orbits and distinguished singularities to distinguished singularities. Moreover, they also preserve separatrices, separatrix connections, periodic orbits, cycles and pseudocycles.

Even if in the literature it has been used the concept of Σ-equivalence (see [KRG03], [BPS01],..), in most of these works, it is not explained how the homeomorphisms h leading to such equivalences are constructed. So, as a far as the authors know, there is not any rigorous proof of Σ-equivalence or topological equivalence between two Filippov vector fields.

In Section 3 we will construct some of these homeomorphisms in the case of regular points and generic singularities. Later, in Section 9, we will show how to construct them for a codimension-2 singularity, which has more involved dynamics.

Thus, it will be necessary to obtain tools to construct these homeomorphisms. One of them will be based on the notion of $\mathcal{C}^r$-conjugation of smooth vector fields. In fact, if we have two smooth vector fields X and $\tilde{X}$ with their corresponding flows $\varphi(t,x)$ and $\tilde{\varphi}(t,x)$, they are $\mathcal{C}^r$-conjugated if there exists a $\mathcal{C}^r$ homeomorphism h such that $h(\varphi(t,x)) = \tilde{\varphi}(t,h(x))$. In this work, we will not use an analogous non-smooth concept but we will use conjugations applied to the smooth components of Filippov vector fields.

Proposition 2.17. *Let us consider any diffeomorphism $h : U \to V$ which conjugates X in $\Sigma^+ \subset U$ and $\tilde{X}$ in $\tilde{\Sigma}^+ \subset V$ and Y in $\Sigma^- \subset U$ and $\tilde{Y}$ in $\tilde{\Sigma}^- \subset V$. Then, it also conjugates the sliding vector fields Z_s and $\tilde{Z}_s$, and therefore h gives a topological equivalence between $Z = (X,Y)$ and $\tilde{Z} = (\tilde{X},\tilde{Y})$.*

Proof. Since h is $\mathcal{C}^r$, we have $h_*X = \tilde{X}$ and $h_*Y = \tilde{Y}$. Therefore, one can see that

$$(h_*Z_s)(p) = Dh\left(h^{-1}(p)\right) Z_s\left(h^{-1}(p)\right) = \tilde{Z}_s(p)$$

since the Lie derivative is invariant modulus change of coordinates. Then h sends orbits to orbits. □

Remark 2.18. *Of course, all the topological equivalences defined using this proposition preserve Σ and therefore are also Σ-equivalences. Thus, in order to construct topological equivalences not preserving Σ other techniques will be needed (see Section 9).*

Remark 2.19. *If we remove the hypothesis of differentiability in Proposition 2.17, that is, if we consider that h is only a homeomorphism this proposition is no more true. As a counterexample we consider the following two vector fields defined in a neighborhood U of the origin and taking as discontinuity curve $\Sigma = \{y = 0\}$:*

$$\tilde{Z}(x,y) = \begin{cases} \tilde{X} = (-1,-1) & \text{if } y > 0 \\ \tilde{Y} = (-1,1) & \text{if } y < 0 \end{cases} \qquad Z(x,y) = \begin{cases} X = (0,-1) & \text{if } y > 0 \\ Y = (0,1) & \text{if } y < 0. \end{cases}$$

In this case $\Sigma = \Sigma^s = \tilde{\Sigma} = \tilde{\Sigma}^s$ and the homeomorphism

$$h(x,y) = \begin{cases} (x-y,y) & \text{if } y > 0 \\ (x,y) & \text{if } y = 0 \\ (x+y,y) & \text{if } y < 0, \end{cases}$$

which is $\mathcal{C}^0$ but not $\mathcal{C}^1$, conjugates $\tilde{X}$ with X with $y > 0$ and $\tilde{Y}$ and Y for $y < 0$ but is not a topological equivalence of Z and $\tilde{Z}$, since the corresponding sliding vector fields are $\tilde{Z}_s(x) = -1$ and $Z_s(x) = 0$ which can not be topologically equivalent.

The definitions of Σ-equivalence and equivalence give rise to the concepts of Σ-structural stability and structural stability.

3 Generic local behavior

In this section we study the generic local behavior of planar Filippov Systems. In each case, we show the local $\mathcal{C}^0$ normal form and we construct the homeomorphism which gives the topological equivalence. We remark that in this work when we consider normal forms we are referring to $\mathcal{C}^0$ normal forms. That is, the equivalence relations of being topologically equivalent or Σ-equivalent divide $\mathcal{Z}^r$ in equivalence classes and a normal form of any of these classes is just a representative of these classes taken as simple as possible.

First we consider the regular points, namely points which are not singularities, that is points which belong to either regular or sliding orbits. It is clear that around regular points which do not belong to Σ applies the Flow-Box Theorem, so that, in this study we only have to deal with points belonging to the discontinuity curve. Next proposition gives the normal form for regular points belonging to Σ

Proposition 3.1. *Given a Filippov vector field $Z = (X, Y)$ with discontinuity surface Σ and $(0,0) \in \Sigma$, then:*

1. *If $(0,0) \in \Sigma^c$, then in a neighborhood $(0,0) \in U$ Z is Σ-equivalent to the vector field*

$$\tilde{Z}(x,y) = \begin{cases} \tilde{X} = \begin{pmatrix} 0 \\ 1 \end{pmatrix} & \text{for } y > 0 \\ \tilde{Y} = \begin{pmatrix} 0 \\ 1 \end{pmatrix} & \text{for } y < 0. \end{cases}$$

   in a neighborhood $(0,0) \in V$, and is equivalent to the smooth vector field $\bar{Z} = (0,1)$.

2. *If $(0,0) \in \Sigma^s$ and satisfies $X(0,0) \nparallel Y(0,0)$, then in a neighborhood $(0,0) \in U$ Z is Σ-equivalent to the vector field*

$$\tilde{Z}(x,y) = \begin{cases} \tilde{X} = \begin{pmatrix} 1 \\ -1 \end{pmatrix} & \text{for } y > 0 \\ \tilde{Y} = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{for } y < 0. \end{cases} \tag{3}$$

   in $(0,0) \in V$.

3. *If $(0,0) \in \Sigma^e$ and satisfies $X(0,0) \nparallel Y(0,0)$, then in a neighborhood $(0,0) \in U$ Z is Σ-equivalent to the vector field*

$$\tilde{Z}(x,y) = \begin{cases} \tilde{X} = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{for } y > 0 \\ \tilde{Y} = \begin{pmatrix} 1 \\ -1 \end{pmatrix} & \text{for } y < 0. \end{cases}$$

   in $(0,0) \in V$.

Proof. In the first case, the construction of the Σ-equivalence is achieved considering φ_X, φ_Y, $\varphi_{\tilde{X}}$ and $\varphi_{\tilde{Y}}$ the flows of the smooth components of both vector fields. Since $(0,0) \in \Sigma^c$ these vector fields are transversal to $\Sigma \cap U$ and $\tilde{\Sigma} \cap V$ respectively. Thus, for any point $p \in \Sigma^+ \cap U$, using the Implicit Function Theorem there exists a time $t(p) \in \mathbb{R}$ depending on p such that $\varphi_X(t(p), p)) \in \Sigma$, and analogously for $\Sigma^- \cap U$ and φ_Y. Thus, imposing that the Σ-equivalence is the identity restricted to Σ, it can be given by:

$$h(p) = \begin{cases} \varphi_{\tilde{X}}\left(-t(p), \varphi_X(t(p), p)\right) & \text{if } p \in \Sigma^+ \\ p & \text{if } p \in \Sigma \\ \varphi_{\tilde{Y}}\left(-t(p), \varphi_Y(t(p), p)\right) & \text{if } p \in \Sigma^- \end{cases} \tag{4}$$

which it can be seen that is $\mathcal{C}^0$, and verifies $\varphi_{\tilde{Z}}(t, h(p)) = h(\varphi_Z(t, p))$.

Finally, in this first case, only remains to point out that in fact $\tilde{Z}$ is a smooth vector field since X and Y coincide. Then, Z is equivalent to the smooth vector field $\tilde{Z} = (0,1)$.

In the second case, in order to construct the homeomorphism, we start with the points in Σ. Since $X(0,0) \nparallel Y(0,0)$ and $\tilde{X}(0,0) \nparallel \tilde{Y}(0,0)$, $(0,0)$ is a regular point of both sliding vector fields Z_s and $\tilde{Z}_s$. Then, the Flow-Box Theorem assures us that there exists a homeomorphism $\bar{h}$ which locally conjugates them. For points away from Σ, the homeomorphism can be extended as in the previous cases by the flow since for any point $p \in \Sigma^+ \cap U$ there exists a time $t(p)$ such that $\varphi_X(t(p), p)) \in \Sigma$ (and analogously for $p \in \Sigma^- \cap U$). Thus, the homeomorphism which gives the Σ-equivalence can be given by

$$h(p) = \begin{cases} \varphi_{\tilde{X}}\left(-t(p), \bar{h}\left(\varphi_X(t(p), p)\right)\right) & \text{if } p \in \Sigma^+ \cap U \\ \bar{h}(p) & \text{if } p \in \Sigma \cap U \\ \varphi_{\tilde{Y}}\left(-t(p), \bar{h}\left(\varphi_Y(t(p), p)\right)\right) & \text{if } p \in \Sigma^- \cap U \end{cases}. \tag{5}$$

The third case, can be studied analogously to the second. ∎

For planar Filippov vector fields, there exist the following generic singularities which are all distinguished singularities (see Definition 2.5):

1. Fold Points or quadratic tangency points: that is $p \in \Sigma$ such that $Xf(p) = 0$ and $X^2 f(p) \neq 0$ and $Yf(p) \neq 0$ or points such that $Yf(p) = 0$ and $Y^2 f(p) \neq 0$ and $Xf(p) \neq 0$.

2. Hyperbolic fixed points of the sliding vector field: that is points $p \in \Sigma^s \cup \Sigma^e$ such that $X(p) \parallel Y(p)$ and hence $Z_s(p) = 0$. Moreover, we impose the generic condition

$$Z_s'(p) \neq 0. \tag{6}$$

Next proposition deals with the normal forms of these generic singularities.

Proposition 3.2. *The following Σ-equivalences hold:*

1. *If $(0,0) \in \Sigma$ is a fold point of the vector field $Z = (X, Y) \in \mathcal{Z}^r$ defined in a neighborhood U of p, then it is Σ-equivalent in a neighborhood V of $(0,0)$ to*

$$Z_{a,b} = \begin{cases} X_a = \begin{pmatrix} 1 \\ ax \end{pmatrix} & \text{for } y > 0 \\ Y_b = \begin{pmatrix} 0 \\ b \end{pmatrix} & \text{for } y < 0 \end{cases} \tag{7}$$

   where $a = \operatorname{sgn}\left(X^2 f(p)\right)$ and $b = \operatorname{sgn}\left(Yf(p)\right)$.

2. *If $(0,0) \in \Sigma^s \cup \Sigma^e$ is a hyperbolic fixed point of the sliding vector field of $Z = (X, Y) \in \mathcal{Z}^r$ defined in a neighborhood U of $(0,0)$, then it is conjugated in a neighborhood V of $(0,0)$ to*

$$Z_{a,b} = \begin{cases} X_{a,b} = (ax, b) \\ Y_b = (ax, -b) \end{cases} \tag{8}$$

   where $b = \operatorname{sgn}\left(Yf(p)\right)$ and $a = \operatorname{sgn}\left(Z_s'(p)\right)$.

Proof. We have to construct an homeomorphism that gives the equivalence in every case, that is for every a and b in both cases. Since they are analogous, we only deal with the most interesting cases for both singularities.

For the fold point, $a > 0$ and $a < 0$ correspond to visible and invisible tangencies respectively. We consider only the case $b > 0$. We can construct, by Flow-Box Theorem, the homeomorphism which conjugates the sliding vector field sending the fold to itself. In order to extend this homeomorphism to the rest of the neighborhood of the fold it has to be done in different ways depending on the sign of a.

In the case of the invisible tangency ($a < 0$), since Σ acts as an attractor in U, the homeomorphism can ge extended through the flow as it has been done in the proof of Proposition 3.2. Nevertheless, in order to obtain a Σ-equivalence time has to be reparametrized by arc-length to ensure that Σ^c is preserved.

In the case $a > 0$ by this procedure we can only define the equivalence in a part of the neighborhood delimited by the separatrices of the fold $W_+^s(0,0)$ and $W_-^s(0,0)$, since the orbits which do not belong to this region, do not hit Σ^s (see Figure 4). Hence, for the points lying on the right of $W_+^s(0,0) \cup W_-^s(0,0)$ the homeomorphism has to be defined in a different way. We define the homeomorphism in different ways depending whether the point belongs to the region delimited by $W_+^s(0,0) \cup W_+^u(0,0)$ or by $W_+^u(0,0) \cup W_-^s(0,0)$. In each region we define sections which are topologically transversal to the corresponding flows. For instance, we can take Π_1 and Π_2 as can be seen in Figure 4. Notice that $\overline{\Sigma^s}$, Π_1 and Π_2 only intersect in the fold $(0,0)$.

In the sections Π_1 and Π_2, we can define a homeomorphism which sends the fold to itself. Finally, the homeomorphism can be extended to the other points by the flow. A posteriori, it can be checked

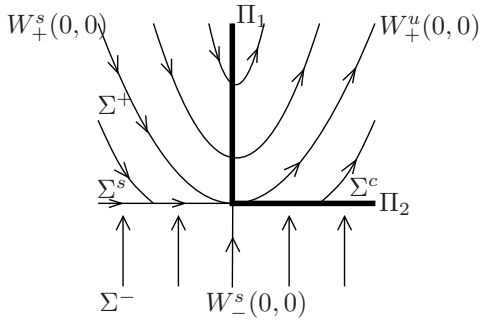

Figure 4: Phase portrait around a generic visible fold. In order to define a homeomorphism between to generic visible folds, one has to define the transversal sections Π_1 and Π_2.

a posteriori that the homeomorphism is indeed continuous since the homeomorphisms defined in each region coincide in the separatrices.

For the hyperbolic critical point we consider only the case $a < 0$ and $b < 0$ (the other ones are analogous) and we proceed as follows. Firstly, since the sliding vector fields Z_s and $\tilde{Z}_s$ have both a fixed attractor point at 0, by Hartmann-Grobman Theorem, there exists a homeomorphism $\bar{h}$ defined in a neighborhood of $(0,0)$ in Σ which conjugate, them. For the points which do not belong to Σ the homeomorphism can be defined as in (4) since the vector field is transversal to Σ in all $p \in \Sigma \cap U$, that is:

$$h(p) = \begin{cases} \varphi_{\tilde{X}}\left(-t(p), \bar{h}\left(\varphi_X(t(p),p)\right)\right) & \text{if } p \in \Sigma^+ \\ \bar{h}(p) & \text{if } p \in \Sigma \\ \varphi_{\tilde{Y}}\left(-t(p), \bar{h}\left(\varphi_Y(t(p),p)\right)\right) & \text{if } p \in \Sigma^- \end{cases}$$

Since all the equivalences considered in the proof send Σ to $\tilde{\Sigma}$, it is clear that all the equivalences stated in Proposition 3.2 are also Σ-equivalences. □

Theorem 3.3. *Let us consider a vector field $Z = (X, Y) \in \mathcal{Z}^r$ in a neighborhood U of $(0,0)$. Then, if $(0,0)$ belongs to a regular or sliding orbit or it is a generic singularity, then Z is locally structurally stable and locally Σ-structurally stable.*

Proof. When $(0,0)$ belongs to a regular or sliding orbit it is enough to recall that the conditions which define these kind of points are open, so that are robust under perturbation. When it is a singularity, it is enough to see that the fold points and the hyperbolic fixed points of the sliding vector field are generic. In fact, considering for instance the fold case, one has to use Implicit Function Theorem and the generic conditions $Yf(0,0) \neq 0$ and $X^2 f(0) \neq 0$, in order to see that if $Z_0 \in \mathcal{Z}^r$ has a fold at 0, then any vector field $Z \in \mathcal{U} \subset \mathcal{Z}^r$ where $\mathcal{U}$ is neighborhood of Z_0, it has also a fold in a point close to (0,0) with the same signs for $X^2 f(p)$ and $Yf(p)$. Thus, since both Z_0 and Z are conjugated to (7) with the same signs a and b, they are conjugated also to each other and therefore Z_0 is locally structurally stable.

Proceeding in the same way, it can be seen also that the hyperbolic critical points of Z_s are generic. Finally, since all the topological equivalences that we have considered are also Σ-equivalences, for any vector field of $\mathcal{Z}^r$ such that $(0,0)$ belongs to a regular or singular orbit, or is a generic singularity, it is locally Σ-structurally stable. □

4 Codimension-1 bifurcations revisited

4.1 Codimension 1 local bifurcations

In this section we make a review of the codimension-1 local bifurcations, focusing on the ones which appear in the unfoldings of the codimension-2 local bifurcations explained in Section 5. Its classification

was achieved by Y. Kuznetsov *et altrii* in [KRG03]. Nevertheless, in that paper, the authors did not mention explicitly all the generic non-degeneracy conditions which had to be satisfied in each singularity to be a codimension-1 bifurcation. However, they exhibit as normal forms of each singularity some models of Filippov vector fields which satisfy these conditions. In this section, we will give some of this lacking non-degeneracy conditions which will be used in Sections 6, 7, 8, 9, 10, 11, 12, 13 and 14 to derive codimension-2 singularities when one of these conditions fails.

In [KRG03], the authors see that the codimension-1 local bifurcations of a Filippov vector field $Z = (X, Y)$ with discontinuity surface $\Sigma = \{f(x, y) = 0\}$ can be classified as:

1 Fold-fold singularity: Both vector fields have a fold or quadratic tangency at $p \in \Sigma$. That is $Xf(p) = 0$, $Yf(p) = 0$, $X^2f(p) \neq 0$ and $Y^2f(p) \neq 0$.

2 Cusp singularity, called double tangency bifurcation in [KRG03]: X has a cusp in $p \in \Sigma$ while Y is transversal to Σ. That is $Xf(p) = 0$, $X^2f(p) = 0$, $X^3f(p) \neq 0$ and $Yf(p) \neq 0$.

3 Z_s has a Saddle-Node singularity in $p \in \Sigma$. That is $Z_s(p) = 0$, $Z_s'(p) = 0$ and $Z_s''(p) = 0$.

4 X has a hyperbolic non-degenerate critical fixed point $p \in \Sigma$ while Y is transversal to Σ. In [KRG03] these bifurcations are classified as *Boundary-Focus*, *Boundary-Node* and *Boundary-Saddle*, and are called *boundary-equilibrium* in [dBBC$^+$08].

We want to remark that the classification of the codimension-1 local bifurcations and their generic unfoldings remain the same with the new definitions of orbit and topological equivalence. This fact will be no longer true in the codimension-2 case as it will be seen in Section 9, where we will find a codimension-2 singularity which has different unfolding whether one considers topological equivalence or Σ-equivalence.

The first and fourth type of singularities need some additional non-degeneracy conditions to be codimension-1 local bifurcations that will be stated in Sections 4.1.1, 4.1.2, 4.1.3 and 4.1.4.

4.1.1 Generic Fold-Fold bifurcation

The generic Fold-Fold singularity takes place when in a point $p \in \Sigma$ both vector fields X and Y have a quadratic tangency or fold. Depending on the visibility or invisibility of both folds, the singularity presents different behavior. In this section we focus our attention on two of these cases which need additional generic non-degeneracy conditions.

The first case in which an additional condition is needed are Filippov vector fields $Z = (X, Y)$ such that at $p \in \Sigma$ the vector fields X and Y have a visible and an invisible fold respectively and satisfy that $X(p)$ and $Y(p)$, which are parallel, points oppositely. Then $p \in \partial\Sigma^s \cap \Sigma^e$, and thus the sliding vector field is defined on both sides of $p \in \Sigma$. In this point, it has a removable singularity and, taking x as a local chart of Σ, it is equivalent to

$$Z_s(x) = \beta + \mathcal{O}(x).$$

Thus, one has to assume the generic non-degeneracy condition $\beta \neq 0$. Depending on the sign of β, one has two different local bifurcations which are called VI_2 and VI_3 in [KRG03].

The second case is when both folds are invisible and $p \in \partial\Sigma^c$. It is called both Fused-focus and II_2 in [KRG03].

To both folds of X and Y, one can associate involutions φ_X and φ_Y which are defined from Σ to itself (see for instance [Tei81, Fil88, KRG03]). They send a point $q \in \Sigma$ to the point in Σ which is the intersection between the orbit of q and Σ , as can be seen in Figure 5.

Then, taking x as a local chart of Σ such that $x = 0$ corresponds to the Fold-Fold point p, one can see that since $\varphi_X^2 = \mathrm{Id}$, these involutions must be of the form

$$\varphi_X(x) = -x + \alpha_X x^2 - \alpha_X^2 x^3 + \mathcal{O}\left(x^4\right) \tag{9}$$

and analogously for φ_Y.

Using both involutions, one can define a return map from $\Pi = \{(x, y) \in \Sigma : x < 0\}$ to itself around the singularity, by composing them: $\varphi = \varphi_Y \circ \varphi_X$. Then, this return map is of the form

$$\varphi(x) = x + (\alpha_Y - \alpha_X)x^2 + (\alpha_Y - \alpha_X)^2 x^3 + \mathcal{O}\left(x^4\right). \tag{10}$$

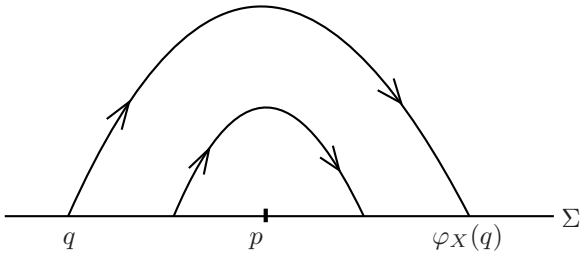

Figure 5: Involution φ_X associated to an invisible fold $p \in \Sigma$ of the vector field X.

Therefore, in order to have a generic Fold-Fold singularity one has to impose that $\alpha_Y - \alpha_X \neq 0$. We call this bifurcation *generic attractor Fold-Fold bifurcation* provided $\alpha_Y - \alpha_X > 0$ and *generic repellor Fold-Fold bifurcation* provided $\alpha_Y - \alpha_X < 0$.

In Section 7 we will study the codimension-2 singularity when $\alpha_Y - \alpha_X = 0$.

Remark 4.1. *In the case in which both X and Y have an invisible fold at $p \in \Sigma$ in such a way that both $X(p)$ and $Y(p)$ point toward the same direction, one has also an involution of the form (9) associated to each fold. Then, even if the return map $\varphi = \varphi_Y \circ \varphi_X$ does not have any dynamical sense, to have a codimension-1 singularity one has to impose $\alpha_X - \alpha_Y \neq 0$ to avoid the appearance of pseudocycles in a generic unfolding (see Definition 2.14).*

4.1.2 Generic Boundary-Saddle bifurcation

In order to have a generic Boundary-Saddle local bifurcation, one has to impose two generic non-degeneracy conditions. First, the eigenspaces of the saddle have to be transversal to Σ. The failure of this condition lead to higher codimension local bifurcations, which will be studied in Section 8.

