Aims

Despite our increased understanding of the genetic basis of dilated cardiomyopathy (DCM), the clinical utility and yield of clinically meaningful findings of comprehensive next-generation sequencing (NGS)-based genetic diagnostics in DCM has been poorly described. We utilized a high-quality oligonucleotide-selective sequencing (OS-Seq)-based targeted sequencing panel to investigate the genetic landscape of DCM in Finnish population and to evaluate the utility of OS-Seq technology as a novel comprehensive diagnostic tool.

Methods and results

Using OS-Seq, we targeted and sequenced the coding regions and splice junctions of 101 genes