On the other hand, it can be seen that the singularity $p = (0,0) \in \Sigma$ belongs either to $\overline{\Sigma^s} \cap \overline{\Sigma^c}$ or $\overline{\Sigma^e} \cap \overline{\Sigma^c}$, and thus the sliding vector field is defined in one side of the critical point. Taking x as a local chart on Σ, a straightforward computation shows that

$$Z_s(x) = \alpha x + \mathcal{O}(x^2), \tag{11}$$

namely the critical point of X creates a critical point of the sliding vector field, at the same point p which is in the boundary of Σ^s or Σ^e. Thus, the second non-degeneracy condition guarantees that this critical point is generic, and equivalently that $\alpha \neq 0$. Depending on the sign of α, one has different behaviors. The failure of this condition, that is, a Boundary-Saddle bifurcation which encounters a Saddle-Node bifurcation of the sliding vector field leads to a codimension-2 local bifurcation. In Section 6, this local bifurcation will be studied for the Boundary-Node case, that is analogous and it is explained in Section 4.1.3.

In [KRG03], the authors see that there are three different Boundary-Saddle local bifurcations, which they call BS_1, BS_2 and BS_3. In the first two cases, on one side of the bifurcation value coexist the saddle with a pseudonode of in Σ^s and Σ^e. Then, in these cases one has to impose the generic condition that at $p \in \Sigma$, the vector field Y and the eigenspaces of the saddle are transversal, to avoid the existence of separatrix connections between these two singularities in the unfolding.

Therefore, imposing these conditions we will obtain a generic codimension-1 Boundary-Saddle bifurcation.

4.1.3 Generic Boundary-Node bifurcation

In the Boundary-Node bifurcation one has to impose also three non-degeneracy conditions. First, both eigenvalues have to be different. Then, the node has two eigenspaces which are tangent to the strong and weak stable (or unstable) manifolds. Even if for smooth systems, these invariant manifolds do not need

to be preserved by $\mathcal{C}^0$-equivalences, in the Filippov Systems setting the strong stable invariant manifold must. Indeed, as can be seen in the central phase portrait in Figure 6, any point above the strong invariant manifold belongs to an orbit which has the node as an arrival point whereas any point below this manifold belong to an orbit which has an arrival point in Σ^s. Therefore, these two open sets must be preserved by topological (and Σ-)equivalence and therefore its common boundary, which is the strong stable manifold, too.

On the other hand, there are infinitely many weak stable manifolds since any other orbit of X, besides the strong invariant manifold, tends to the node tangent to the weak eigenspace. Therefore, the second non-degeneracy condition, as in the Boundary-Saddle bifurcation, is that both eigenspaces are transversal to Σ.

On the other hand, as in the Boundary-Saddle case, for this singularity it has also has to be imposed that the extended sliding vector field, which also has a critical point at p is of the form (11) with $\alpha \neq 0$.

Remark 4.2. *This last non-degeneracy condition seems to be not considered in [KRG03], since they assume that if a Filippov vector field $Z = (X, Y)$ is such that X has an attracting node $p = (0, 0) \in \Sigma$ and Y points towards Σ, this implies that the extended sliding vector field Z_s has an attractor pseudonode at p, namely it is of the form (11) with $\alpha < 0$. Nevertheless, the constant α can take either positive or negative sign. Indeed, for the Boundary-Node bifurcation satisfying $\alpha > 0$, one can take as a normal form $f(x, y) = x + y$ and*

$$Z(x,y) = \begin{cases} X(x,y) = \begin{pmatrix} -4x \\ -y \end{pmatrix} & \text{if } x+y > 0 \\ Y(x,y) = \begin{pmatrix} 2 \\ -1 \end{pmatrix} & \text{if } x+y < 0 \end{cases}, \tag{12}$$

where we have chosen the normal form with Σ with negative slope, to be allowed to take X in diagonal form. In this case, one can see that $Z_s(x) = 6x + \mathcal{O}(x^2)$, and thus $x = 0$ is repellor. In Figure 6 we show the generic unfolding of this local bifurcation.

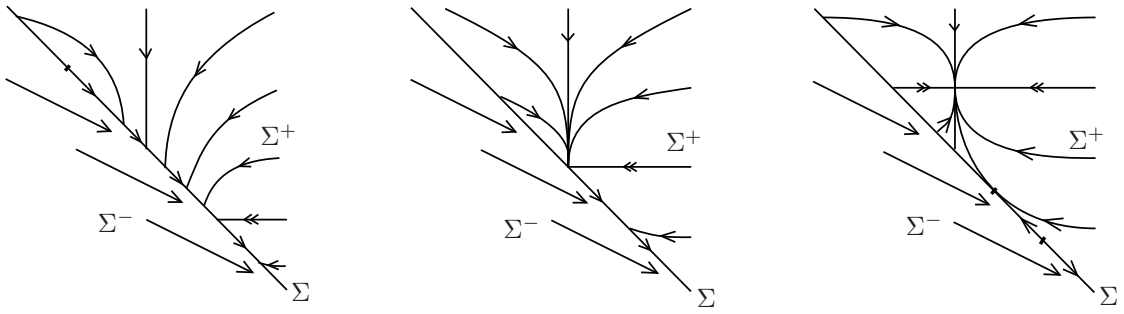

Figure 6: Bifurcation diagram of a generic unfolding of (12).

Let us observe that in this unfolding, on the left of the bifurcation value there does not exist any critical point of X, Y nor Z_s and the only singularity present is an invisible fold. On the other hand, on the right of the bifurcation value coexist a node of X with a pseudosadle of Z_s.

4.1.4 Generic Boundary-Focus bifurcation

As in the Boundary-Saddle and Boundary-Node bifurcations, the singularity $p = (0, 0) \in \Sigma$ belongs to $\overline{\Sigma^c} \cap \overline{\Sigma^s}$ or $\overline{\Sigma^c} \cap \overline{\Sigma^e}$, and is a critical point of the extended vector field which is of the form (11). So one has to impose again the non-degeneracy condition $\alpha \neq 0$.

Finally, in the case in which X has a repellor focus, Y points towards Σ and $\alpha > 0$ one has to impose another generic non-degeneracy condition since there exist two different behaviors which are called BF_1 and BF_2 in [KRG03]. This condition, which only depends on the unperturbed system, avoids the existence of a separatrix connection in the unfolding between the visible fold and the pseudosaddle.

4.2 Codimension-1 global bifurcations

As it happens in classical smooth dynamical systems, in generic unfoldings of codimension-2 local bifurcations appear several codimension-1 global bifurcations. Thus, a good understanding of them is necessary.

In [KRG03], the authors classify some codimension-1 global bifurcations, as done in classical dynamical systems, involving bifurcations of periodic orbits (which in the present paper are named periodic orbits and cycles) and separatrix connections between a saddle in $\Sigma^+ \cup \Sigma^-$ and a hyperbolic pseudoequilbrium, between two hyperbolic pseudoequilbria or between a fold and a saddle or hyperbolic pseudoequilibrium. Nevertheless, recall that in Filippov systems there can exist separatrix connections with finite time (for instance between two folds). In fact, all the codimension-1 bifurcations of periodic orbits and cycles can be considered as a particular case of separatrix connections between folds. Therefore, the approach that seems more systematic for these systems (proposed by M. A. Teixeira in [Tei77]) is to study all the cases of connections of separatrices, and from them derive the bifurcation of cycles and periodic orbits as a particular case. With this new approach, we will see in this section that there exist more codimension-1 global bifurcations than the ones established in [KRG03]. In particular, in that paper, the authors did not consider cycles containing sliding and escaping parts, whose existence is shown in this section.

We can classify the codimension-1 global bifurcations given by a separatrix connection, depending on the departing and arrival points. Each of these points, which have to be generic singularities (see Section 3) can be: a fold, a pseudo-saddle or a pseudo-node in $\Sigma^s \cup \Sigma^e$ or a saddle in $\Sigma^+ \cup \Sigma^-$. Recall that for Filippov systems the pseudo-nodes do have separatrices since following our definitions they are the unique regular orbits which arrive to them from Σ^+ and Σ^- (see Remark 2.11).

All the separatrix connections involving saddles and pseudoequilibria besides pseudonodes were studied in [KRG03]. In fact, the pseudonode case can be done analogously and we will not give the details here. In [KRG03], the authors also study all the separatrix connections between a fold and any other singularity. However, the separatrix connections between folds are not studied there systematically. Only the cases which lead to the existence of cycles are considered and studied as bifurcations of periodic orbits. So in this paper, we will propose a systematic approach to study separatrix connections between two folds and we will encounter the cases studied in [KRG03] as particular cases. In fact, we will see that the fold-fold separatrix connections may lead to bifurcations of periodic orbits or not. On the other hand, this approach seems the best one to generalize to higher dimensional systems in order to study global bifurcations, which up to now have been only studied from other points of view (see for instance [DBFHH99, dBKN02, dBKN03, KdB05, KP08]).

4.2.1 Separatrix connections between folds

The separatrix connections between folds can be preliminary classified whether the arrival and departing folds are visible or invisible and whether they are on the boundary of an escaping or sliding region. We will say escaping fold and sliding fold depending whether are in the boundary of Σ^e and Σ^s. As can be seen in Figure 7, these four types of folds have different number of stable and unstable separatrices. Therefore, one can systematically classify the Fold-Fold separatrix connections considering pairs of stable and unstable separatrices of folds. Thus, these connections can be classified as:

- Homoclinic connections: the departing and arrival point are the same fold. They can be reduced only to four cases: $W^s_+(p) \equiv W^u_+(p)$, both for escaping and sliding visible folds, $W^u_+(p) \equiv W^s_-(p)$, for sliding folds, and $W^u_-(p) \equiv W^s_+(p)$, for escaping folds.

- Heteroclinic connections: the arrival and departing points are different folds. There are 16 cases, since there are four possible stable and four possible unstable separatrices (see Figure 7). Some of them, but not all, may lead to bifurcations of cycles.

We devote the rest of the section to study the cases which lead to more interesting dynamics. The other cases can be studied analogously.

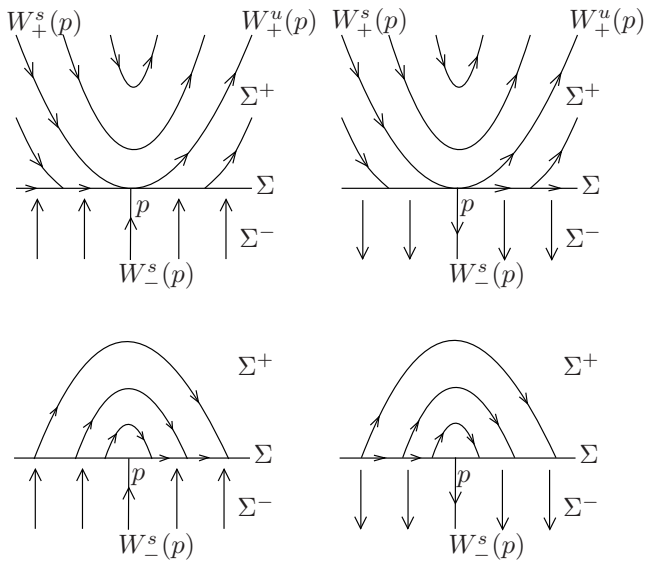

Figure 7: The left and right upper pictures show respectively a sliding visible and a escaping visible folds. The lower ones show respectively sliding invisible and escaping invisible. In this picture we also show the way of denoting the separatrices. They are denoted by $W^*_\pm(\mathrm{p})$, where p is the fold point, $\pm$ denotes whether they are departing or arriving from $\Sigma^\pm$ and $*=s,u$ denotes whether the separatrix is stable or unstable.

Homoclinic connections As all the homoclinic connections lead to bifurcations of cycles, they are carefully studied in [KRG03] and thus, we just summarize their results.

The case $W^s_+(p)\equiv W^u_+(p)$, both for sliding and escaping folds, was called TC_1 and TC_2 in [KRG03], and it is also called *grazing-sliding bifurcation* (see [DBFHH99, dBKN02]).

The connections $W^u_+(p)\equiv W^s_-(p)$ for a sliding fold and $W^u_-(p)\equiv W^s_+(p)$ for a escaping fold were called CC in [KRG03], and are also sometimes called *crossing-sliding bifurcations* [DBFHH99, dBKN02].

In all these cases, depending on the attracting or repelling character of the pseudohomoclinic connection two different bifurcations can occur. In one case, a periodic orbit becomes a pseudohomoclinic cycle on the bifurcation value it hits either Σ^s or Σ^e. In the other case, on one side of the bifurcation value coexist a periodic orbit and a cycle which merge at the bifurcation giving birth to a semistable cycle (the pseudohomoclinic connection) which afterwards disappear. The study of the same bifurcations from a Catastrophe Theory point of view can be seen in [JH09].

Heteroclinic connections In [KRG03], the authors study two of these cases as bifurcations of periodic orbits. The first case, which they call SC is the connection $W^s_+(p_1)\equiv W^s_-(p_2)$ where p_1 and p_2 are visible folds.

The other case are the connections $W^u_+(p_2)\equiv W^s_+(p_1)$ where p_1 is a invisible sliding fold of Y and p_2 is a visible sliding fold of X, and $W^u_+(p_1)\equiv W^s_+(p_2)$ where p_1 and p_2 are respectively an invisible escaping fold of Y and visible escaping fold of X. These connections can lead to bifurcations of cycles as it can be seen in the upper pictures of Figure 8 and they are usually called *switching-sliding bifurcation* [DBFHH99, dBKN02] or *buckling bifurcation* [KRG03]. Nevertheless, the same bifurcation can occur in other settings, as it can be seen in the lower pictures of Figure 8. It is in that sense, that we believe that the separatrix connection approach is the most useful in that cases, since focuses its attention on the part of the phase portrait where the bifurcation occurs, that is, in a neighborhood of the connection.

Finally, we show some cases which do not appear in [KRG03]. The first one corresponds to the case $W^u_+(p_1)\equiv W^s_+(p_2)$ where p_1 and p_2 are visible sliding folds, which is sometimes interpreted as another type of *grazing-sliding bifurcation*, but which involves two different folds. That case can lead also to

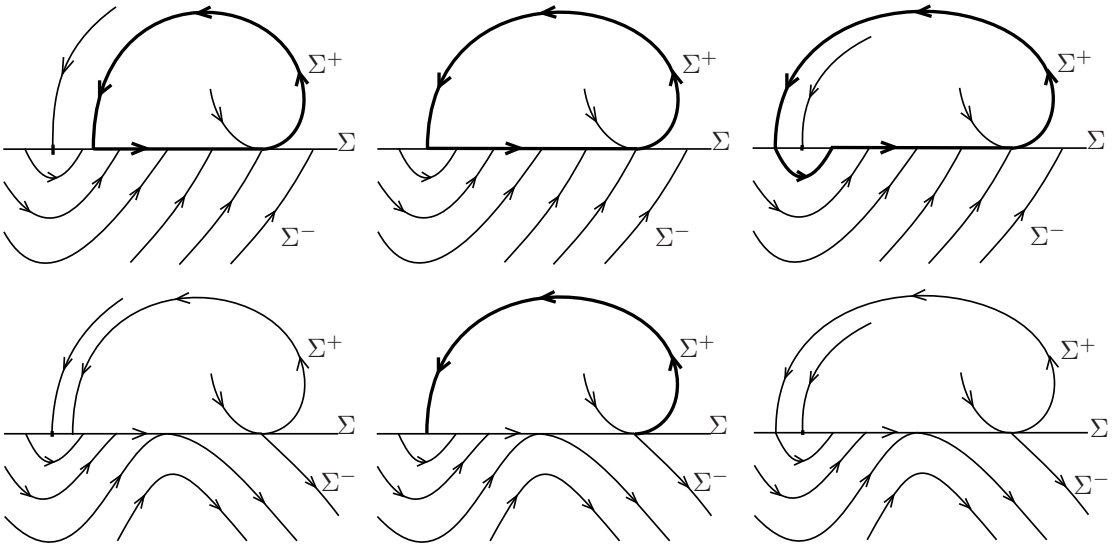

Figure 8: Bifurcation diagram of two different generic unfoldings of the separatrix connection $W^u_+(p_2) \equiv W^s_+(p_1)$ where p_1 is a invisible sliding fold of Y and p_2 is a visible sliding fold of X. In the first case, the separatrix connection leads to a bifurcation of a cycle and is usually called *switching-sliding bifurcation* [DBFHH99, dBKN02] or *buckling bifurcation* [KRG03], whereas in the second one does not exist any cycle.

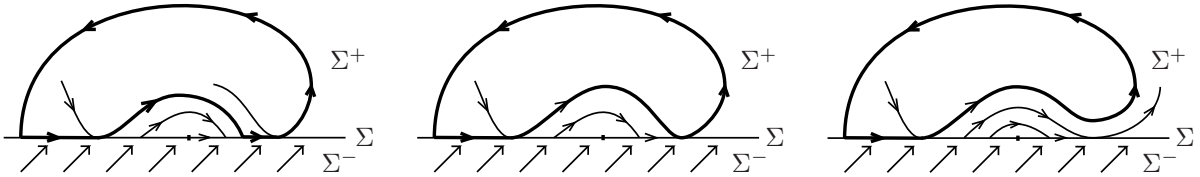

Figure 9: Bifurcation diagram of a generic unfolding of the separatrix connection $W^u_+(p_1) \equiv W^s_+(p_2)$ where p_1 and p_2 are visible sliding folds.

a bifurcation of cycles, and in its generic unfolding, as it can be seen in Figure 9, the cycle is always persistent in both sides of the bifurcating point and always contains a segment of Σ^s.

The remaining cases, which lacked in [KRG03], are those which involve two folds that are in the boundary of the sliding and the escaping regions respectively. The most interesting one is when $W^u_+(p_1) \equiv W^s_+(p_2)$ where p_1 and p_2 are respectively sliding and escaping visible folds. Depending on the behavior of Y nearby Σ, the Filippov vector field can have interesting dynamics.

The upper part of Figure 10 illustrates the generic case in which $W^u_-(p_2)$ has an arrival point in Σ^s. Then, there exists a cycle composed by $W^u_-(p_2)$, a sliding segment and the separatrix connection. Moreover, it coexists with a continuum of cycles composed by the separatrix connection, a segment of Σ^e, a regular orbit in Σ^- and a segment of Σ^s. When we unfold this codimension-1 global bifurcation, on one side, all these cycles disappear whereas in the other, only the one composed by $W^u_+(p_1)$ and a sliding segment persists.

The lower part of Figure 10 illustrates the symmetric case in which $W^s_-(p_1)$ has an arrival point in Σ^e.

Remark 4.3. *We point out that an analytical approach to study these separatrix connections is to use a Melnikov-like theory. As we are dealing with planar autonomous systems, the distance between the perturbed separatrices is given up to first order by a coefficient which is proportional to the perturbation*

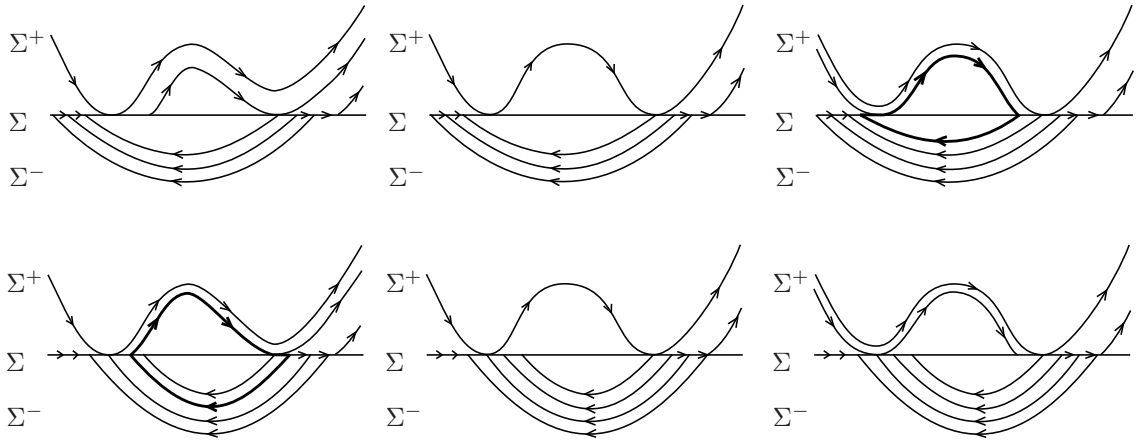

Figure 10: Two different settings in which a codimension-1 global bifurcation given by a separatrix connection between a visible escaping fold and a visible sliding fold lead to a bifurcation of cycles. Let us observe that in both cases in the bifurcating value there exist a continuum of cycles. In the top case, only persist one on the right, which contains a sliding segment, and no one persist on the left, whereas in the bottom case, on the left persist one with escaping segment and on the right all break down.

parameter. This coefficient is obtained through a finite time Melnikov computation, since in this case the unperturbed separatrix connection is continuous but piecewise differentiable. Generically, this coefficient is non-zero and then the connections are destroyed.

5 Codimension-2 local bifurcations. Preliminary classification

The full list of different codimension-2 local bifurcations for planar Filippov Systems is considerably large. Therefore, in this section we establish a preliminary classification of them. As we have explained in Section 4.1, to obtain this classification we have to consider a codimension-1 bifurcation and violate one of the non-degeneracy conditions.

We assume that the singularity is located at $p = (0, 0)$. The first set of codimension-2 local bifurcations refers to the singularities related to tangency points:

- One of the vector fields has a fourth order tangency at p whereas the other one is transversal to Σ.
- One of the vector fields has a cusp or cubic tangency at p whereas the other has a fold or quadratic tangency. We call to this bifurcation *Cusp-Fold* and is carefully studied in Section 12.
- The Filippov vector field has a degenerate Fold-Fold bifurcation since one of the non-degeneracy generic conditions explained in Section 4.1.1 fails. One of these bifurcations will be explained in Section 7.

The second set of codimension-2 local bifurcations refers to the Filippov vector fields $Z = (X, Y)$ such that X, Y or Z_s has a critical point at $p \in \Sigma$.

- X (or Y) has a non-hyperbolic critical point at $p \in \Sigma$, which is a codimension-1 singularity for X (or Y), that is a Saddle-Node or a Hopf singularity, whereas Y (or X) is transversal to Σ. These two bifurcations will be studied in more detail in Section 13 and 14.
- $p \in \Sigma$ is a hyperbolic critical point of X and a fold of Y (or vice versa). Two of these bifurcations, the Focus-Fold and the Saddle-Fold will be explained respectively in Sections 10 and 11, since they are the cases which present more interesting behavior.

- $p \in \Sigma$ is a hyperbolic critical point of X whereas Y is transversal to Σ but one of the non-degeneracy generic conditions specified in Section 4.1 fails.
- The sliding vector field Z_s has a cusp bifurcation (in the sense of Singularity Theory).

Some of these codimension-2 local bifurcations do not present more interesting behavior than the behaviors encountered around codimension-1 local bifurcations in [KRG03]. In Sections 6, 7, 8, 9, 10, 11, 12, 13 and 14, we will study in more detail the cases that present more rich behavior. On the other hand, as we explained for the codimension-1 case in Section 4.2, in order to have codimension-2 bifurcations one has to impose generic non-degeneracy conditions. These conditions will be specified for the cases that will be studied in the corresponding sections.

We want to point out that in order to clarify the explanation we will mostly work with simple normal forms. Nevertheless, all the bifurcation diagrams we will show are generic and remain the same if we change the normal form.

6 Codimension-2 Boundary-Node singularity

As it has been explained in Sections 4.1.2, 4.1.3 and 4.1.4, when one considers a Boundary-Focus, node or saddle in $p = (0,0) \in \Sigma$, the sliding vector field which gives the motion in one side of p is of the form $Z_s(x) = \alpha x + \mathcal{O}(x^2)$ (see (11)). Thus, in order to guarantee that the singularity has codimension-1, it has to be imposed $\alpha \neq 0$ in such a way that $\alpha = 0$ leads to several codimension-2 singularities. In this section we will study one of the cases of Boundary-Node singularity since the others (and also the Boundary-Saddle and Boundary-Focus cases) can be studied analogously, and they do not lead to new interesting dynamics.

We consider a Filippov vector field $Z = (X, Y)$ such that X has an attractor node at $p = (0,0) \in \Sigma$ and Y is transversal to Σ and points towards it, in such a way that the corresponding sliding vector field is of the form $Z_s(x) = \beta x^2 + \mathcal{O}(x^3)$ with $\beta > 0$. We want to point out that the other generic non-degeneracy conditions explained in Section 4.1.3 still have to hold, that is, the eigenvalues of the node have to be different and the weak and strong eigenspaces have to be transversal to Σ.

To consider a normal form such that the linearization of X at p is diagonal, we have to take Σ transversal to the eigenspaces of X at p. We choose coordinates such that $\Sigma = \{x + y = 0\}$ and

$$Z(x,y) = \begin{cases} X(x,y) = \begin{pmatrix} -x + x^2 \\ -2y \end{pmatrix} & \text{if } x + y > 0 \\ Y(x,y) = \begin{pmatrix} -1 \\ 2 \end{pmatrix} & \text{if } x + y < 0 \end{cases}$$

since then, taking x as a local chart of Σ, the sliding vector field is given by

$$Z_s(x) = \frac{2x^2}{1 - x - x^2} = 2x^2 + \mathcal{O}(x^3).$$

The dynamics of Z is illustrated in Figure 11. Let us observe that it is not possible to take a normal form with X and Σ linear to obtain a sliding vector field without linear part and not identically zero. Therefore, to avoid this degeneracy, we consider quadratic terms in X.

A generic unfolding of this singularity can be given by

$$Z_{\mu,\varepsilon}(x,y) = \begin{cases} X_\mu(x,y) = \begin{pmatrix} -x + x^2 + \mu \\ -2y - \mu \end{pmatrix} & \text{if } x + y > 0 \\ Y_\varepsilon(x,y) = \begin{pmatrix} -1 - \varepsilon \\ 2 + \varepsilon \end{pmatrix} & \text{if } x + y < 0 \end{cases} \tag{13}$$

in such a way that the node of X_μ is given by

$$N = \left(\frac{1 - \sqrt{1 - 4\mu}}{2}, \frac{-\mu}{2} \right)$$

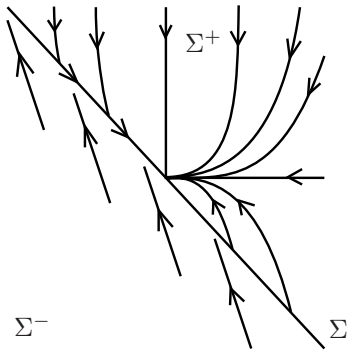

Figure 11: Phase portrait of the degenerate Boundary-Node bifurcation.

and therefore it is visible for $\mu > 0$ and invisible for $\mu < 0$. On the other hand, we have chosen the unfolding parameters in such a way that when N is away from Σ, that is when $\mu \neq 0$, the vector field X_μ has a fold located at $F_+ = (0, 0)$. The parameter ε unfolds to the other degeneracy, namely, when $\varepsilon \neq 0$, it appears linear part in the sliding vector field, since it is given by

$$Z_s(x) = \frac{\mu + \varepsilon x + (2+\varepsilon)x^2}{1 - x - x^2}.$$

Computing the critical points of Z_s, it is straightforward to see that Z_s undergoes a Saddle-Node bifurcation provided $\varepsilon^2 - 4\mu(2+\varepsilon) = 0$. Nevertheless, the Saddle-Node point

$$Q = \left(-\frac{\varepsilon}{2(2+\varepsilon)}, \frac{\varepsilon}{2(2+\varepsilon)} \right)$$

only belongs to Σ^s provided $\varepsilon > 0$.

First we study the codimension-1 local bifurcations which undergoes the unfolding $Z_{\mu,\varepsilon}$ (see the bifurcation diagram in Figure 12). The line $\{\mu = 0\}$ corresponds to two different kinds of codimension-1 Boundary-Node bifurcations: for $\varepsilon < 0$ is the bifurcation BN_1 described in [KRG03] and for $\varepsilon > 0$ is the bifurcation explained in Remark 4.2.

On the other hand, in the curve

$$\gamma = \left\{ \mu = \frac{\varepsilon^2}{4(2+\varepsilon)} \quad \text{for } \varepsilon > 0 \right\}$$

takes place a Saddle-Node bifurcation of the sliding vector field (called *pseudo-Saddle-Node* in [KRG03]). In these two curves occur the only possible local bifurcations of the unfolding, which moreover are the same independently whether we use Σ or topological equivalence.

Finally, studying the regions delimited by these curves it can be easily seen that any two vector fields in any of these regions are Σ-equivalent (and thus topologically equivalent). Therefore, there can not appear global bifurcations.

7 Codimension-2 invisible fold-fold singularity

We take $\Sigma = \{y = 0\}$ and the Fold-Fold point at $p = (0, 0)$. Then, as we have explained in Section 4.1.1, we can define a return map in $\Pi = \{(x, y) \in \Sigma, x < 0\}$, which is of the form (10).

Then, for the generic codimension-1 Fold-Fold singularity (called II_2 in [KRG03]), one has to impose that $\alpha_X - \alpha_Y \neq 0$ (see (10)). Therefore, taking $\alpha_X - \alpha_Y = 0$ leads to a codimension-2 singularity, whose return map is of the form

$$\varphi(x) = x + \beta x^4 + \mathcal{O}\left(x^5\right). \tag{14}$$

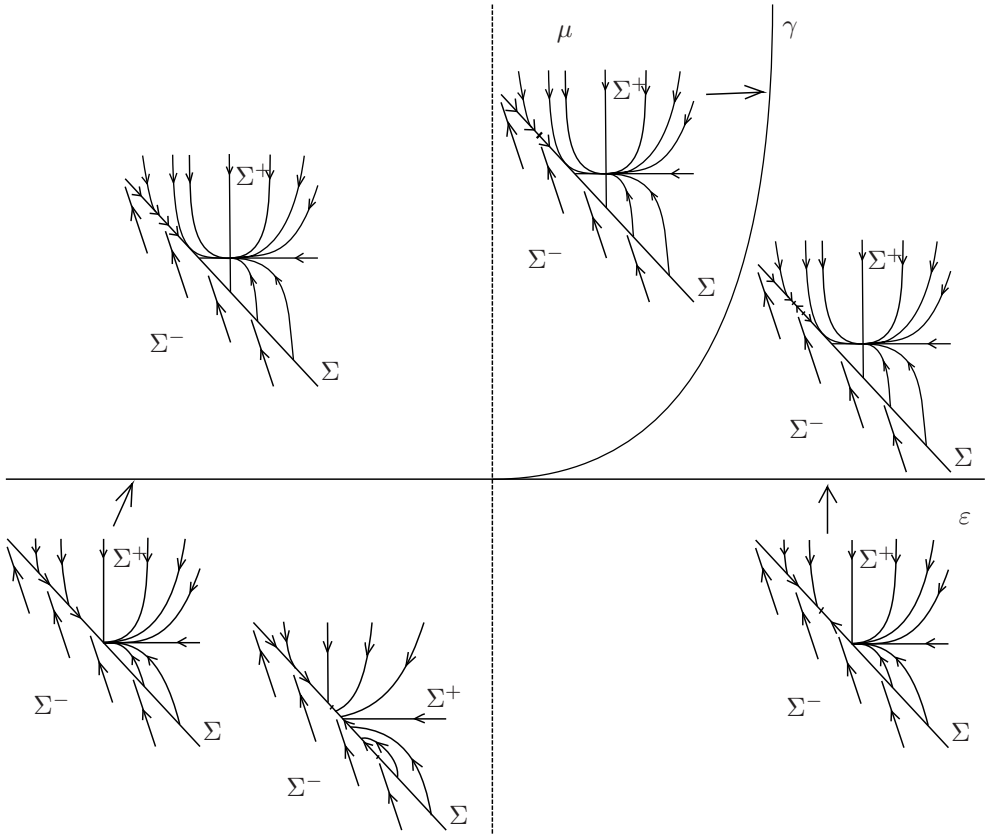

Figure 12: Bifurcation diagram of the generic unfolding of the degenerate Boundary-Node, which is given by (13). Notice, that in the curve γ occurs the Saddle-Node bifurcation of the sliding vector field.

where we assume the generic non-degeneracy condition $\beta \neq 0$. More concretely, we will focus on the case $\beta < 0$, and then p acts as a repellor focus, and the case $\beta > 0$ can be studied analogously.

We take as a normal form

$$Z(x,y) = \begin{cases} X(x,y) = \begin{pmatrix} 1 \\ -x + x^4 \end{pmatrix} & \text{if } y > 0 \\ Y(x,y) = \begin{pmatrix} -1 \\ -x \end{pmatrix} & \text{if } y < 0. \end{cases}$$

whose associated return map is

$$\varphi(x) = x - \frac{2}{5}x^4 + \mathcal{O}(x^5)$$

and thus, it is of the form (14).

A generic unfolding of this singularity can be given by

$$Z_{\mu,\varepsilon}(x,y) = \begin{cases} X_\varepsilon(x,y) = \begin{pmatrix} 1 \\ -x + \varepsilon x^2 + x^4 \end{pmatrix} & \text{if } y > 0 \\ Y_\mu(x,y) = \begin{pmatrix} -1 \\ -(x-\mu) \end{pmatrix} & \text{if } y < 0, \end{cases} \tag{15}$$

in such a way that for $\mu \neq 0$ the folds of X_ε and Y_μ are $F_+ = (0,0)$ and $F_- = (\mu, 0)$ respectively.

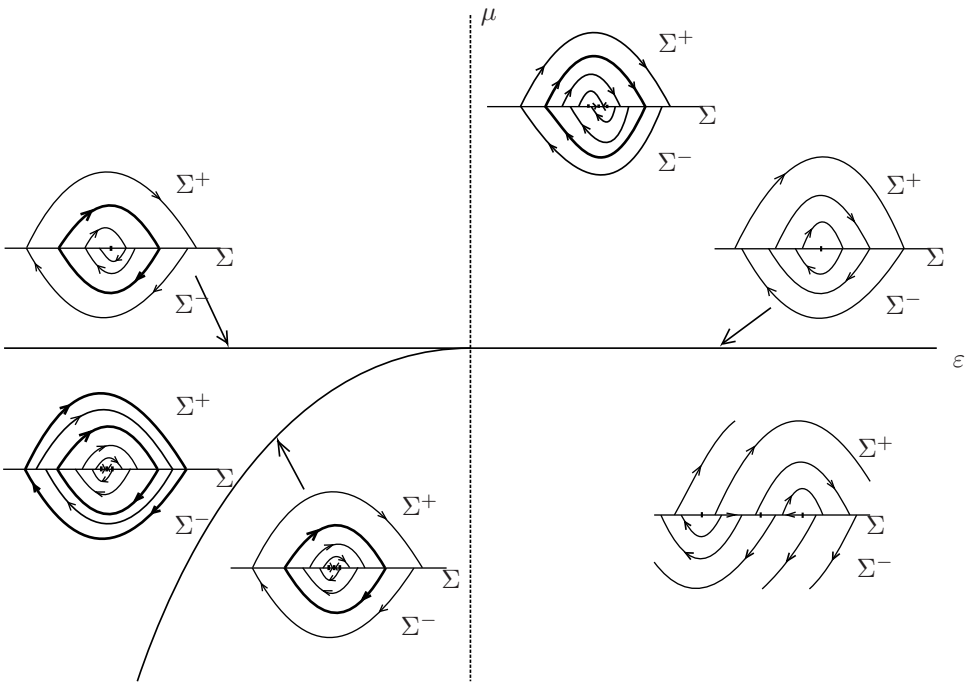

Figure 13: Bifurcation diagram of (15). It remains the same independently whether we use Σ-equivalences or topological equivalences.

On the other hand, ε unfolds the degeneracy of the return map. Indeed, for $\mu = 0$, the return map around the Fold-Fold point $p = (0, 0)$ is given by

$$\varphi_\varepsilon(x) = x - \frac{2}{3}\varepsilon x^2 + \frac{4}{9}\varepsilon^2 x^3 - \left(\frac{2}{5} + \frac{16}{27}\varepsilon^3\right) x^4 + \mathcal{O}\left(x^5\right). \tag{16}$$

Therefore, p is a generic repellor Fold-Fold for $\varepsilon > 0$ and is a generic attractor Fold-Fold for $\varepsilon < 0$.

On the other hand, for $\mu \neq 0$, it appears a small sliding region between F_+ and F_- (for $\mu > 0$) or a small escaping region between F_- and F_+ (for $\mu < 0$). In both cases, taking x as a local chart of Σ, the sliding vector field is given by

$$Z_s(x) = \frac{\mu - x + \varepsilon x^2 + x^4}{\mu + x - \varepsilon x^2 - x^4}$$

which has a pseudonode $N = (N_x, 0)$ for any $\mu \neq 0$, which satisfies $N_x = \mathcal{O}(\mu)$.

In the unfolding (15) there exist both local and global bifurcations as can be seen in the following proposition (see Figure 13 for the bifurcation diagram).

Proposition 7.1. *For (ε, μ) small enough the vector field $Z_{\mu,\varepsilon}$ in (15) undergoes the following bifurcations*

- *A generic attractor Fold-Fold bifurcation (see Section 4.1.1) in $\{\mu = 0, \varepsilon < 0\}$.*
- *A generic repellor Fold-Fold bifurcation (see Section 4.1.1) in $\{\mu = 0, \varepsilon > 0\}$.*
- *A Saddle-Node bifurcation of periodic orbits in the curve γ (see Figure 13) which is given by*

$$\mu = -\frac{5}{36}\varepsilon^2 + \mathcal{O}(\varepsilon^3),\ \varepsilon < 0.$$

Proof. We start studying the local bifurcations. Since both folds are given by $F_+ = (0,0)$ and $F_- = (\mu, 0)$, $Z_{\mu,\varepsilon}$ undergoes a Fold-Fold bifurcation in $\{\mu = 0\}$. From the return map (16), one can see that for $\varepsilon < 0$ the Fold-Fold is attracting and for $\varepsilon > 0$ it is repelling. On the other hand, from (16) it is straightforward to see that in $\{\mu = 0, \varepsilon < 0\}$ there exists a repelling periodic orbit, whose intersection points with Σ are given by $Q^{\pm} = (Q_x^{\pm}, 0)$ with

$$Q_x^{\pm} = \pm\sqrt{-\frac{5}{3}\varepsilon} + \mathcal{O}(\varepsilon).$$

and which persists for $\mu \neq 0$ and $\varepsilon < 0$.

Therefore, considering also the periodic orbit which appears due to the Fold-Fold generic bifurcation (see Section 4.1.1), we have that close to the curve $\{\mu = 0, \varepsilon < 0\}$ there exists a periodic orbit for $\mu > 0$ and two periodic orbits for $\mu < 0$ and close to the curve $\{\mu = 0, \varepsilon > 0\}$ there exists a periodic orbit for $\mu > 0$ and none for $\mu < 0$. These bifurcations are illustrated in Figure 13.

As a consequence any two vector fields in $\{\mu > 0\}$ are Σ-equivalent (and thus topological equivalent).

In $\{\mu < 0\}$, it is clear that a global bifurcation leading to the disappearance of the periodic orbits takes place. In order to detect it, it is enough to point out that in this region these periodic orbits are given by fixed points of the return map $\varphi_{\mu,\varepsilon}$ associated to $Z_{\mu,\varepsilon}$. Thus, this bifurcation corresponds to the existence of a double zero of the equation $\varphi_{\mu,\varepsilon}(x) = x$. Using that $\varphi_{\mu,\varepsilon}$ is given by

$$\varphi_{\mu,\varepsilon}(x) = 2\mu + x - \frac{2}{3}\varepsilon x^2 + \frac{4}{9}\varepsilon^2 x^3 - \left(\frac{2}{5} + \frac{16}{27}\varepsilon^3\right) x^4 + \mathcal{O}(x^5),$$

it is straightforward to see that the curve γ in which the Saddle-Node bifurcation of periodic orbits takes place is given by

$$\mu = -\frac{5}{36}\varepsilon^2 + \mathcal{O}(\varepsilon^3)$$

for $\varepsilon < 0$.

□

8 Boundary-Saddle with a invariant manifold tangent to Σ

In order to have a codimension-1 Boundary-Saddle bifurcation, one has to impose that the invariant manifolds of the saddle are transversal to Σ and $\alpha \neq 0$ where α is the linear part of the sliding vector field given in (11) (see Section 4.1.2). Therefore, if Σ and one of these manifolds are tangent, the singularity has higher codimension. In this section we consider vector fields $Z = (X, Y)$ having the following property: one of the invariant manifold of the saddle $p \in \Sigma$ of X has a quadratic contact with Σ.

This singularity can present different behaviors depending on

- Which invariant manifold is tangent (the stable or the unstable one).
- The sign of $Yf(p)$ (that is, whether Y points toward Σ or away from Σ).
- Whether one or the two invariant manifolds are visible.
- The sign of α.

We observe that the visibility of the invariant manifolds is a property which depends on the second order terms of the jet of Σ and X (see Figure 14). On the other hand, we point out that even though in this case Σ^s is collapsed to $(0,0)$ it is worth to consider Z_s as in (11) since the condition $\alpha \neq 0$ is needed to deal with a codimension-2 bifurcation.

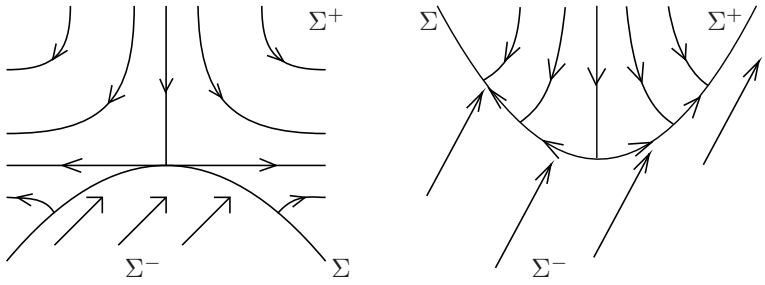

Figure 14: Two kinds of Boundary-Saddle with a invariant manifold tangent to Σ. In the left one both invariant manifolds are visible whereas on the right one, only the stable manifold is visible.

In this section, we focus ourselves on the case in which Σ is tangent to the unstable invariant manifold, both invariant manifolds are visible, Y points toward Σ (see left picture in Figure 14) and $\alpha > 0$. In this case, it is straightforward to see that the saddle $p = (0,0) \in \Sigma$ belongs to the boundary of two components of Σ^c.

To consider a normal form for this singularity, we distort Σ in order to be allowed to consider X as a linear vector field in diagonal form. We take coordinates such that $\Sigma = \{y + x^2 = 0\}$ and the vector field

$$Z(x,y) = \begin{cases} X(x,y) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} & \text{if } y + x^2 > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{if } y + x^2 < 0 \end{cases}$$

in such a way that Σ and $W^u(p)$ are tangent to the x-axis at $p = (0,0)$. In order to consider a generic unfolding of this singularity, we deform again Σ making it depend on one of the parameters:

$$\Sigma \equiv \Sigma_\varepsilon = \{f(x,y) = y + \varepsilon x + x^2 = 0\}$$

and consider as vector field

$$Z_{\mu,\varepsilon}(x,y) = \begin{cases} X_\mu(x,y) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} x \\ y - \mu \end{pmatrix} & \text{if } y + \varepsilon x + x^2 > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{if } y + \varepsilon x + x^2 < 0. \end{cases} \tag{17}$$

Then, the saddle of X is $Q = (0,\mu)$ and therefore it is visible for $\mu > 0$ and invisible for $\mu < 0$.

On the other hand, the tangencies of X_μ when $\mu \neq 0$ are the solutions of equation $X_\mu f = 0$. This equation reads $3x^2 + 2\varepsilon x + \mu = 0$ whose discriminant is given by $\Delta = 4\varepsilon^2 - 12\mu$. Thus, in the curve $\gamma_1 = \{\mu = \varepsilon^2/3\}$, X_μ has a cusp (a cubic tangency). Above this curve does not exist any fold and below it there are two (see Figure 15) which we call F_1 and F_2. Therefore, above γ_1, $\Sigma = \Sigma^c$ and below it appears a small sliding region of diameter $\mathcal{O}(\sqrt{\Delta})$ given by

$$\Sigma^s = \left\{ (x,y) \in \Sigma : x \in \left(\frac{-2\varepsilon - \sqrt{4\varepsilon^2 - 12\mu}}{6}, \frac{-2\varepsilon + \sqrt{4\varepsilon^2 - 12\mu}}{6} \right) \right\}.$$

In Σ^s, we can compute the sliding vector field taking x as a local chart, and is given by

$$Z_s(x) = \frac{-\mu + (1-\varepsilon)x - x^2}{1 + \varepsilon - \mu + 2(1-\varepsilon)x - 3x^2}$$

that has a pseudosaddle $S \equiv S(\mu,\varepsilon)$ provided $\mu < 0$.

Next proposition summarizes all the local and global bifurcations which occur nearby the singularity we are considering (see the bifurcation diagram in Figure 15).

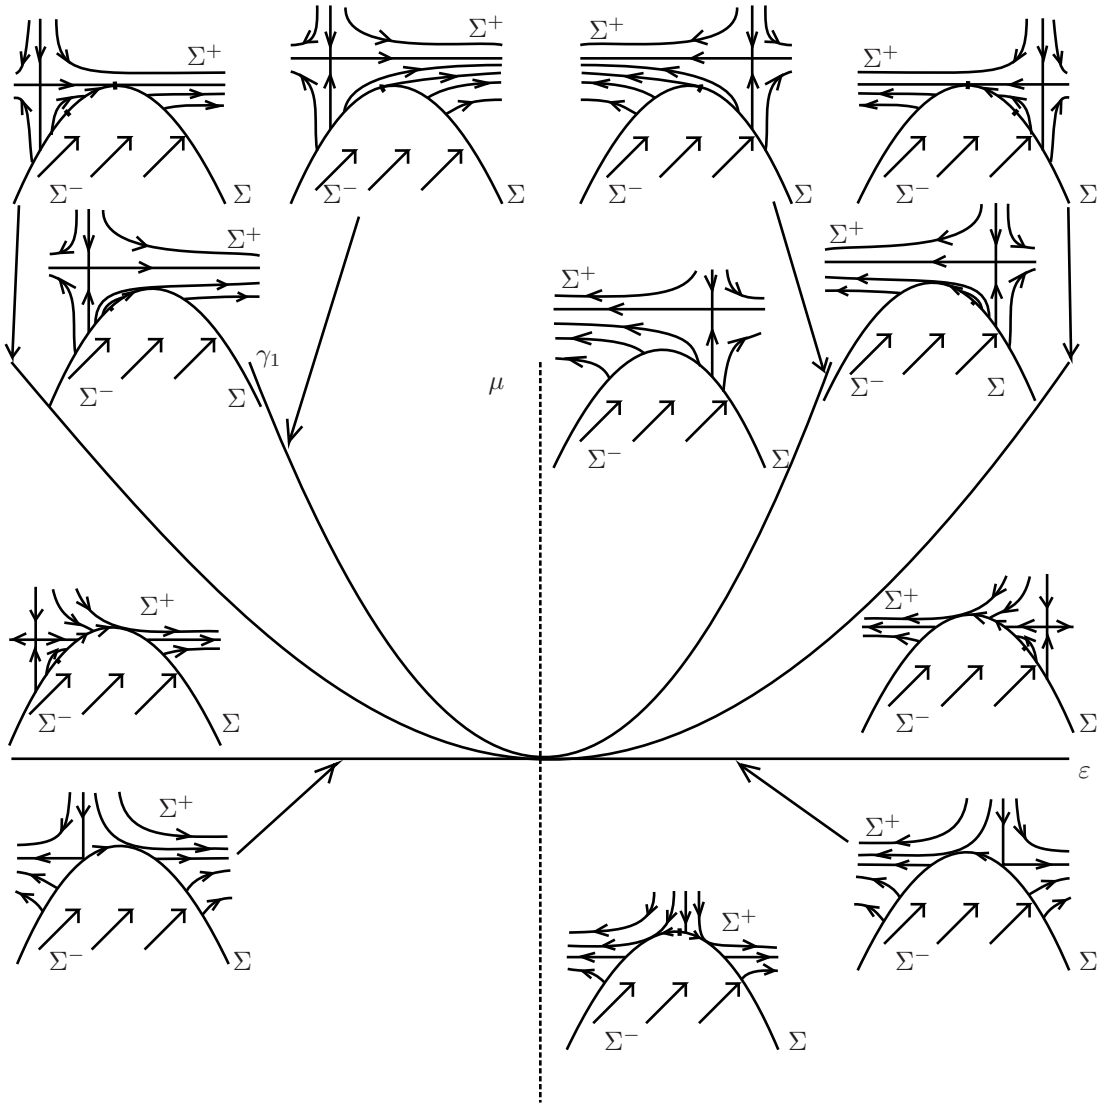

Figure 15: Bifurcation diagram of (17) using Σ-equivalences.

Proposition 8.1. *For (ε, μ) small enough the vector field $Z_{\mu,\varepsilon}$ in* (17) *undergoes the following local bifurcations:*

- *A Boundary-Saddle, called BS_3 in [KRG03], in $\{\mu = 0, \varepsilon \neq 0\}$.*
- *A cusp bifurcation, called DT_1 in [KRG03], in the curve $\gamma_1 = \{\mu = \varepsilon^2/3\}$.*
- *A connection of separatrices between the saddle p and the fold F_1, that is $W^u(p) \equiv W^s_+(F_1)$, in $\{\mu = \varepsilon^2/4, \varepsilon < 0\}$.*
- *A connection of separatrices between the saddle p and the fold F_2, that is $W^u(p) \equiv W^s_+(F_2)$, in $\{\mu = \varepsilon^2/4, \varepsilon > 0\}$.*

Proof. The proof of the existence of the local bifurcations is immediate from the study of tangencies and critical points of $Z_{\mu,\varepsilon}$, which has already been done. In $\{\mu = 0, \varepsilon \neq 0\}$, the saddle Q belongs to Σ and

thus this line corresponds to the codimension-1 Boundary-Saddle bifurcation called BS_3 in [KRG03]. On the other hand, in γ_1 occurs a cusp bifurcation which is called DT_1 in [KRG03]. In these two curves in the (ε, μ) parameter space occur all the possible codimension-1 local bifurcations, either considering topological equivalence or Σ-equivalence, which exist in any generic unfolding of the singularity.

Secondly, we study the codimension-1 global bifurcation curves of the unfolding $Z_{\mu,\varepsilon}$. For that purpose, we study the behavior of the vector field in the three regions delimited by the curves above explained.

In $\{\mu < 0\}$ it can be checked easily that any two vector fields are Σ-equivalent (and thus topologically equivalent). In the region $\{0 < \mu < \varepsilon^2/3\}$, there occurs a global bifurcation given by a separatrix connection between the saddle $Q = (0, \mu)$ and one of the two visible folds, that is $W^u(p) \equiv W^s_+(F_1)$ and $W^u(p) \equiv W^s_+(F_2)$ for $\varepsilon > 0$ and for $\varepsilon < 0$ respectively. To compute the curve in the parameter space where these connections take place it is enough to recall that the saddle is in diagonal form and thus its invariant manifolds are just straight lines. Then, it is enough to impose that the y-coordinates of the saddle and one of the folds coincide to obtain that the connection takes place in $\{\mu = \varepsilon^2/4\}$

Finally, above γ_1 do not appear any other global bifurcation and therefore any two vector fields belonging to that region are Σ-equivalent (and thus topologically equivalent). □

It is worth to point out that the description of the bifurcation diagram is independent whether we use Σ-equivalence or topological equivalence.

9 Non-diagonalizable node in Σ

In this section we study the Boundary-Node bifurcation in the case in which both eigenvalues coincide and so one of the generic non-degeneracy conditions stated in Section 4.1.3 is violated. Then, to be a codimension-2 local bifurcation, the linear part can not be diagonalizable.

As it was noticed in [KRG03] (see also [Tei77]), the Boundary-Focus and Boundary-Node are different singularities in planar Filippov systems (see also Sections 4.1.3 and 4.1.4). This fact is genuinely discontinuous since, as it is well known by Hartmann-Grobman Theorem, in the smooth case a focus and a node are topologically equivalent (in fact topologically conjugated). Nevertheless, the conjugacy provided by Hartmann-Grobman Theorem can not be used to construct a homeomorphism as in Proposition 2.17, since it twists the neighborhood of the critical point and therefore, it does not preserve Σ^+.

Let us consider a Filippov vector field $Z = (X, Y)$ in a neighborhood U of $p \in \Sigma$ such that Y is transversal to Σ and X has a node at $p \in \Sigma$ whose Jordan normal form is

$$\begin{pmatrix} \lambda & 0 \\ 1 & \lambda \end{pmatrix} \tag{18}$$

in such a way that the eigenspace associated with the unique eigenvector is transversal to Σ. Then, Z undergoes a codimension-2 local bifurcation at p, independently whether we consider topological equivalences or Σ-equivalences.

We will see that this singularity has a feature not present in any codimension-1 one: in its generic (2 parametric) unfolding we will find different codimension-1 bifurcation curves depending whether we use topological equivalence or Σ-equivalence. In this second case it emerges from the singularity one more curve in the parameter space which corresponds to a codimension-1 global bifurcation.

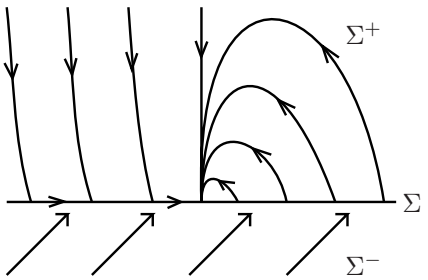

Figure 16: Phase portrait of (19).

As said before, this codimension-2 singularity appears when Y is transversal to Σ and X has non-diagonalizable linear part with a real non-zero eigenvalue. We only deal with the case of negative eigenvalue ($\lambda < 0$) and $Yf(p) > 0$, since the other ones can be studied in a similar way. In that case, $p \in \partial\Sigma^s \cap \partial\Sigma^c$, and $Z_s(p) = 0$. Therefore, it can be seen as a critical point of the (extended) sliding vector field. In order to have a generic codimension-2 singularity, this critical point has to be hyperbolic. So, as $Z_s(x) = \alpha x + \mathcal{O}(x^2)$ (taking x as a local chart of Σ around p), $\alpha \neq 0$ must hold. In this section we assume that $\alpha < 0$.

One can choose as a normal form $f(x, y) = y$ and

$$Z(x,y) = \begin{cases} X(x,y) = \begin{pmatrix} -1 & 0 \\ 1 & -1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} & \text{if } y > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{if } y < 0 \end{cases} \tag{19}$$

which satisfies the explained generic conditions (see Figure 16).

A generic unfolding of this singularity can be given by

$$Z_{\varepsilon,\mu}(x,y) = \begin{cases} X_{\varepsilon,\mu}(x,y) = \begin{pmatrix} -1 & \varepsilon \\ 1 & -1 \end{pmatrix} \begin{pmatrix} x \\ y-\mu \end{pmatrix} & \text{if } y > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{if } y < 0 \end{cases} \tag{20}$$

in such a way that μ measures the distance of the hyperbolic fixed point to Σ and ε the deformation of the eigenvalues.

The hyperbolic fixed point $P = (0, \mu) \in \Sigma^+$ is visible for $\mu > 0$ and invisible for $\mu < 0$ (see Figure 17). On the other hand, P is a focus for $\varepsilon < 0$ and a node for $\varepsilon > 0$.

Moreover, it is straightforward to see that for any value of the parameters, the point $F = (-\mu, 0) \in \Sigma$ is a visible fold of X for $\mu > 0$ and an invisible fold of X for $\mu < 0$. Moreover, the sliding vector field is given by

$$Z_s(x) = \frac{-2x - \mu - \mu\varepsilon}{1 - x - \mu},$$

which is defined in $\Sigma^s = \{(x, y) \in \Sigma : x < -\mu\}$. This vector field has a pseudonode $N = (-(\mu + \mu\varepsilon)/2, 0)$ provided $\mu < 0$.

As already said, the line $\{\mu = 0\}$ in the parameter space corresponds to two codimension-1 bifurcation curves (for $\varepsilon > 0$ and $\varepsilon < 0$) in which they occur the Boundary-Focus bifurcation BF_4 (with reversed time) and Boundary-Node bifurcation BN_1, both studied in [KRG03].

We study the possible existence of codimension-1 global bifurcation curves in the unfolding $Z_{\mu,\varepsilon}$. First we consider Σ-equivalences. One can see that any two vector fields $Z_{\mu,\varepsilon}$ and $Z_{\bar{\mu},\bar{\varepsilon}}$ are Σ-equivalent (and thus equivalent) provided $\mu\bar{\mu} > 0$ and $\varepsilon\bar{\varepsilon} > 0$. One can easily construct a homeomorphism which preserves Σ and gives the equivalence.

The line $\{\varepsilon = 0, \mu > 0\}$ corresponds to the parameter values in which the visible hyperbolic fixed point P changes from a focus to a node. Even if $X_{\mu,\varepsilon}$ and $X_{\bar{\mu},\bar{\varepsilon}}$ with $\mu > 0$, $\bar{\mu} > 0$, $\varepsilon < 0$ and $\bar{\varepsilon} > 0$ are locally equivalent in Σ^+ around the hyperbolic fixed point P, next proposition will show that $Z_{\mu,\varepsilon}$ and $Z_{\bar{\mu},\bar{\varepsilon}}$ are not Σ-equivalent. Consequently, the homeomorphism which gives the local equivalence in Σ^+ can not be extended to a neighborhood intersecting Σ and Σ^-. Moreover, on the line $\{\varepsilon = 0, \mu > 0\}$ occurs a global bifurcation involving the arrival orbits of Σ^s. On the other hand, we will see that the same happens for $Z_{\mu,\varepsilon}$ and $Z_{\bar{\mu},\bar{\varepsilon}}$ with $\mu < 0$, $\bar{\mu} < 0$, $\varepsilon < 0$ and $\bar{\varepsilon} > 0$.

Proposition 9.1. *The Filippov vector fields $Z_{\mu,\varepsilon}$ and $Z_{\bar{\mu},\bar{\varepsilon}}$ with $\mu\bar{\mu} > 0$, $\varepsilon < 0$ and $\bar{\varepsilon} > 0$ are not Σ-equivalent.*

Proof. When $\mu > 0$ and $\bar{\mu} > 0$, the corresponding folds F and $\bar{F}$ are visible, and then they have three separatrices (see Figure 17). If we consider the separatrix $W^s_+(F)$, it intersects Σ^c whereas $W^s_+(\bar{F})$ does not. In fact, the same occurs with all the arrival orbits of points of Σ^s. Therefore, since both $W^s_+(F)$ and Σ^c have to be preserved by Σ-equivalences, their intersection too, and thus the vector fields $Z_{\mu,\varepsilon}$ and $Z_{\bar{\mu},\bar{\varepsilon}}$ with $\mu > 0$, $\bar{\mu} > 0$, $\varepsilon < 0$ and $\bar{\varepsilon} > 0$, can not be Σ-equivalent.

For $\mu < 0$ and $\bar{\mu} < 0$, it can be seen analogously that $Z_{\mu,\varepsilon}$ and $Z_{\bar{\mu},\bar{\varepsilon}}$ with $\varepsilon < 0$ and $\bar{\varepsilon} > 0$ can neither be equivalent. In fact, for $Z_{\mu,\varepsilon}$ all the orbits in Σ^+, which have an arrival point in Σ^s, hit also Σ^c in backward time, but for $Z_{\bar{\mu},\bar{\varepsilon}}$ there exist orbits which arrive to Σ^s but remain in Σ^+ in backward time. Thus, since Σ^c and Σ^s have to be preserved, the vector fields in the domains $\{\mu < 0, \varepsilon > 0\}$ $\{\mu < 0, \varepsilon < 0\}$ can not be Σ-equivalent. □

Using Σ-equivalences one obtains that the unfolding has four different generic behaviors depending on the signs of ε and μ and that the codimension-1 bifurcations only occur in $\{\mu = 0\}$ or $\{\varepsilon = 0\}$ (see Figure 17).

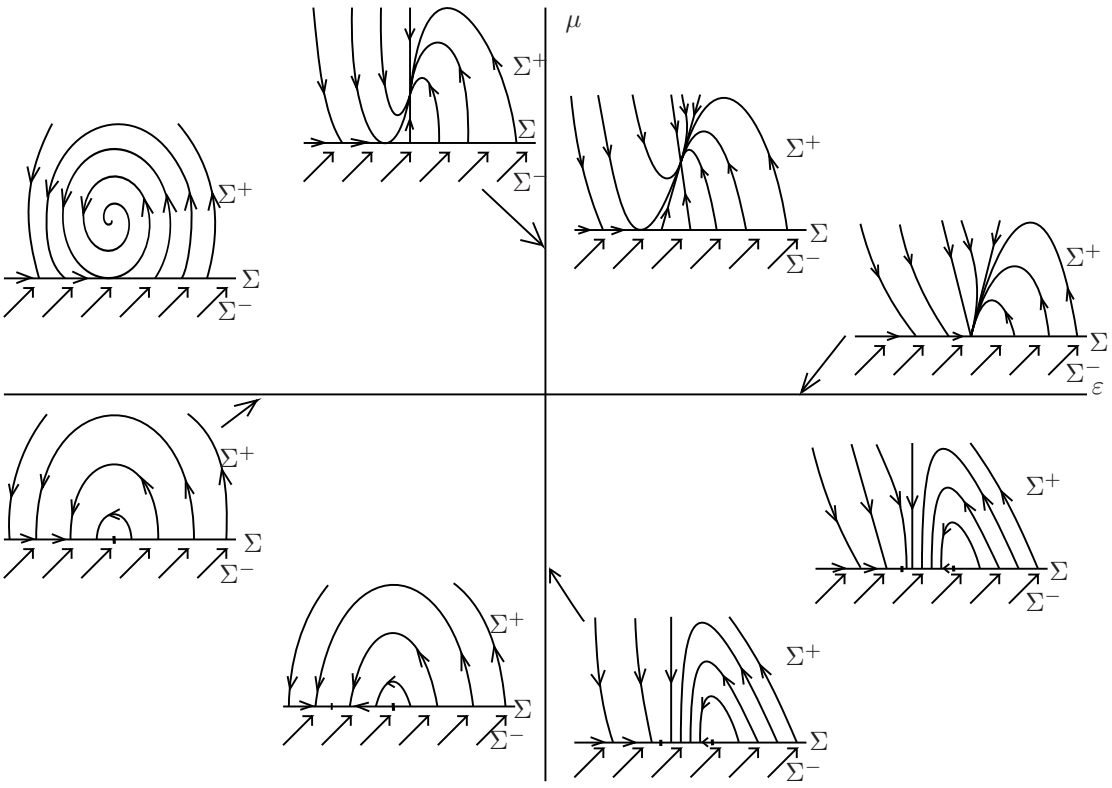

Figure 17: Bifurcation diagram of (20) using Σ-equivalences. For the bifurcation diagram using topological equivalences, it is enough to remove the bifurcation curve $\varepsilon = 0$.

If one considers topological equivalences instead of Σ-equivalences, we will see that the unfolding only presents two generic behaviors. Observe that the line $\{\varepsilon = 0\}$ is not a codimension one bifurcation curve.

Proposition 9.2. *For μ and ε small enough, the Filippov vector fields $Z_{\mu,\varepsilon}$ and $Z_{\mu',\varepsilon'}$ with $\mu\mu' > 0$ are topologically equivalent.*

Proof. We will prove that any two vector fields $Z_{\mu,\varepsilon}$ and $Z_{\mu',\varepsilon'}$ with $\mu\mu' > 0$, $\varepsilon < 0$ and $\varepsilon' \geq 0$ are topologically equivalent. We will construct the homeomorphism h which gives the equivalence piecewise in different regions of the phase space checking *a posteriori* that it is continuous. First we consider neighborhoods $U \subset \Sigma^+$ and $U' \subset \Sigma^+$ of the focus $P = (0, \mu)$ of $Z_{\mu,\varepsilon}$ and the node $P' = (0, \mu')$ of $Z_{\mu',\varepsilon'}$. We choose U and U' such that their boundary intersect the orbits of the corresponding vector fields transversally. On the other hand, since the separatrices $W^u_+(F)$ and $W^u_+(F')$ tend to P and P' respectively, there exist points $Q = W^u_+(F) \cap \partial U$ and $Q' = W^u_+(F') \cap \partial U'$. As a first step we use Hartmann-Grobman Theorem to define the homeomorphism $h : U \to U'$. Moreover, the homeomorphism given by this theorem can be chosen in such a way that $h(Q) = Q'$, and therefore $h(W^u_+(F) \cap U) = W^u_+(F') \cap U'$.

In order to extend the homeomorphism h we define regions A and B which are delimited by the separatrices $W^s_-(F) \cup W^s_+(F)$, in such a way that $U \subset A$ (see Figure 18). In the next step we extend h to the full region A. For this purpose we use the flows of both $Z_{\mu,\varepsilon}$ and $Z_{\mu',\varepsilon'}$ reparameterized by the arc-length in order to assure that $h(F) = F'$. With this construction is clear that h is continuous at ∂U and that $h(W^u_+(F)) = W^u_+(F')$. Moreover, since h is continuous, it can be extended to ∂A, which is made up of $W^s_+(F)$ and $W^s_-(F)$ and thus these separatrices are also preserved.

Finally, in order to extend h to region B (see Figure 18), we define it first in Σ^s. Since it is only one orbit, h can be trivially extended in such a way that $h(F) = F'$. Let us observe that any $R \in \Sigma^s$ reaches F, that is, exists $t_R > 0$ such that $\varphi_{Z_s}(t, R) \to F$ as $t \to t_R$. For the other points in B, we define h using the flows $Z_{\mu,\varepsilon}$ and $Z_{\mu',\varepsilon'}$ and reparameterizing again by the arc-length to assure that h is continuous in ∂B since in these points the definition has to coincide with the one established in ∂A.

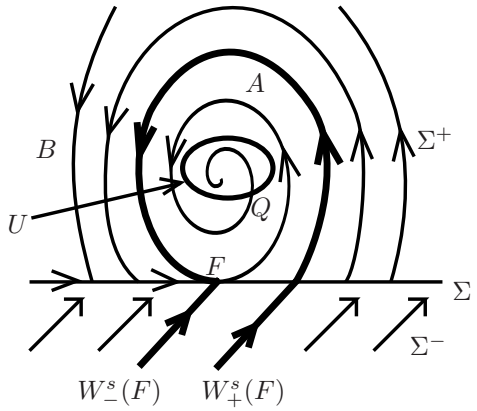

Figure 18: Phase portrait of $Z_{\mu,\varepsilon}$ with $\mu > 0$ and $\varepsilon < 0$. To define the homeomorphism between $Z_{\mu,\varepsilon}$ and $Z_{\mu',\varepsilon'}$ with $\mu' > 0$ and $\varepsilon' > 0$ on has to consider Regions A and B delimited by the separatrices $W^s_-(F) \cup W^s_+(F)$.

For $\mu < 0$, the construction of the homeomorphism is simpler. In order to construct h we start by defining it on Σ^s. By Hartmann-Grobman Theorem, we can define an orientation preserving homeomorphism $h : \overline{\Sigma^s} \to \overline{\Sigma^{s\prime}}$ such that $h(N) = N'$ and $h(F) = F'$. As the orbit of any point of $\Sigma^+ \cup \Sigma^-$ has an arrival point in Σ^s, h can be extended through the flow to them as it has been done for the points in Region B in the case $\mu > 0$ (see Figure 18). Let us observe that with this construction $h(W^s_-(F)) = W^s_-(F')$, $h(W^s_-(N)) = W^s_-(N')$ and $h(W^s_+(N)) = W^s_+(N')$.

□

10 Focus-Fold singularity

A Filippov vector field $Z = (X, Y)$ has a Focus-Fold singularity when X has a hyperbolic focus at $p \in \Sigma$ and Y has a fold at the same point. This singularity presents a particular interest since in some of its generic unfoldings can appear several global bifurcations as existence of separatrix connections and bifurcations of cycles, which were explained in [KRG03] and have been reviewed in Section 4.2. Of course, this singularity can present different behavior depending whether the focus is attracting or repelling, the fold is visible or invisible and whether p belongs to the boundary of two components of Σ^c or between Σ^s and Σ^e (see Figure 19).

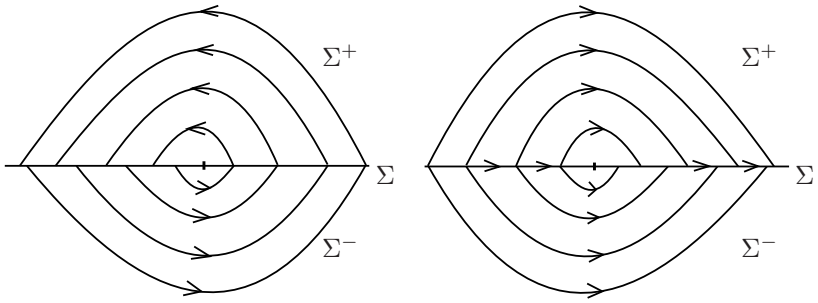

Figure 19: Two kinds of Focus-Fold singularities. In both, the focus is repelling, the fold is invisible. Nevertheless, in the first one $p \in \partial\Sigma^c$, whereas in the right one $p \in \partial\Sigma^e \cap \partial\Sigma^s$.

In this section we study the case in which p is a repelling focus of X and an invisible fold of Y such that $p \in \partial\Sigma^c$, since this case gives raise to more interesting dynamics around the singularity.

We choose as a normal form $f(x, y) = y$ and

$$Z(x,y) = \begin{cases} X(x,y) = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} & \text{if } y > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ x \end{pmatrix} & \text{if } y < 0 \end{cases}.$$

As in the Fold-Fold singularity (see Section 4.1.1), both vector fields have associated an involution φ_X and φ_Y defined in a neighborhood of Σ around p. Taking x as a local chart in Σ, it can be easily seen that the return map $\varphi = \varphi_X \circ \varphi_Y$ is of the form $\varphi(x) = \alpha x + \mathcal{O}(x^2)$ with $\alpha > 1$, and thus p behaves as a repelling focus for Z.

A generic unfolding of this singularity can be given by

$$Z_{\varepsilon,\mu}(x,y) = \begin{cases} X_\mu(x,y) = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} x+\mu \\ y-\mu \end{pmatrix} & \text{if } y > 0 \\ Y_\varepsilon(x,y) = \begin{pmatrix} 1 \\ x-\varepsilon \end{pmatrix} & \text{if } y < 0 \end{cases}. \tag{21}$$

in such a way that μ measures the distance of the focus $P = (-\mu, \mu)$ to Σ. Moreover, P is visible for $\mu > 0$ and invisible for $\mu < 0$. On the other hand, we have chosen X_μ in such a way that the fold which appears when the focus P is away from Σ is given by $F_+ = (0, 0)$. In this way, ε measures the distance between the fold $F_- = (\varepsilon, 0)$ of Y_ε and the fold $F_+ = (0, 0)$ of X_μ.

It can be checked that for $\varepsilon > 0$,

$$\Sigma = \overline{\Sigma^e} \cup \overline{\Sigma^c} \text{ with } \Sigma^e = (0, \varepsilon) \text{ and } \Sigma^c = \{x < 0\} \cup \{x > \varepsilon\},$$

and for $\varepsilon < 0$,

$$\Sigma = \overline{\Sigma^s} \cup \overline{\Sigma^c} \text{ with } \Sigma^s = (\varepsilon, 0) \text{ and } \Sigma^c = \{x < \varepsilon\} \cup \{x > 0\}.$$

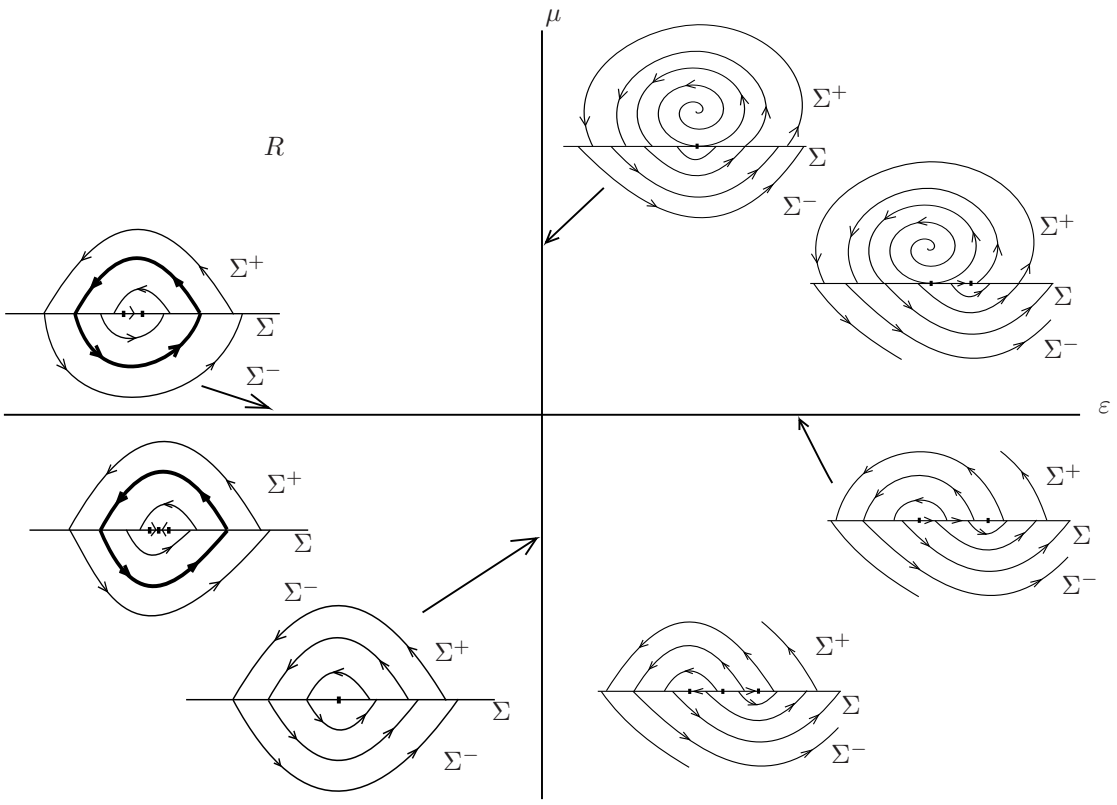

Figure 20: Bifurcation diagram of (21) using either topological or Σ-equivalences. The behavior in Region R can be seen in Figure 21.

In both Σ^s and Σ^e, the sliding vector field is given by

$$Z_s(x) = \frac{2\mu\varepsilon + (1 - 2\mu + \varepsilon)x + x^2}{\varepsilon}$$

and it can be seen that for $\mu < 0$, it has a pseudonode $N \equiv N(\mu, \varepsilon)$ which is attracting for $\varepsilon > 0$ and repelling for $\varepsilon < 0$.

First we study the existence of local bifurcations in this unfolding (see Figure 20). The line $\{\mu = 0\}$ in the parameter space corresponds to two different codimension-1 Boundary-Focus bifurcations, for $\varepsilon > 0$ and $\varepsilon < 0$, since the focus $P = (0, 0)$ belongs to Σ. For $\varepsilon > 0$, $P \in \partial\Sigma^e$ and then occurs the Boundary-Focus bifurcation BF_3 explained in [KRG03], whereas for $\varepsilon < 0$ the Boundary-Focus bifurcation BF_4 in [KRG03] takes place, since $P \in \partial\Sigma^s$. Moreover, in the transition from $\varepsilon < 0$ to $\varepsilon > 0$ it occurs a non-smooth Hopf-like bifurcation since it gives raise to the birth of a periodic orbit. We give the name Hopf-like bifurcation to this phenomenon since, as in the smooth case, P changes from unstable (for $\varepsilon > 0$) to stable (for $\varepsilon < 0$) due to the appearance of escaping and sliding region for $\varepsilon > 0$ and $\varepsilon < 0$ respectively.

The line $\{\varepsilon = 0\}$ also corresponds to two codimension-1 local bifurcations, since in this line both folds F_+ and F_- coincide at $(0, 0)$, being both invisible for $\mu < 0$ and being F_+ visible and F_- invisible for $\mu > 0$. Therefore, for $\mu > 0$ and $\mu < 0$ occur respectively bifurcations VI_1 and II_2, which are explained in [KRG03] (see also Section 4.1.1). This last one gives birth to a periodic orbit for $\varepsilon < 0$. Let us observe that as μ goes to zero, we obtain the codimension-2 bifurcation, in which the fold-fold singularity becomes a focus-fold at the same time of the birth of the periodic orbit.

In these two lines in the (ε, μ) parameter space all the possible codimension-1 local bifurcations occur,

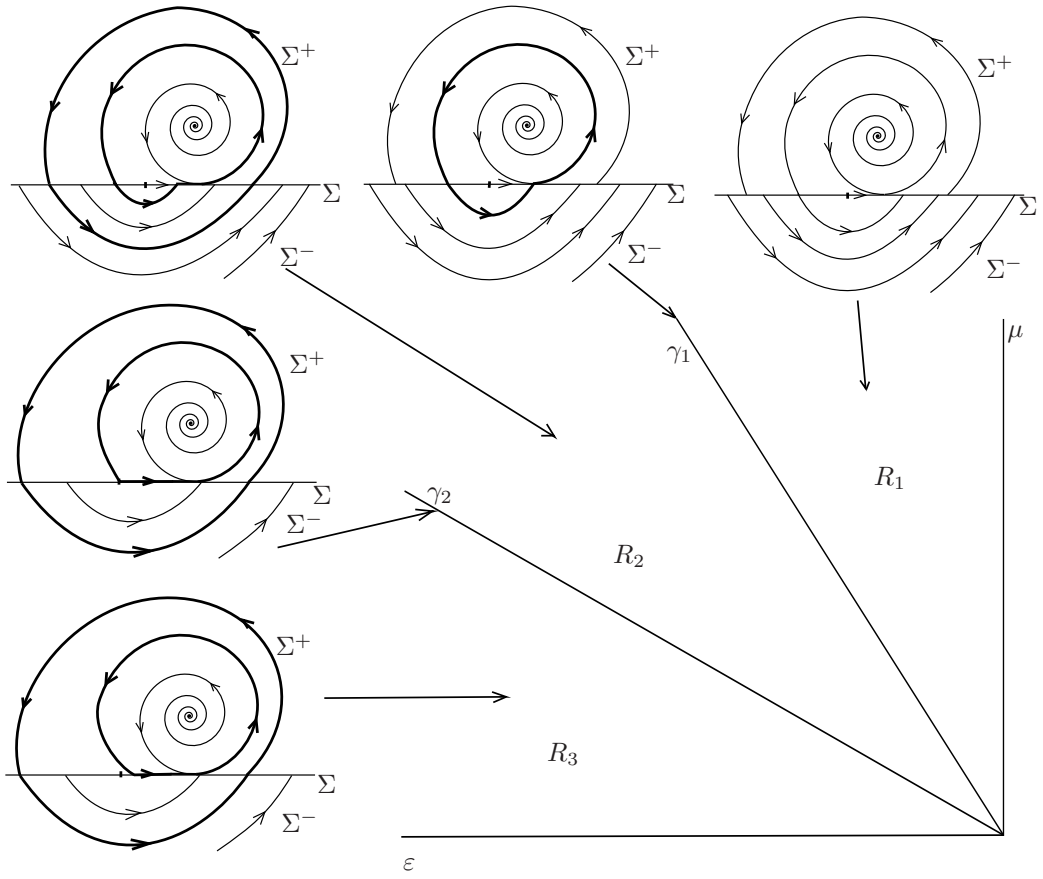

Figure 21: Bifurcation diagram of (21) for parameters belonging to $R = \{(\varepsilon, \mu) : \varepsilon < 0, \mu > 0\}$. The bifurcations undergone in this region of the parameter space remain the same either either Σ-equivalences or topological equivalences.

either considering topological or Σ-equivalence, which exist in any generic unfolding of the singularity.

We study the possible existence of codimension-1 global bifurcation curves of the unfolding $Z_{\mu,\varepsilon}$. For that purpose, we study the behavior of the vector field in the four quadrants considering the signs of μ and ε. In the quadrants $\{\mu > 0, \varepsilon > 0\}$, $\{\mu < 0, \varepsilon > 0\}$ and $\{\mu < 0, \varepsilon < 0\}$, one can see that any two vector fields with parameters belonging to the same quadrant are Σ-equivalent (and thus topologically equivalent).

Next proposition shows that in the region $R = \{\mu > 0, \varepsilon < 0\}$ the systems presents a richer dynamics.

Proposition 10.1. *There exist two curves γ_1 and γ_2 in $R = \{\mu > 0, \varepsilon < 0\}$ where the Filippov vector field $Z_{\mu,\varepsilon}$ in* (21)*, undergoes codimension-1 global bifurcations characterized by:*

- *If $(\varepsilon, \mu) \in \gamma_1$, then there exists a homoclinic connection of the fold F_+, $W^u_+(F_+) \equiv W^s_-(F_+)$, which is semistable and gives raise to a bifurcation of cycles called CC_2 in [KRG03].*
- *If $(\varepsilon, \mu) \in \gamma_2$, then there exists a heteroclinic connection between the folds F_+ and F_-, $W^u_+(F_+) \equiv W^s_+(F_-)$, which gives raise to a bifurcation of cycles called* buckling bifurcation *in [KRG03] and* switching sliding *in [dBBC$^+$08, KdBC$^+$06] .*

Proof. In R there exist a visible fold F_+ and an invisible fold F_- which have respectively three and one separatrices. We will see that the bifurcations that appear in this region correspond to two different separatrix connections, which give raise to cycles (see Section 4.2).

We describe the different behaviors changing parameters in anti-clockwise sense in R. We consider regions R_1, R_2 and R_3 as can be seen in Figure 21.

In the vertical line we have a Fold-Fold bifurcation (see Figure 20) in such a way that in R_1 it appears a small silding region between F_- and F_+.

The first bifurcation to occur (in the curve γ_1) is the connection between $W^u_+(F_+)$ and $W^s_-(F_+)$ (a pseudohomoclinic orbit), which gives rise to a cycle. To see that this cycle is semistable, we recall that for $(\varepsilon, \mu) = (0, 0)$ the Focus-Fold behaves as a reppeling focus and the same hapens for (ε, μ) small enough. Nevertheless, all the points in the interior of the cycle tend to Σ^s in finite time and so are globally attracted by the fold F_+. Therefore, the cycle is attracting from inside and reppeling from outside. This bifurcation, called CC_2 in [KRG03], is described in that paper (see also Section 4.2). In R_1 there is no cycle whereas when we cross γ_1, it appears a repellor periodic orbit and an attracting cycle, which is composed by a sliding segment, $W^u_+(F_+)$ and F_+. Both the cycle and the periodic orbit are persistent in all region R_2.

In γ_2 it occurs another separatrix connection: $W^u_+(F_+) \equiv W^s_+(F_-)$ (a heteroclinic orbit). This bifurcation is called *buckling bifurcation* in [KRG03] (and *switching-sliding* in [dBBC$^+$08, KdBC$^+$06]) and in both R_2 and R_3 the attracting cycle is persistent. Moreover in R_3, itdoes not intersect Σ^-. The repelling periodic orbit does not undergo any change and it persists also in R_3. Finally, in R_3, the attracting cycle shrinks when the parameters tend to $\{\mu = 0\}$ and it merges with the focus P as it tends to Σ, whereas the repellor periodic orbit becomes the periodic orbit which also exists for $\mu = 0$ and $\varepsilon < 0$. □

Let us observe that the description of the bifurcation diagram coincides either considering topological equivalence or Σ-equivalence.

11 Saddle-Fold singularity

One of the local bifurcations which present an unfolding with a rich behavior is the Saddle-Fold bifurcation. In this case the unfolding of the codimension-2 singularity has infinitely many codimension-1 bifurcation curves which accumulate. This singularity occurs when the vector field X has a saddle at a point $p \in \Sigma$ and the vector field Y has a fold or quadratic tangency at the same point. In order to have a generic codimension-2 singularity one has to impose non-degeneracy conditions: the eigenspaces of the saddle have to be transversal to Σ and the modulus of the eigenvalues of the saddle have to be different. The reason why this last condition is needed will be clear later when we unfold the singularity. Of course, this singularity can present different behavior depending on which eigenvalue has bigger modulus and depending whether p belongs to the boundary of two components of Σ^c or to the boundary between Σ^s and Σ^e (see Figure 22).

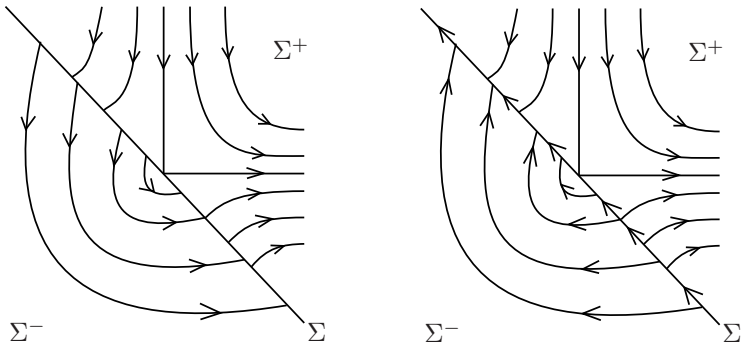

Figure 22: Two kinds of saddle fold singularities. In the first case, $p \in \partial\Sigma^c$ and in the second one $p \in \partial\Sigma^s \cap \partial\Sigma^e$.

In this section we study the case in which the positive eigenvalue has bigger modulus than the negative one and $p \in \partial\Sigma^c$, which is shown in the left picture of Figure 22. The other ones can be studied analogously.

For this case, we can choose $\Sigma = \{f(x,y) = x + y = 0\}$ to be allowed to take the normal form with the saddle with diagonal linear part. So, we can take

$$Z(x,y) = \begin{cases} X(x,y) = \begin{pmatrix} \lambda_1 x \\ -\lambda_2 y \end{pmatrix} & \text{if } x+y > 0 \\ Y(x,y) = \begin{pmatrix} 1+x-y \\ -1+x-y \end{pmatrix} & \text{if } x+y < 0 \end{cases}.$$

with $\lambda_1 > \lambda_2$. In fact, the higher order terms in X will not play any role in the discussion of the bifurcation diagram.

We have taken Y in such form since then, taking x as a local chart for Σ, the involution associated to the fold is given simply by $\varphi_Y(x) = -x$, which makes the explanation clearer. On the other hand, for the normal form we could have taken (for instance) $\lambda_1 = 2$ and $\lambda_2 = 1$, that would make the computations simpler. Nevertheless, for this singularity we will keep the constants λ_1 and λ_2 in order to make clear why the condition $\lambda_1 \neq \lambda_2$ is needed to have a codimension-2 singularity.

A generic unfolding of this singularity is given by

$$Z_{\mu,\varepsilon}(x,y) = \begin{cases} X_\mu(x,y) = \begin{pmatrix} \lambda_1 x - \mu \\ -\lambda_2 y + \mu \end{pmatrix} & \text{if } x+y > 0 \\ Y_\varepsilon(x,y) = \begin{pmatrix} 1+x-y-\varepsilon \\ -1+x-y-\varepsilon \end{pmatrix} & \text{if } x+y < 0 \end{cases} \tag{22}$$

in such a way that the saddle is given by $S = (\mu/\lambda_1, \mu/\lambda_2)$ and therefore it is visible for $\mu > 0$ and invisible for $\mu < 0$. On the other hand, when $\mu \neq 0$, the vector field X_μ has a fold located at $F_+ = (0,0)$. The fold of Y_ε is given by $F_- = (\varepsilon/2, -\varepsilon/2)$ in such a way that the parameter ε unfolds the other degeneracy: for $\mu \neq 0$, the two folds F_+ and F_- are different provided $\varepsilon \neq 0$.

The different singularities and regions present in Σ for $Z_{\mu,\varepsilon}$ in (22) are summarized in the following proposition, whose proof is straightforward and is omitted.

Proposition 11.1. *For (ε, μ) small enough, the Filippov vector field $Z_{\mu,\varepsilon}$ in (22) satisfies:*

- *For $\varepsilon \neq 0$, $F_- = (\varepsilon/2, -\varepsilon/2)$ is a fold of Y_ε and $F_+ = (0,0)$ is a fold of X_μ.*
- *Σ is divided as:*
  - *For $\varepsilon > 0$: $\Sigma^e = \{(x,y) \in \Sigma : 0 < x < \varepsilon/2\}$ and $\Sigma^c = \Sigma \setminus \overline{\Sigma^e}$.*
  - *For $\varepsilon = 0$: $\Sigma^c = \Sigma \setminus \{(0,0)\}$.*
  - *For $\varepsilon < 0$: $\Sigma^s = \{(x,y) \in \Sigma : \varepsilon/2 < x < 0\}$ and $\Sigma^c = \Sigma \setminus \overline{\Sigma^s}$.*
- *The sliding vector field Z_s defined in Σ^e for $\varepsilon > 0$ and in Σ^s for $\varepsilon < 0$, has a pseudonode $P \equiv P(\mu, \varepsilon)$, which is repelling for $\varepsilon > 0$ and attracting for $\varepsilon < 0$.*

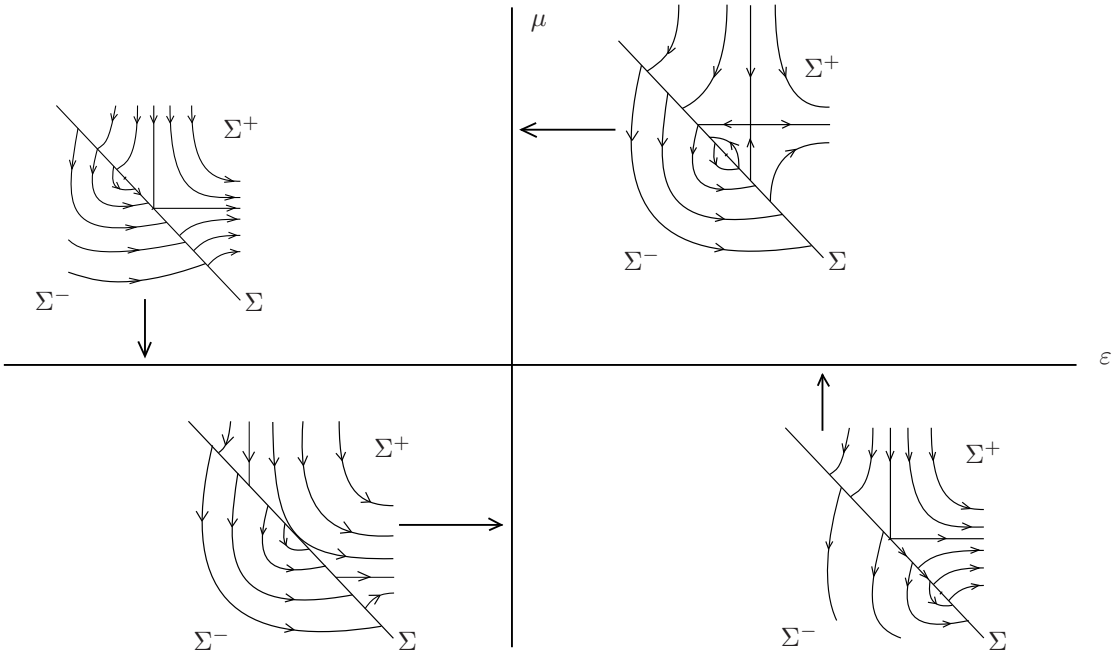

Figure 23: Codimension 1 local bifurcations which appear in a generic unfolding of the Saddle-Fold singularity.

11.1 Codimension-1 local bifurcations of the unfolding

First we study the existence of local bifurcations in the unfolding (see Figure 23). The line $\{\mu = 0\}$ in the parameter space corresponds to two different codimension-1 Boundary-Saddle bifurcations, for $\varepsilon > 0$ and $\varepsilon < 0$, since the saddle $S = (0, 0)$ belongs to Σ (see Section 4.1.2). In the case $\varepsilon > 0$, $p \in \partial\Sigma^e$ and then occurs the bifurcation BS_2 explained in [KRG03], whereas in $\varepsilon < 0$, since $p \in \partial\Sigma^s$, reversing time it takes place the bifurcation BS_2 in [KRG03].

The line $\{\varepsilon = 0\}$ also corresponds to two codimension-1 local bifurcations, since in this line both folds F_+ and F_- coincide in $(0, 0)$. Moreover, F_+ is invisible for $\mu > 0$ and invisible for $\mu < 0$. Therefore, for $\mu > 0$ and $\mu < 0$ occur respectively bifurcations VI_1 and II_2 explained in [KRG03] (see also 4.1.1).

The first one, as it was seen in that paper, gives birth to a periodic orbit in one side of the bifurcation parameter. To know in which side of the bifurcation point appears this periodic orbit, one has to study whether the return map associated to the Fold-Fold (see 4.1.1) is contracting or expanding. For this purpose, we have to compute the expansion of this return map. Straightforward computations give that, taking x as a local chart for Σ, the return map for $x < 0$ is given by

$$\varphi(x) = x - \frac{2}{3\mu}(\lambda_1 - \lambda_2)x^2 + \mathcal{O}(x^3).$$

Therefore, since in the generic case we have $\lambda_1 \neq \lambda_2$, we will have that the return map is attracting provided $\lambda_1 < \lambda_2$ and repelling provided $\lambda_1 > \lambda_2$. For the case $\lambda_1 = \lambda_2$, which would have more codimension, we would need to study the higher order terms of φ to detect the local behavior around the singularity. In the case we are studying, in which $\lambda_1 > \lambda_2$, the singularity acts as a repellor focus, and therefore the periodic orbit appears for $\varepsilon < 0$.

In these two lines in the (ε, μ) parameter space occur all the possible codimension-1 local bifurcations, either considering topological equivalence or Σ-equivalence, which exist in any generic unfolding of the singularity we are considering.

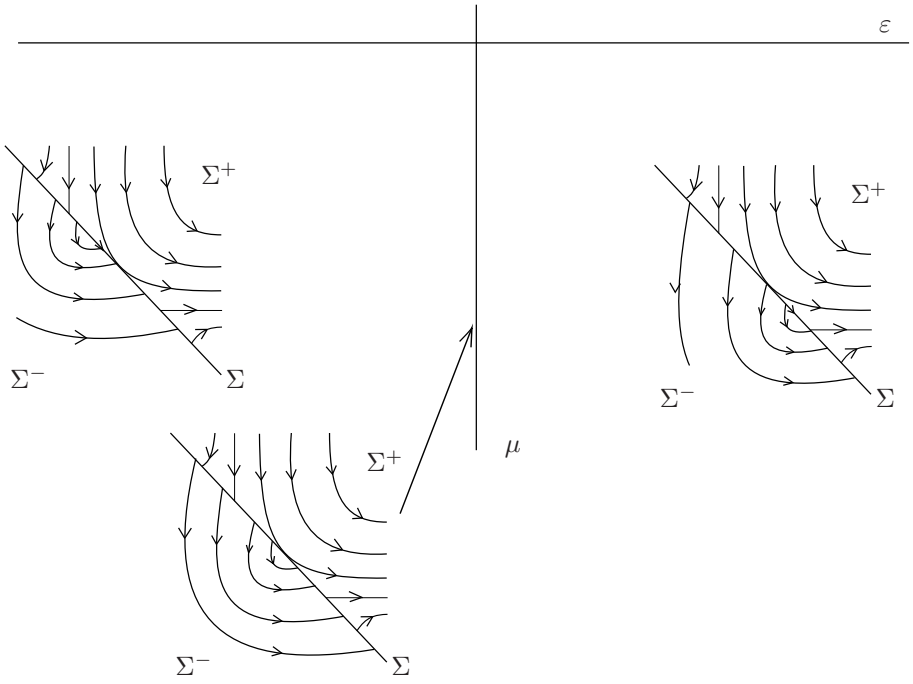

Figure 24: Different dynamics around the Saddle-Fold local bifurcation given by (22) for $\mu < 0$. Recall that for this range of parameters, the saddle is non-visible.

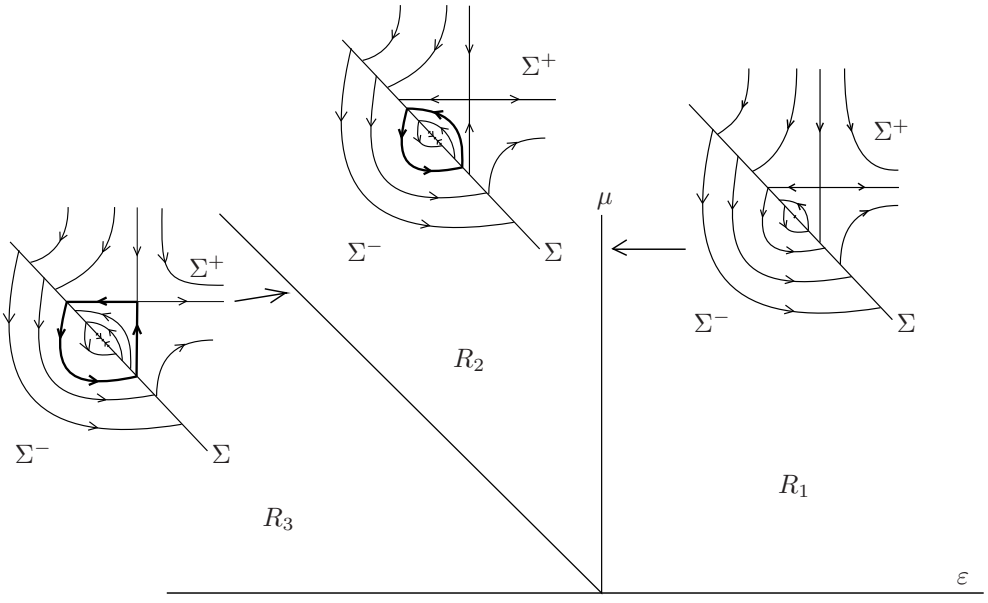

Figure 25: Different dynamics around the Saddle-Fold local bifurcation given by (22) for $\mu > 0$. Recall that for this range of parameters, the saddle is visible. In the curve γ it appears a homoclinic connection which is a global codimension-1 bifurcation.

11.2 Codimension-1 global bifurcations of the unfolding

Next step is to study the possible existence of codimension-1 global bifurcation curves in the unfolding $Z_{\mu,\varepsilon}$. We start with the region of the parameter space with $\mu < 0$. In that region, it is straightforward

to see that in the quadrants $\{\mu < 0, \varepsilon > 0\}$ and $\{\mu < 0, \varepsilon < 0\}$ any two vector fields with parameters belonging to the same quadrant are Σ-equivalent (and thus topologically equivalent) since they have the same dynamics (see Figure 24).

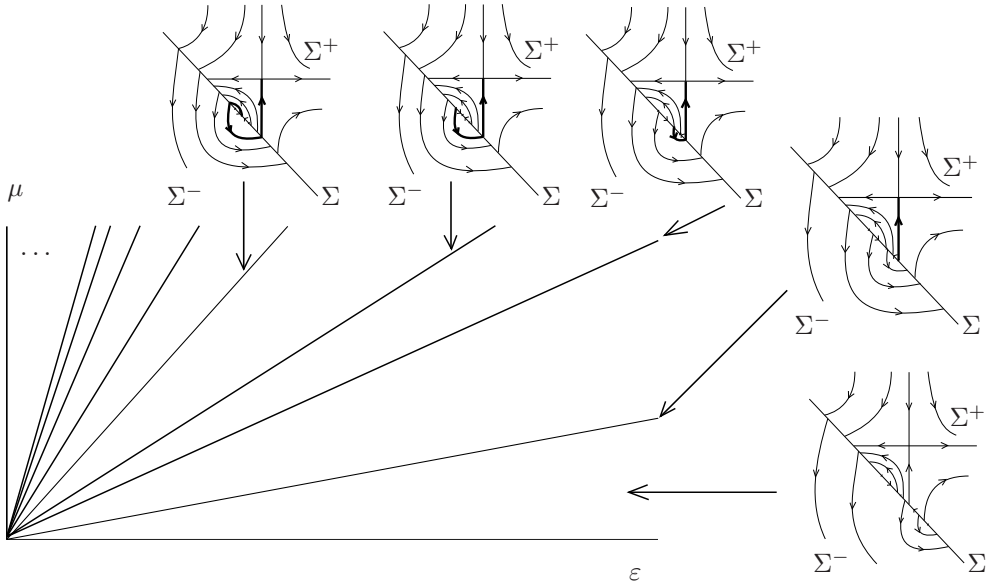

Figure 26: Different dynamics in Region R_1 (see Figure 25). In this region there exists infinitely many codimension-1 bifurcations curves which accumulate to the vertical axis $\{\varepsilon = 0\}$.

The region $\{\mu > 0\}$ has richer behavior since it presents infinitely many curves where global bifurcations occur. We study it in three steps. First, recall that in the vertical axis $\{\varepsilon = 0, \mu > 0\}$ occurs a Fold-Fold bifurcation which gives birth to a periodic orbit for $\varepsilon < 0$. This periodic orbit is repellor and is persistent in all region R_2 of the parameter space (see Figure 25). This periodic orbit breaks down when it hits the stable and unstable invariant manifolds of the saddle S becoming an homoclinic orbit. Using that the involution associated to the fold of Y_ε is $\varphi_{Y_\varepsilon}(x) = -x + \varepsilon$, it is straightforward to see that this global bifurcation occurs in the curve

$$\gamma = \left\{ \mu = -\frac{\lambda_1 \lambda_2}{\lambda_1 - \lambda_2} \varepsilon \right\} \tag{23}$$

(see Figure 25). As a second step, we study the possible global bifurcations in R_1 (see Figure 25). Recall that for parameters in R_1 the saddle S is visible and that in Σ we have a small segment of Σ^e and three singularities which, from left to right, are F_-, the pseudonode P and F_+.

Proposition 11.2. *Let us consider $(\varepsilon, \mu) \in R_1$ small enough. Then, there exists a family of curves $\{\eta_n\}_{n \geq 1}$ in the parameter space emanating from $(0,0)$ which accumulates to the vertical axis. Moreover, in these curves takes place the following separatrix connections:*

- *If $n = 4k + 1$ with $k \geq 0$: $W^s(S) \equiv W^u_+(F_-)$.*
- *If $n = 4k + 2$ with $k \geq 0$: $W^s(S) \equiv W^u_-(P)$.*
- *If $n = 4k + 3$ with $k \geq 0$: $W^s(S) \equiv W^u_-(F_+)$.*
- *If $n = 4k + 4$ with $k \geq 0$: $W^s(S) \equiv W^u_+(P)$.*

Proof. We describe the different behaviors anticlockwise. In the horizontal line of the parameter space (for $\varepsilon > 0$), the saddle S belongs to Σ and it is on the left of the fold F_-, in such a way that between

these two points there exists a small escaping region. Moving the parameters anti-clockwise, the saddle becomes visible in such a way that the departing point of $W^s(S)$ belongs to Σ^e (see Figure 26). Recall that Z_s has a pseudonode P which can be seen that is located on the left of the departing point of the unstable manifold. As the parameters change, the folds F_+ and F_- become closer and therefore Σ^e shrinks. The first bifurcation to occur, in η_1, is a separatrix connection between the saddle S and F_-, that is $W^s(S) \equiv W^u_+(F_-)$. After this curve, $W^s(S)$ crosses Σ^c and then hits Σ^e from Σ^-. Thus, the next bifurcations to occur, in η_2 is a separatrix connection between the saddle S and the pseudonode P: $W^s(S) \equiv W^u_-(P)$, and in the following curve η_3 a separatrix connection between the saddle and F_+: $W^s(S) \equiv W^u_-(F_+)$. After this bifurcation, $W^s(S)$ crosses twice Σ^c. Therefore, varying the parameters we encounter two more consecutive curves η_4 and η_5 that correspond respectively $W^s(S) \equiv W^u_+(P)$ and $W^s(S) \equiv W^u_+(F_-)$. This procedure can be repeated iteratively in such a way that we obtain a sequence of curves which correspond to global bifurcations given by separatrix connections which make more and more turns around the folds as we change the parameters: $W^s(S) \equiv W^u_+(F_-)$, $W^s(S) \equiv W^u_-(P)$, $W^s(S) \equiv W^u_-(F_+)$, $W^s(S) \equiv W^u_+(P)$, $W^s(S) \equiv W^u_+(F_-)$, ... This infinitely many curves accumulate to the vertical axis where both folds collapse to a single point and therefore Σ^e disappears. □

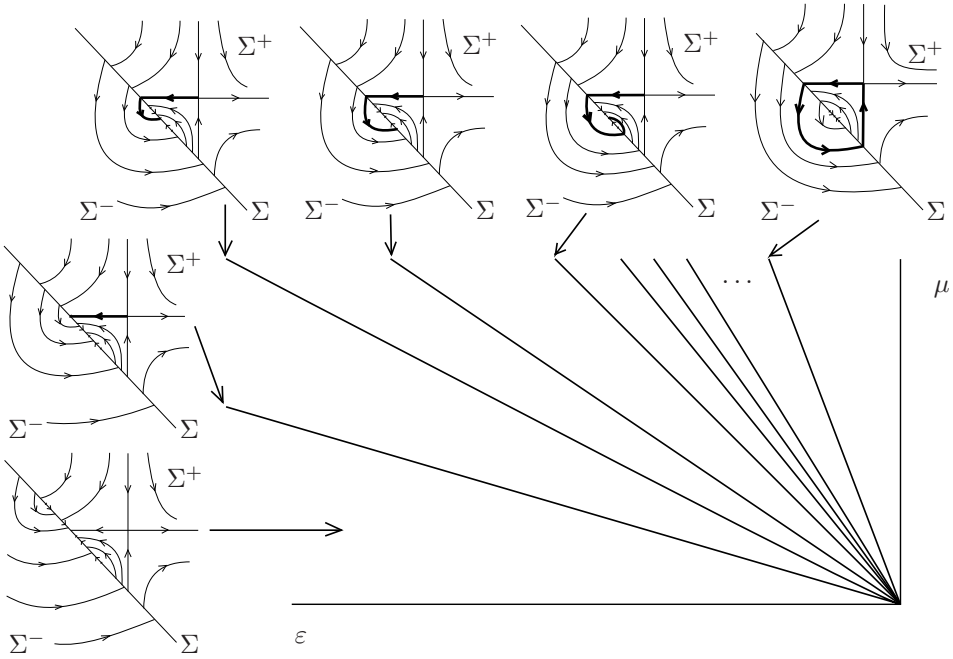

Figure 27: Different dynamics in Region R_3 (see Figure 25). In this region there exists infinitely many codimension-1 bifurcations curves which accumulate to the curve γ.

Finally, we study the global bifurcations in region R_3. In this region we find a similar structure as the one in region R_1, but in this case the connections are between the unstable manifold of the saddle and the unstable pseudopseparatrices of F_+, P and F_- (see Figure 27). The other main difference with respect to the region R_1 is that the bifurcation curves do not accumulate to the vertical axis when both folds coincide in the same point and the sliding region collapses but they accumulate to the curve γ, in (23), in which exists the homoclinic orbit of the saddle, that we have found before.

12 Fold-cusp singularity

In this section we unfold the Fold-Cusp singularity. This singularity occurs when at the same point $p \in \Sigma = \{f(x, y) = 0\}$ X has a cubic tangency or cusp ($Xf(p) = 0$ and $X^2 f(p) = 0$) whereas Y has a

quadratic tangency or fold ($Yf(p) = 0$). The most important feature of this singularity, as it happened in the Saddle-Fold singularity studied in Section 11, is that its generic unfolding presents infinitely many codimension-1 global bifurcation branches related to separatrix connections and bifurcations of periodic orbits and cycles. In order to have a generic codimension-2 singularity, one has to impose the non-degeneracy conditions $X^3f(p) \neq 0$ and $Y^2f(p) \neq 0$. Depending on the sign of these two constants and depending whether $X(p)$ and $Y(p)$, which are parallel, point towards the same or opposite direction, the singularity presents different behavior. In this section we focus our attention on the case $X^3f(p) < 0$, $Y^2f(p) > 0$ (invisible tangency) and $X(p)$ and $Y(p)$ pointing oppositely (see Figure 28). All the other cases can be studied analogously. In this case we take $f(x, y) = y$, $p = (0, 0)$ and

$$Z(x,y) = \begin{cases} X(x,y) = \begin{pmatrix} -1 \\ -x^2 \end{pmatrix} & \text{if } y > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ x \end{pmatrix} & \text{if } y < 0 \end{cases}.$$

whose phase portrait can be seen in Figure 28. We have chosen Y in such form since then the involution associated to the fold is given in its normal form by $\varphi_Y(x) = -x$. It is straightforward to see that for Z, $\Sigma^c = \{(x, y) \in \Sigma : x < 0\}$ and $\Sigma^s = \{(x, y) \in \Sigma : x > 0\}$. In Σ^s we can define the sliding vector field Z_s which satisfies $Z_s(0) < 0$.

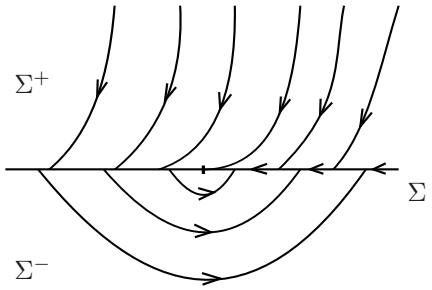

Figure 28: The Cusp-Fold singularity satisfying $X^3f(p) < 0$ and $Y^2f(p) > 0$.

A generic unfolding of this singularity can be given by

$$Z_{\mu,\varepsilon}(x,y) = \begin{cases} X_\varepsilon(x,y) = \begin{pmatrix} -1 \\ -x^2 + \varepsilon \end{pmatrix} & \text{if } y > 0 \\ Y_\mu(x,y) = \begin{pmatrix} 1 \\ x - \mu \end{pmatrix} & \text{if } y < 0. \end{cases} \tag{24}$$

in such a way that ε unfolds the cusp singularity, as it is done in [KRG03], where the cusp singularity is called double tangency. On the other hand, the fold of Y_μ is given by $F_- = (\mu, 0)$ and therefore, when $\varepsilon = 0$, μ gives the distance between the cusp and the fold F_-.

When $\varepsilon \neq 0$ the cusp point disappears in such a way that X_ε is transversal to Σ for $\varepsilon < 0$ and for $\varepsilon > 0$ an invisible fold $F_+^1 = (-\sqrt{\varepsilon}, 0)$ and a visible one $F_+^2 = (\sqrt{\varepsilon}, 0)$ appear. Next proposition, whose proof is straightforward, show how the regions Σ^e, Σ^c and Σ^s for $Z_{\mu,\varepsilon}$ change drastically depending on the values of the parameters μ and ε.

Proposition 12.1. *For μ and ε small enough, the Filippov vector field in* (24) *satisfies the following statements:*

- *For $\varepsilon < 0$, it has the fold $F_- = (\mu, 0)$ and for $\varepsilon > 0$ it has the folds $F_- = (\mu, 0)$, $F_+^1 = (-\sqrt{\varepsilon}, 0)$ and $F_+^2 = (\sqrt{\varepsilon}, 0)$.*
- *The escaping and the sliding regions are given by,*

- *In* $R_1 = \{(\varepsilon,\mu) : \varepsilon < 0\}$*, then* $\Sigma^s = \{(x,y) \in \Sigma : x > \mu\}$ *and* Σ^e *does not exist.*
- *In* $R_2 = \{(\varepsilon,\mu) : \varepsilon > 0, \mu > \sqrt{\varepsilon}\}$*, then* $\Sigma^s = \{(x,y) \in \Sigma : x > \mu\}$ *and* $\Sigma^e = \{(x,y) \in \Sigma : -\sqrt{\varepsilon} < x < \sqrt{\varepsilon}\}$*.*
- *In* $R_3 = \{(\varepsilon,\mu) : \varepsilon < 0, \sqrt{\varepsilon} < \mu < \sqrt{\varepsilon}\}$*, then* $\Sigma^s = \{(x,y) \in \Sigma : x > \sqrt{\varepsilon}\}$ *and* $\Sigma^e = \{(x,y) \in \Sigma : -\sqrt{\varepsilon} < x < \mu\}$*.*
- *In* $R_4 = \{(\varepsilon,\mu) : \varepsilon < 0, \mu < -\sqrt{\varepsilon}\}$*, then* $\Sigma^s = \{(x,y) \in \Sigma : \mu < x < -\sqrt{\varepsilon}\} \cup \{(x,y) \in \Sigma : x > \varepsilon\}$ *and* Σ^e *does not exist.*

- *For any* $(\varepsilon,\mu) \in R_1 \cup R_2 \cup R_3 \cup R_4$*, the sliding vector field defined in* $\Sigma^s \cup \Sigma^e$*, is given by*

$$Z_s(x) = \frac{-x + x^2 + \mu - \varepsilon}{x^2 + x - \mu - \varepsilon} \tag{25}$$

and it has a critical point given by

$$P = \left(\frac{1 - \sqrt{1 - 4(\mu - \varepsilon)}}{2}, 0 \right). \tag{26}$$

- *If* $(\varepsilon,\mu) \in R_1 \cup R_2 \cup R_4$*,* $P \in \Sigma^s$ *and it is an attractor pseudonode. Otherwise, if* $(\mu,\varepsilon) \in R_3$*,* $p \in \Sigma^e$ *and it is a repellor pseudonode.*

- *Therefore the singularities in* Σ *are ordered as*
  - *If* $(\varepsilon,\mu) \in R_1$*:* $F_- < P$*.*
  - *If* $(\varepsilon,\mu) \in R_2$*:* $F_+^1 < F_+^2 < F_- < P$*.*
  - *If* $(\varepsilon,\mu) \in R_3$*:* $F_+^1 < P < F_- < F_+^2$*.*
  - *If* $(\varepsilon,\mu) \in R_4$*:* $F_- < P < F_+^1 < F_+^2$*.*

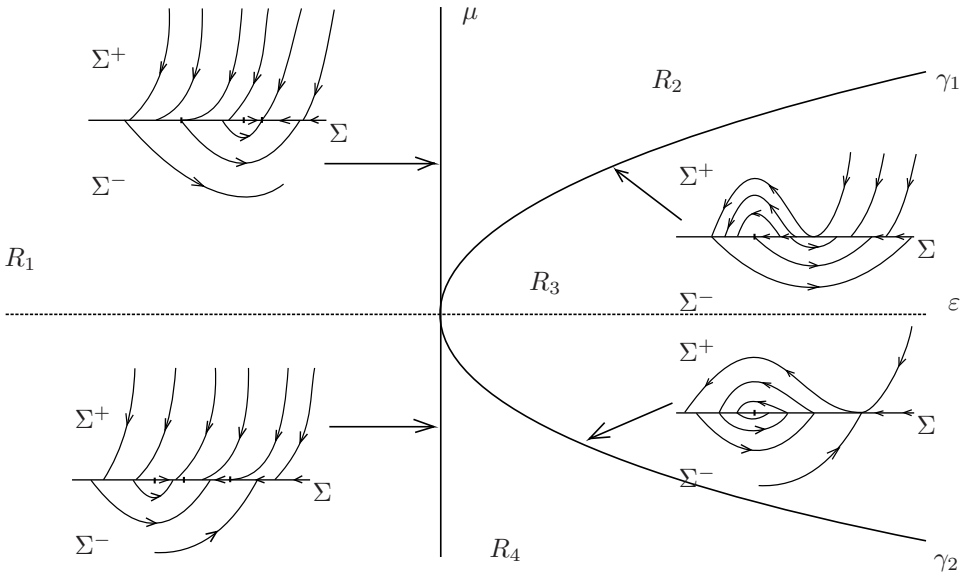

Figure 29: Codimension 1 local bifurcations which appear in the unfolding of the Cusp-Fold singularity given by (24).

12.1 Codimension-1 local bifurcations of the unfolding

First, we study the existence of codimension-1 local bifurcations (see Figure 29). All the local bifurcations of the unfolding take place in the boundaries between the regions R_i defined in Proposition 12.1.

The line $\{\varepsilon = 0\}$ in the parameter space corresponds to two different cusp bifurcations. For $\mu > 0$, the cusp point belongs to $\overline{\Sigma^c}$ and then in this curve takes place the bifurcation DT_1 in [KRG03] whereas for $\mu < 0$ it belongs to $\overline{\Sigma^s}$ and then in this curve takes place the bifurcation DT_2 in [KRG03].

On the other hand, for either $\mu > 0$ or $\mu < 0$, the pseudonode P of Z_s in (26) which existed in R_1, R_2, R_3 and R_4, also exists and lies on the left of the cusp for $\mu < 0$.

On the other hand, in the curves

$$\gamma_1 = \{\mu = \sqrt{\varepsilon}, \varepsilon > 0\} \quad \text{and} \quad \gamma_2 = \{\mu = -\sqrt{\varepsilon}, \varepsilon > 0\} \tag{27}$$

take place the Fold-Fold bifurcations VI_2 and II_2 studied in [KRG03] respectively, since in the first curve we have $F_- = F_+^2$ and in the second one $F_- = F_+^1$.

In γ_1, the two folds F_- and F_+^2 merge with the pseudonode P in $(\mu, 0)$. Furthermore, in γ_1 the extended sliding vector field Z_s in (25) has a removable singularity in this point. In fact, it is equivalent to

$$Z_s(x) = \frac{-1 + \sqrt{\varepsilon} - x}{1 + \sqrt{\varepsilon} + x}$$

which is regular at the Fold-Fold point.

On the other hand, in γ_1, there exist infinitely many cycles which are given by a segment of Σ^s, the Fold-Fold point, a segment of Σ^e and a regular orbit. There exists also another cycle $\Gamma_{\mu,\varepsilon}$, which is given by a segment of Σ^s, the Fold-Fold point and its unique unstable separatrix. This last one, is the only one which persists for parameters below this curve as an attractor cycle coexisting with the repellor node P. For parameters above the curve, all the cycles break down and then the pseudonode P becomes a global attractor.

Finally, we analyze the Fold-Fold bifurcation $F_- = F_+^1$ that takes place in γ_2. Since both F_- and F_+^1 are invisible folds, we can consider the return map to study the dynamics around it (see Section 4.1.1).

As a first step, we consider the involutions associated to both folds. It is straightforward to see that the one associated to F_- is given by

$$\varphi_{Y_\mu}(x) = -x + 2\mu. \tag{28}$$

The involution associated to the fold F_+^1 of X_ε is well defined between the fold F_+^2 and the point

$$Q = (-2\sqrt{\varepsilon}, 0) \tag{29}$$

which is the arrival of $W_+^u(F_+^2)$ in Σ^c. This involution φ_X can be also computed explicitly integrating the differential equation and it is given by

$$\varphi_{X_\varepsilon}(x) = x - \frac{3x + \sqrt{12\varepsilon - 3x^2}}{2} = -\sqrt{\varepsilon} - \left(x + \sqrt{\varepsilon}\right) + \frac{1}{3\sqrt{\varepsilon}}\left(x + \sqrt{\varepsilon}\right)^2 + \mathcal{O}_3\left(x + \sqrt{\varepsilon}\right) \tag{30}$$

and therefore, since $\mu = -\sqrt{\varepsilon}$ in γ_2, it can be seen that for $x < -\sqrt{\varepsilon}$,

$$\varphi(x) = \varphi_{X_\varepsilon} \circ \varphi_{Y_\mu}(x) = -\sqrt{\varepsilon} + \left(x + \sqrt{\varepsilon}\right) + \frac{1}{3\sqrt{\varepsilon}}\left(x + \sqrt{\varepsilon}\right)^2 + \mathcal{O}_3\left(x + \sqrt{\varepsilon}\right)$$

and thus it is contracting. This fact combined with the appearance of a small escaping segment for parameters in R_3, as it was seen in Section 4.1.1, implies that, coexisting with the repellor pseudonode $P \in \Sigma^e$ (see Proposition 12.1), appears a small attractor periodic orbit. On the other hand, in region R_4 only appears a small sliding segment which contains the pseudonode P, that is a global attractor.

As we will see in Section 12.2, when the parameters move in R_3, this periodic orbit undergoes a crossing-sliding bifurcation and becomes the cycle $\Gamma_{\mu,\varepsilon}$ born in γ_1. For this reason, we will also denote this periodic orbit by $\Gamma_{\mu,\varepsilon}$

In these curves in the (ε, μ) parameter space occur all the possible codimension-1 local bifurcations, either considering topological equivalence or Σ-equivalence, which exist in any generic unfolding of the singularity we are considering.

12.2 Codimension-1 global bifurcations of the unfolding

Next step is to study the possible existence of codimension-1 global bifurcation curves in the unfolding $Z_{\mu,\varepsilon}$. We study them in the four regions defined in Proposition 12.1 (see also Figure 29).

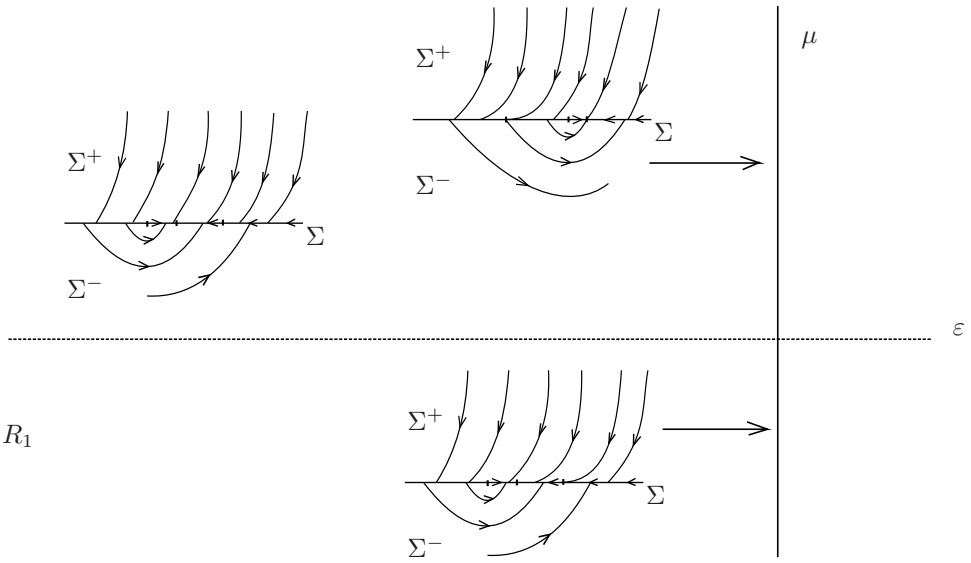

Figure 30: Different dynamics of the unfolding (24) for parameters $(\varepsilon, \mu) \in R_1$ defined in Proposition 12.1. In that region do not take place any codimension-1 global bifurcation.

We start in region R_1. In that region, it is straightforward to see that any two vector fields with parameters belonging to the same quadrant are Σ-equivalent (and thus topologically equivalent) since they have the same dynamics (see Figure 30).

To describe the dynamics in R_2 we move the parameters clockwise. Recall that, by Proposition 12.1, the four singularities in Σ are ordered as $F_+^1 < F_+^2 < F_- < P$ (see Figure 31). When the parameters cross the vertical line, the folds $F_+^1 = (-\sqrt{\varepsilon}, 0)$ and $F_+^2 = (\sqrt{\varepsilon}, 0)$ and a small escaping region between them appear (see Proposition 12.1). Moreover, $W_-^u(F_+^2)$ has an arrival point in Σ^s which lies on the right of the pseudonode P.

When we move the parameters clockwisely, this arrival point moves to the left until, in a codimension-1 bifurcation curve, it coincides with P giving birth to a separatrix connection between F_+^2 and P given by $W_-^u(F_+^2) \equiv W_-^s(P)$. The bifurcation curve is given by the equation $\varphi_{Y_\mu}(F_+^2) = P$ where φ_{Y_μ} is the involution given in (28). Expanding asimptotically, one obtains that this curve is given by

$$\mu = \sqrt{\varepsilon} + 8\varepsilon + \mathcal{O}(\varepsilon^{3/2})$$

for $\varepsilon > 0$. This global bifurcation is the only one in R_2. Below this curve, in R_2, the arrival points of the unstable separatrices $W_+^u(F_+^2)$ and $W_-^u(F_+^1)$ lie always on the right of P, so no other separatrix connections are possible in this region. Finally, the folds F_+^2 and F_- become closer until they collide in γ_1 (see (27)).

Before studying R_3, we consider R_4 since it is simpler. In region R_4 we will see that all the codimension-1 global bifurcations are related to separatrix connections. As it happened in the Saddle-Fold bifurcation explained in Section 11, we will obtain an infinite sequence of codimension-1 bifurcation curves associated to separatrix connections which accumulate to the Fold-Fold bifurcation curve γ_2 (see Figure 32).

Proposition 12.2. *Let us consider $(\varepsilon, \mu) \in R_4$ small enough. Then, there exists a family of curves $\{\eta_n\}_{n\geq 1}$ in the parameter space emanating from $(0,0)$, which accumulate to γ_2 (see (27)). Moreover, in these curves take place the following separatrix connections:*

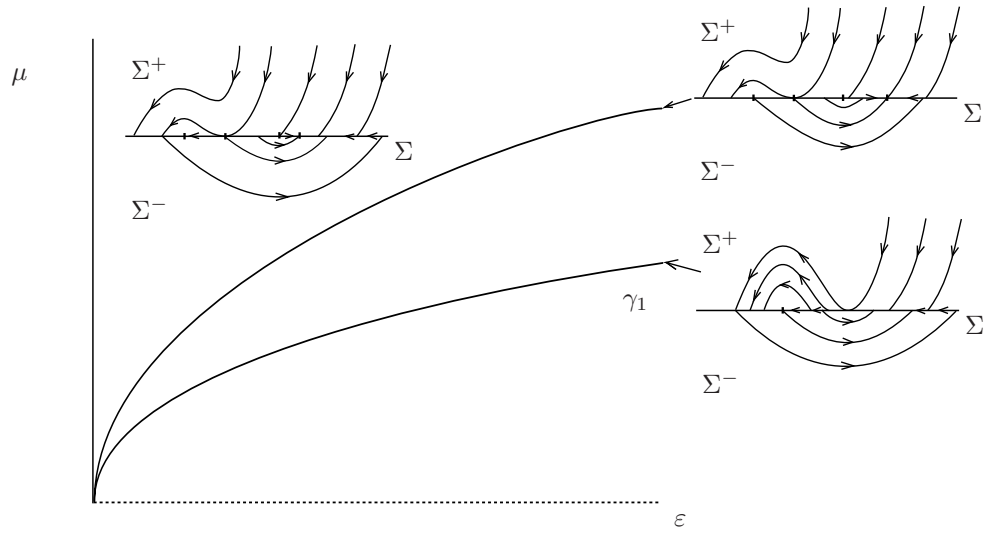

Figure 31: Different dynamics of the unfolding (24) for parameters $(\varepsilon, \mu) \in R_2$ defined in Proposition 12.1. In that region only takes place a codimension-1 global bifurcation given by a separatrix connection.

- *If* $n = 4k + 1$ *with* $k \geq 0$*:* $W^u_+(F^2_+) \equiv W^s_+(P)$.
- *If* $n = 4k + 2$ *with* $k \geq 0$*:* $W^u_+(F^2_+) \equiv W^s_+(F_-)$.
- *If* $n = 4k + 3$ *with* $k \geq 0$*:*$W^u_+(F^2_+) \equiv W^s_-(P)$.
- *If* $n = 4k + 4$ *with* $k \geq 0$*:* $W^u_+(F^2_+) = W^s_-(F^1_+)$.

Proof. In order to analyze $\{\eta_n\}$, we describe the different dynamics anticlockwisely in R_4. Recall that in the vertical axis $\varepsilon = 0$ there exists a cusp bifurcation which gives birth to the folds $F^1_+ = (-\sqrt{\varepsilon}, 0)$ and $F^2_+ = (\sqrt{\varepsilon}, 0)$ for $\varepsilon > 0$ (see Figure 32). Therefore, for parameters belonging to R_4, the four singularities which exist in Σ are ordered as: $F_- < P < F^1_+ < F^2_+$ (see Proposition 12.1). Recall, moreover, that the point Q which is the arrival point of $W^u_+(F^2_+)$ in Σ is given by (29) and therefore after crossing $\{\varepsilon = 0\}$ satisfies $P < Q < F^1_+$. Then, the first bifurcation to occur is a separatrix connection between F^2_+ and P given by $W^u_+(F^2_+) \equiv W^s_+(P)$ in η_1 whose equation is given by $P = Q$.

Then, as the parameters change the fold F_- become closer to F^1_+, in such a way that takes place a connection $W^u_+(F^2_+) \equiv W^s_+(F_-)$ in η_2 whose equation is given by $Q = F_-$. Then, $W^u_+(F^2_+)$ hits Σ^c, namely $Q \in \Sigma^c$, and then it arrives to Σ^s through Σ^-, in such a way that the next global bifurcation is given by the connection $W^u_+(F^2_+) \equiv W^s_-(P)$ in η_3 whose equation is given by $\varphi_Y(Q) = P$.

The last possible separatrix connection is when $W^u_+(F^2_+) = W^s_-(F^1_+)$, which takes place in η_4, whose equation is given by $\varphi_Y(Q) = F^1_+$.

As the parameters change anticlockwisely, we encounter the sequence of global bifurcations given by separatrix connections which make more and more turns around Σ^s that accumulate to γ_2 where F_-, F^1_+ and P collapse and one of the components of Σ^s disappear. □

The existence of global bifurcations for parameters in region R_3, is summarized in next proposition.

Proposition 12.3. *Let us consider* $(\varepsilon, \mu) \in R_3$ *small enough. Then,*

- *There exists a curve* ν_∞ *arising from* $(0, 0)$*, in which takes place a codimension-1 global bifurcation in which the periodic orbit* $\Gamma_{\mu,\varepsilon}$ *becomes the pseudohomoclinic connection* $W^u_+(F^2_+) \equiv W^u_-(F^2_+)$.
- *There exists a sequence of curves* $\{\nu_n\}$ *in the parameter space arising from* $(0, 0)$*, which accumulate to* ν_∞*. Moreover, in these curves take place the following separatrix connections:*

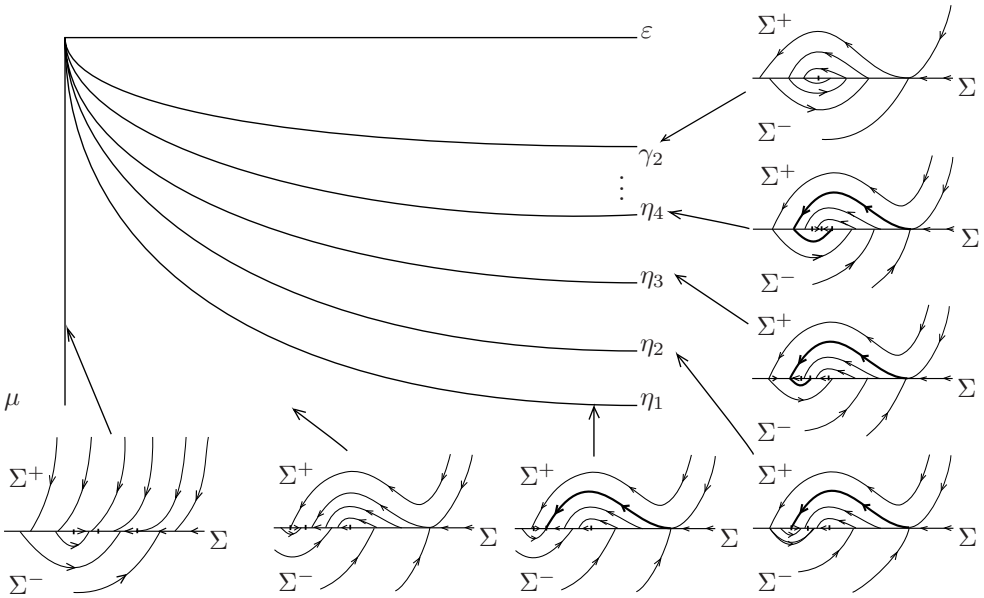

Figure 32: Different dynamics of the unfolding (24) for parameters $(\varepsilon, \mu) \in R_4$ defined in Proposition 12.1. In that region, as is stated in Proposition 12.2, take place an infinite number of codimension-1 global bifurcations in the curves $\{\eta_n\}_{n\geq 1}$ given by separatrix connections.

- *If* $n = 4k+1$ *with* ≥ 0*:* $W^s_-(F^2_+) \equiv W^u_-(P)$.
- *If* $n = 4k+2$ *with* ≥ 0*:* $W^s_-(F^2_+) \equiv W^u_-(F^1_+)$.
- *If* $n = 4k+3$ *with* ≥ 0*:* $W^s_-(F^2_+) \equiv W^u_+(P)$.
- *If* $n = 4k+4$ *with* ≥ 0*:* $W^s_-(F^2_+) \equiv W^u_+(F_-)$.

Proof. First, we consider parameters close to the curve γ_2 and we vary them anticlockwisely. Recall that, as we have explained in Proposition 12.1, when the parameters cross γ_2, it appears a small escaping region which contains P, in such a way that the singularities in Σ are ordered as $F^1_+ < P < F_- < F^2_+$. On the other hand, it also appears the periodic orbit $\Gamma_{\mu,\varepsilon}$ (see Section 4.1). Considering the involutions (28) and (30), one can compute the intersecting points between $\Gamma_{\mu,\varepsilon}$ and Σ^c which are given by $\Gamma^{\pm}_{\mu,\varepsilon} = (x_\pm, 0)$ with

$$x_\pm = \mu \pm \sqrt{3(\varepsilon - \mu^2)}.$$

Let us observe, that they satisfy $\Gamma^-_{\mu,\varepsilon} < F^1_+ < P < F_- < \Gamma^+_{\mu,\varepsilon}$. Furthermore, as the parameters change anticlockwisely, the periodic orbit becomes bigger until it hits F^2_+, giving rise to a pseudohomoclinic connection $W^u_+(F^2_+) \equiv W^u_-(F^2_+)$ in such a way that the periodic orbit becomes a cycle. This bifurcation is usually called crossing-sliding bifurcation (see Section 4.2), and takes place in the curve ν_∞ where holds $F^2_+ = \Gamma^+_{\mu,\varepsilon}$, namely $x_+ = \sqrt{\varepsilon}$. It can be seen that $\nu_\infty = \{\mu = -\sqrt{\varepsilon}/2\}$.

We study the rest of region R_3 changing the parameters clockwisely from γ_1. As we have explained in Section 12.1, below the curve γ_1 only persists the attractor cycle $\Gamma_{\mu,\varepsilon}$ (see Section) which is given by a sliding segment, the fold F^2_+ and its unique unstable separatrix $W^u_+(F^2_+)$. An easy computation shows that $\Gamma_{\mu,\varepsilon}$ exists until the parameters reach the crossing-sliding bifurcation curves ν_∞ (see Figure 33), when it becomes a pseudohomoclinic connection to F^2_+ and afterwards a periodic orbit which do not hit Σ^s.

On the other hand, since in region R_3 the four singularities in Σ are ordered as $F^1_+ < P < F_- < F^2_+$, for parameters below γ_1 all the unstable separatrices of F^1_+, P and F_- have an arrival point in Σ^s. The first bifurcation to occur is a separatrix connection $W^u_-(P) \equiv W^s_-(F^2_+)$ in the curve ν_1 given by

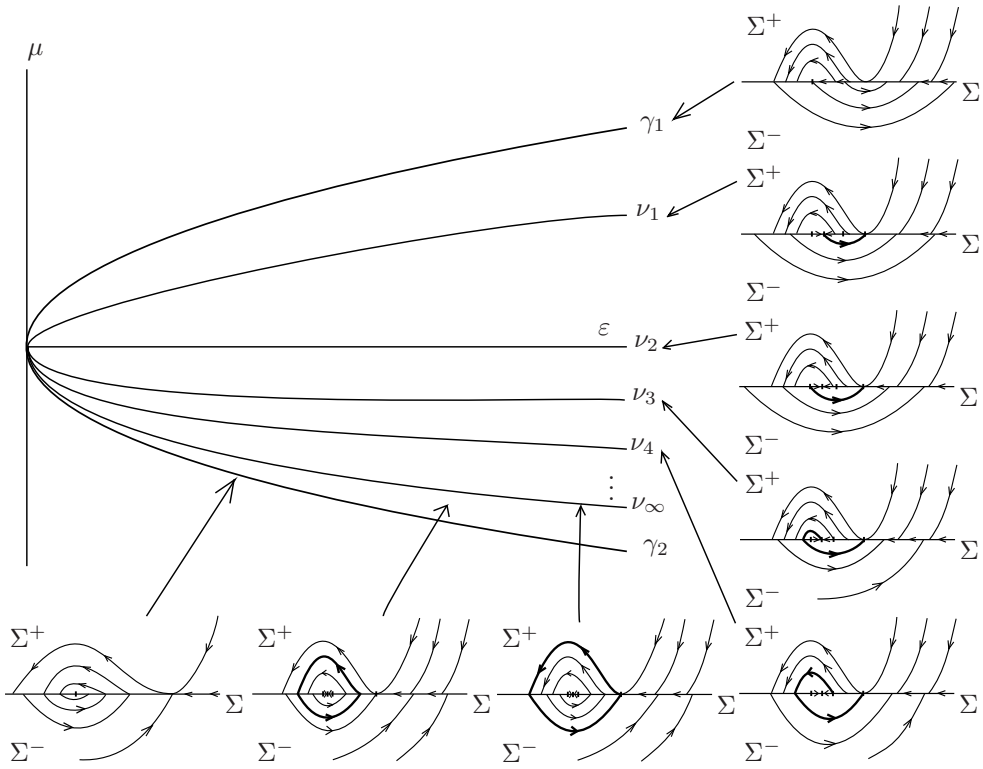

Figure 33: Different dynamics of the unfolding (24) for parameters $(\varepsilon, \mu) \in R_3$ defined in Proposition 12.1. In that region, as is stated in Proposition 12.3, take place an infinite number of codimension-1 global bifurcations in the curves $\{\nu_n\}_{n\geq 1}$ given by separatrix connections.

$\varphi_{Y_\mu}(P) = F_+^2$. Therefore, it can be seen that ν_1 has the following asymptotic expansion

$$\mu = \sqrt{\varepsilon} - 2\varepsilon^{3/2} + \mathcal{O}\left(\varepsilon^2\right).$$

After that, we encounter the connection $W_-^u(F_+^1) \equiv W_-^s(F_+^2)$ in the curve ν_2 given by $\varphi_{Y_\mu}(F_+^1) = F_+^2$, and therefore $\nu_2 = \{\mu = 0, \varepsilon > 0\}$. Now, the point $\varphi_{Y_\mu}(F_+^2)$ lies in Σ^c, and therefore next bifurcation occurs when $\varphi_{X_\varepsilon} \circ \varphi_{Y_\mu}(F_+^2) = P$. In this curve ν_3 takes place $W_-^s(F_+^2) \equiv W_+^u(P)$, and has asymptotic expansion

$$\mu = -\frac{2}{7}\sqrt{\varepsilon} + \frac{75}{343}\varepsilon + \mathcal{O}\left(\varepsilon^{3/2}\right).$$

The last possible separatrix connection is $W_-^s(F_+^2) \equiv W_+^u(F_-)$. It takes place in ν_4 and happens when $\varphi_{X_\varepsilon} \circ \varphi_{Y_\mu}(F_+^2) = F_-$. Using this equation, one can obtain the following asymptotic expansion for ν_4

$$\mu = -\frac{2}{7}\sqrt{\varepsilon} + \mathcal{O}\left(\varepsilon^{3/2}\right).$$

Changing the parameters clockwisely, there exist, as it happened in region R_4 an infinite sequence of codimension-1 global bifurcations curves given by separatrix connections between $W_-^s(F_+^2)$ and consecutively $W_-^u(P)$, $W_-^u(F_+^1)$, $W_+^u(P)$ and $W_+^u(F_-)$, which accumulate to the crossing sliding curve ν_∞. □

We want to point out that the description of the unfolding is exactly the same either we consider topological equivalence or Σ-equivalence.

13 Boundary-Saddle-Node singularity

A Filippov vector field $Z = (X, Y)$ has a Boundary-Saddle-Node local bifurcation when X has a Saddle-Node singularity at $p \in \Sigma$ whereas Y is transversal to Σ at that point. In order to have a generic codimension-2 singularity one has to impose non-degeneracy conditions. First of all, the eigenspaces of $DX(p)$ have to be transversal to Σ. On the other hand, as $p \in \partial\Sigma^e \cap \partial\Sigma^c$ or $p \in \partial\Sigma^s \cap \partial\Sigma^c$ (depending whether Y points towards Σ or away from Σ), there exists a sliding vector field defined on one side of p. Taking x as a local chart of Σ, it is of the form

$$Z_s(x) = \alpha x + \mathcal{O}(x^2).$$

Therefore, as it happened in the Boundary-Saddle, Boundary-Node and Boundary-Focus bifurcations explained in Sections 4.1.3, 4.1.2 and 4.1.4 respectively, one has to impose that $\alpha \neq 0$. In the Saddle-Node case, this condition is equivalent to impose that $Y(p)$ and the eigenspace associated to the non-zero eigenvalue of the Saddle-Node are not collinear.

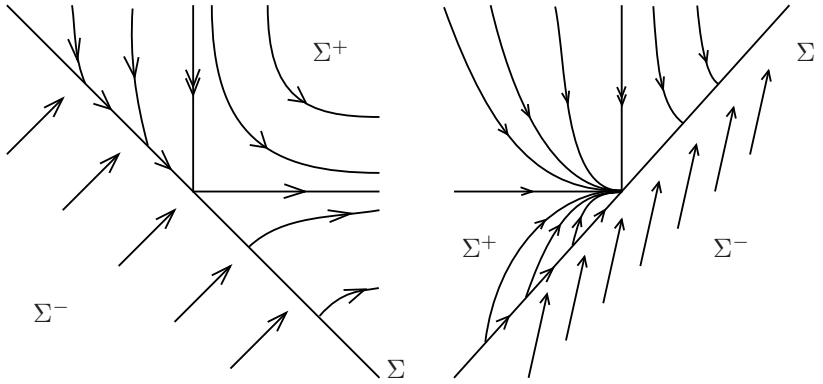

Figure 34: To kinds of Boundary-Saddle-Node singularities in which Y points towards Σ and $\alpha < 0$. In the left one it is visible the "saddle part" of the central manifold and on the right one, the "node part".

Of course this singularity can present different behavior depending on several factors. First of all, it depends whether $p \in \partial\Sigma^e \cap \partial\Sigma^c$ or $p \in \partial\Sigma^s \cap \partial\Sigma^c$ and also on the signs of α and the non-zero eigenvalue of the Saddle-Node. Finally, we can obtain different behaviors depending on which half of the eigenspace of 0 eigenvalue is visible (see Figure 34).

In this section, we focus our attention on the case $p \in \partial\Sigma^s \cap \partial\Sigma^c$, such that the non-zero eigenvalue of the Saddle-Node is negative, $\alpha < 0$ and that the visible part of the eigenspace of the 0 eigenvalue is the "saddle one". All the other cases present similar behavior and can be studied analogously.

We take $p = (0, 0)$ and $\Sigma = \{f(x, y) = x + y = 0\}$ to be allowed to take the normal form with the Saddle-Node diagonalized. Thus,

$$Z(x,y) = \begin{cases} X(x,y) = \begin{pmatrix} x^2 \\ -y \end{pmatrix} & \text{if } x + y > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{if } x + y < 0 \end{cases}.$$

whose phase portrait can be seen in the left picture of Figure 34. It is straightforward to see that for Z, $\Sigma^s = \{(x, y) \in \Sigma : x < 0\}$ and $\Sigma^c = \{(x, y) \in \Sigma : x > 0\}$. In Σ^s we can define the sliding vector field Z_s which satisfies $Z_s'(0) < 0$.

A generic unfolding of this singularity can be given by

$$Z_{\mu,\varepsilon}(x,y) = \begin{cases} X_{\mu,\varepsilon}(x,y) = \begin{pmatrix} x^2 + \varepsilon \\ -y + \mu \end{pmatrix} & \text{if } x + y > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{if } y < 0 \end{cases}. \tag{31}$$

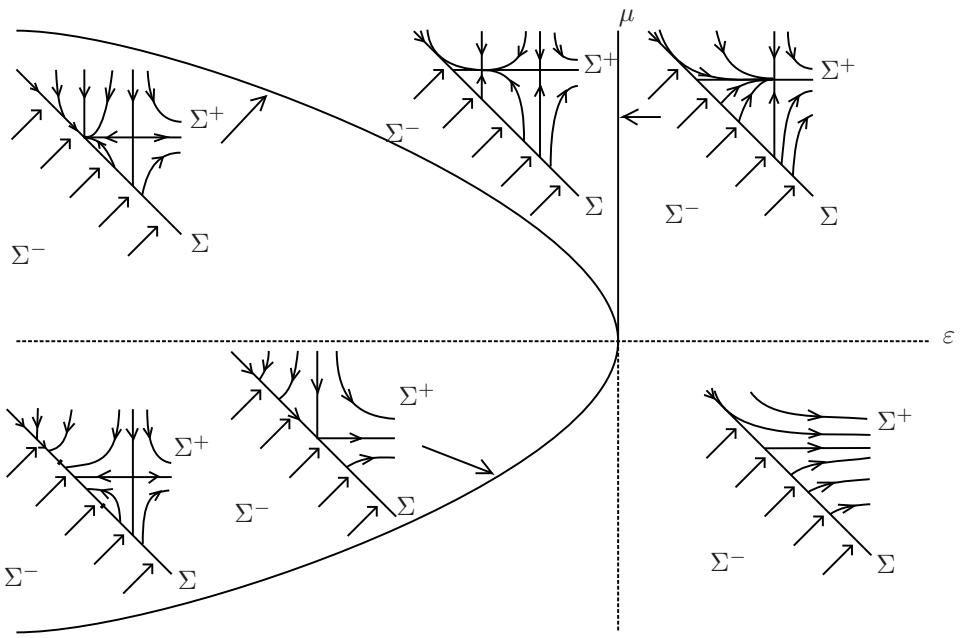

Figure 35: Different dynamics of the unfolding (31).

in such a way that ε unfolds the Saddle-Node bifurcation of X. On the other hand, when $\varepsilon = 0$ the Saddle-Node is given by $Q = (0, \mu)$, and then is visible for $\mu > 0$ and invisible for $\mu < 0$.

For $\varepsilon > 0$, $X_{\mu,\varepsilon}$ does not have critical point whereas for $\varepsilon < 0$ it has a node $N = (-\sqrt{-\varepsilon}, \mu)$ and a saddle $S = (\sqrt{-\varepsilon}, \mu)$. Nevertheless, they are only visible provided $\mu > \sqrt{-\varepsilon}$ and $\mu > -\sqrt{-\varepsilon}$ respectively.

Moreover, when $\mu \neq 0$ it appears a fold of X in Σ,

$$F = \left(\frac{-1 + \sqrt{1 - 4(\varepsilon + \mu)}}{2}, \frac{1 - \sqrt{1 - 4(\varepsilon + \mu)}}{2} \right)$$

which is always the boundary between Σ^s and Σ^c. In Σ^s, taking x as a local chart, the sliding vector field is given by

$$Z_s(x) = \frac{\varepsilon + \mu - x + x^2}{2 - \mu - \varepsilon - x - x^2}.$$

which has a pseudonode

$$P = \left(\frac{-1 + \sqrt{1 - 8(\mu + 2\varepsilon)}}{4}, \frac{1 - \sqrt{1 - 8(\mu + 2\varepsilon)}}{4} \right),$$

that is visible provided $\varepsilon < 0$ and $-\sqrt{-\varepsilon} < \mu < \sqrt{-\varepsilon}$.

In the unfolding of the Boundary-Saddle-Node bifurcation only appear codimension-1 local bifurcations as it is shown in next proposition (see also Figure 35).

Proposition 13.1. *For (ε, μ) small enough the vector field $Z_{\mu,\varepsilon}$ in (31) undergoes the following local bifurcations:*

- *A smooth Saddle-Node bifurcation in Σ^+ in the line $\{\varepsilon = 0, \mu > 0\}$.*
- *A Boundary-Node bifurcation, called BN_2 in [KRG03], in $\{\mu = \sqrt{-\varepsilon}, \varepsilon < 0\}$.*
- *A Boundary-Saddle bifurcation, called BS_1 in [KRG03], in $\{\mu = -\sqrt{-\varepsilon}, \varepsilon < 0\}$.*

The bifurcations stated in this proposition, whose proof is straightforward, are the only possible local bifurcations of the unfolding. Moreover, they are the same independently whether we use Σ-equivalence or topologically equivalence.

Finally, studying the regions delimited by these curves it can be easily seen that any two vector fields in any of these regions are Σ-equivalent (and thus topologically equivalent). Therefore, there can not appear global bifurcations for (ε, μ) small enough.

14 Boundary-Hopf singularity

A Filippov vector field $Z = (X, Y)$ has a Boundary Hopf singularity when X has a Hopf singularity at $p \in \Sigma$ whereas Y is transversal to Σ at that point. In order to have a generic codimension-2 singularity one has to impose an additional generic non-degeneracy condition. Since $p \in \partial\Sigma^c \cap \partial\Sigma^s$ or $p \in \partial\Sigma^c \cap \partial\Sigma^e$, there exists a sliding vector field Z_s which is defined on one side of p. Taking x as a local chart of Σ, Z_s is of the form

$$Z_s(x) = \alpha x + \mathcal{O}\left(x^2\right).$$

Therefore, one has to impose $\alpha \neq 0$.

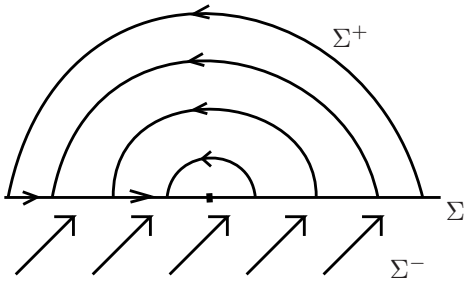

Figure 36: Phase portrait of the Hopf singularity in (32) in which $p \in \partial\Sigma^c \cap \partial\Sigma^s$. In the supercritical ($\sigma = -1$) and subcritical ($\sigma = 1$) cases the phase portrait is topologically equivalent.

Of course, this singularity can present different behaviors depending whether $p \in \partial\Sigma^c \cap \partial\Sigma^s$ or $p \in \partial\Sigma^c \cap \partial\Sigma^e$ (namely, Y points towards Σ or away from Σ), whether the Hopf bifurcation is supercritical or subcritical and on the sign of α.

In this section, taking $p \in \partial\Sigma^c \cap \partial\Sigma^s$ and $\alpha < 0$, we will study both the supercritical and subcritical cases. All the other cases present similar behavior and can be studied analogously. In this case, we take $p = (0, 0)$, $\Sigma = \{f(x, y) = y = 0\}$ and

$$Z^\sigma(x,y) = \begin{cases} X^\sigma(x,y) = \begin{pmatrix} -y + \sigma x\left(x^2+y^2\right) \\ x + \sigma y\left(x^2+y^2\right) \end{pmatrix} & \text{if } y > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{if } y < 0. \end{cases} \tag{32}$$

where $\sigma = -1, +1$ corresponds to the supercritical and subcritical cases. The phase portrait of both Z^σ are topologically equivalent and can be seen in Figure 36. It is straightforward to see that for both Z^σ, $\Sigma^c = \{(x, y) \in \Sigma : x > 0\}$, $\Sigma^s = \{(x, y) \in \Sigma : x < 0\}$ and $Z_s^{\sigma\prime}(0) < 0$.

A generic unfolding of these singularities can be given by

$$Z^\sigma_{\mu,\varepsilon}(x,y) = \begin{cases} X^\sigma_{\mu,\varepsilon}(x,y) = \begin{pmatrix} \varepsilon x - (y-\mu) + \sigma x\left(x^2+(y-\mu)^2\right) \\ x + \varepsilon(x-\mu) + \sigma y\left(x^2+(y-\mu)^2\right) \end{pmatrix} & \text{if } y > 0 \\ Y(x,y) = \begin{pmatrix} 1 \\ 1 \end{pmatrix} & \text{if } y < 0 \end{cases} \tag{33}$$

in such a way that ε unfolds the Hopf bifurcation. On the other hand, $X^{\sigma}_{\mu,\varepsilon}$ has a critical point $P=(0,\mu)$ which is visible for $\mu>0$ and invisible for $\mu<0$. Therefore, μ moves P transversally to Σ.

When $\mu\neq 0$, it appears a fold $F=(F_x,0)$ which is visible for $\mu>0$ and invisible for $\mu<0$ and satisfies

$$F_x=\frac{1-\sqrt{1-4\sigma\mu(\mu\varepsilon+\sigma\mu^3)}}{2\mu}. \tag{34}$$

In Σ^s, taking $x<F_x$ as a local chart, the sliding vector field is given by

$$Z^{\sigma}_s(x)=\frac{\mu-\mu\varepsilon-\sigma\mu^3+\left(-1+\varepsilon\sigma\mu^2\right)x-\sigma\mu x^2+\sigma x^3}{1+\mu\varepsilon+\sigma\mu^3-x+\sigma\mu x^2}$$

and has a pseudonode $N=(N_x,0)$ which satisfies $N_x=\mu+o(\mu,\varepsilon)$ and exists provided $\mu<0$ for both $\sigma=\pm 1$, since $F_x<N_x$ for $\mu<0$.

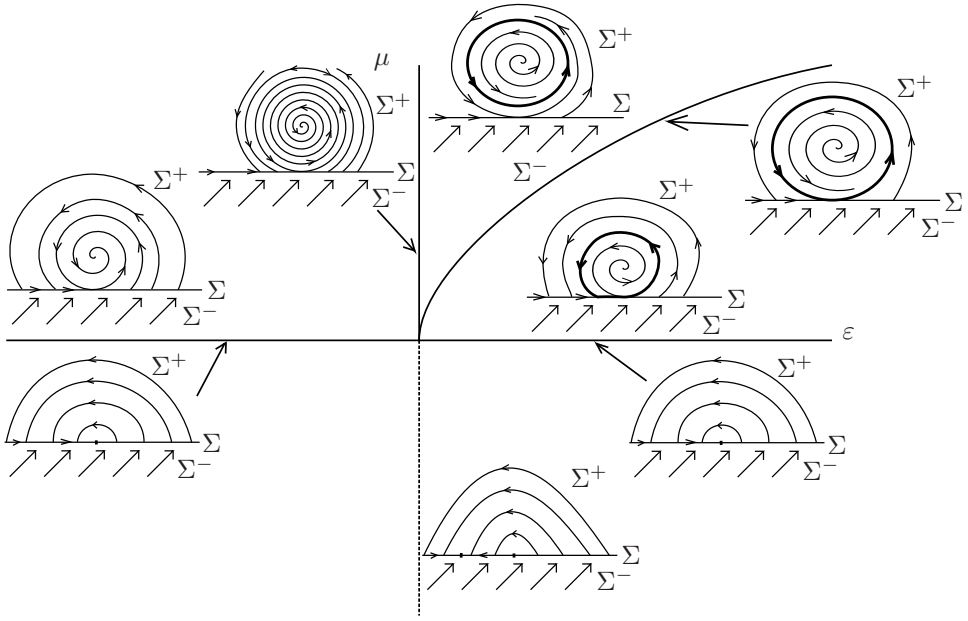

Figure 37: Different dynamics of the unfolding (33) with $\sigma=-1$.

In the unfolding of $Z^{\sigma}_{\mu,\varepsilon}$ in (33) there exist both local and global bifurcations as can be seen in the following proposition.

Proposition 14.1. *For (ε,μ) small enough the vector field $Z^{\sigma}_{\mu,\varepsilon}$ in (33) undergoes the following bifurcations*

- *A Boundary-Focus bifurcation, called BF_3 in [KRG03], in $\{\mu=0,\varepsilon>0\}$.*
- *A Boundary-Focus bifurcation, which corresponds to BF_4 in [KRG03] with reversed time, in $\{\mu=0,\varepsilon<0\}$.*
- *A smooth Hopf bifurcation in $\{\varepsilon=0,\mu>0\}$.*
- *For $\sigma=-1$ (supercritical case) in $\{\mu=\sqrt{\varepsilon},\varepsilon>0\}$ takes place a separatrix connection $W^u_+(F)=W^s_+(F)$, which is in fact a grazing-sliding bifurcation (called TC_1 in [KRG03]) .*
- *For $\sigma=+1$ (subcritical case) in $\{\mu=\sqrt{-\varepsilon},\varepsilon<0\}$ takes place a separatrix connection $W^u_+(F)=W^s_+(F)$, which is in fact a grazing-sliding bifurcation (called TC_2 in [KRG03]) .*

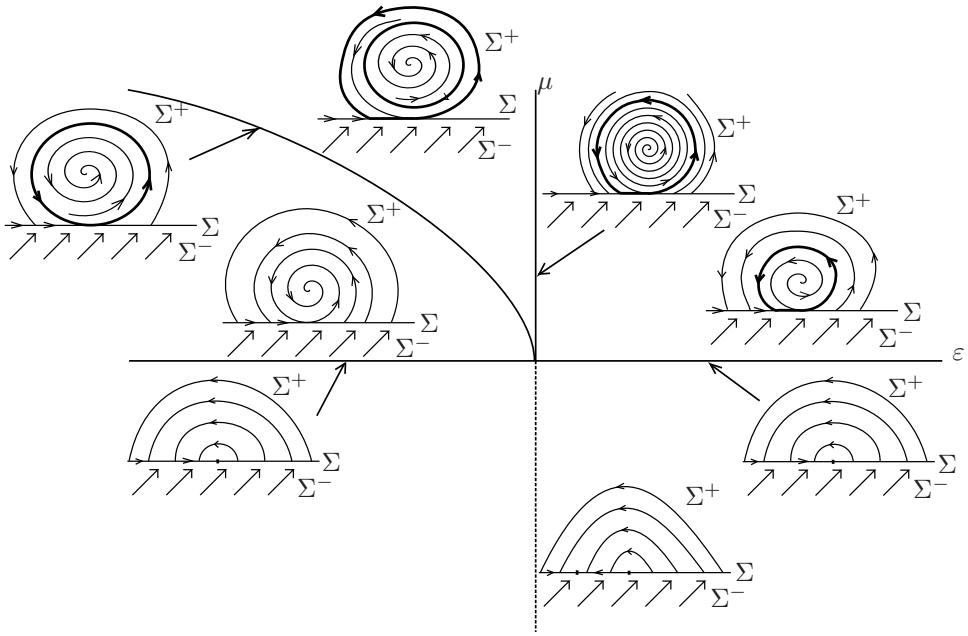

Figure 38: Different dynamics of the unfolding (33) with $\sigma = 1$.

Proof. The local bifurcations for both the supercritical and subcritical cases are the same. $X^{\sigma}_{\mu,\varepsilon}$ has a critical point $P = (0, \mu)$ which is a hyperbolic focus provided $\varepsilon \neq 0$. Moreover, it is attractor for $\varepsilon < 0$ and repellor for $\varepsilon > 0$. Therefore, since for $\mu = 0$, $P \in \Sigma$, in $\{\mu = 0, \varepsilon > 0\}$ and $\{\mu = 0, \varepsilon < 0\}$ takes place respectively BF_3 and BF_4 with time reversed.

When $\varepsilon = 0$ the critical point P looses its hyperbolicity and undergoes a Hopf bifurcation, which is visible provided $\mu > 0$. Therefore in the supercritical case it appears a periodic orbit in Σ^+ for $\varepsilon > 0$ and in the subcritical for $\varepsilon < 0$.

In these three curves occur all the possible local bifurcations of $Z^{\sigma}_{\mu,\varepsilon}$. Regarding the global bifurcations, the unfolding of the supercritical and subcritical cases differ.

We first consider the supercritical case (see Figure 37). It can be easily seen that any two vector fields in the regions $\{\mu < 0\}$ are Σ-equivalent (and thus topologically equivalent), and the same happens in $\{\varepsilon < 0, \mu > 0\}$. In $\{\varepsilon > 0, \mu > 0\}$ appears a global bifurcation. We describe the dynamics clockwisely. In the vertical axis the Hopf bifurcation takes place, and thus for $\varepsilon > 0$ it appears a small attractor periodic orbit which coexists with the repellor focus. For the normal form in (33), this periodic orbit is given $x^2 + (y - \mu)^2 = \varepsilon$ and therefore, as we change the parameters clockwisely, it increases until it hits Σ tangentially at $\mu = \sqrt{\varepsilon}$ at the fold F in (34) leading to the separatrix connection . Therefore, in this curve takes place a so-called grazing bifurcation (TC_1 in [KRG03]). If we continue changing the parameters, the periodic orbit becomes a cycle which has a small sliding segment. Finally this cycle shrinks until it disappears in the Boundary-Focus bifurcation (BF_3 in [KRG03]) which takes place in $\{\mu = 0, \varepsilon > 0\}$.

Finally, we describe the global bifurcations of the subcritical case (see Figure 38). It can be easily seen that any two vector fields in the region $\{\mu < 0\}$ and also in $\{\varepsilon < 0, \mu > 0\}$ are Σ-equivalent (and thus topologically equivalent). In this last region, it exists an attractor cycle which appears due to the Boundary-Focus Bifurcation (BF_3 in [KRG03]) in $\{\mu = 0, \varepsilon > 0\}$, which coexists with the repellor focus P.

In $\{\varepsilon > 0, \mu > 0\}$ appears a global bifurcation. We describe the dynamics anticlockwisely. In the vertical axis the Hopf bifurcation of P takes place, and thus for $\varepsilon < 0$ it appears a small repellor periodic orbit which coexists with the attractor focus P and the cycle. As we change the parameters, the periodic orbit becomes bigger and closer to the cycle. Reasoning as in the supercritical case, it can be seen that the cycle and the periodic orbit merge at the same time as they graze tangentially Σ in $\mu = \sqrt{-\varepsilon}$. Therefore,

in this curve takes place a grazing bifurcation called TC_2 in [KRG03]. If we cross this curve, the periodic orbit and the cycle disappear in such a way that the attractor focus becomes a global attractor, which becomes closer to Σ until it hits it in $\{\mu = 0, \varepsilon < 0\}$ in the Boundary-Focus bifurcation.
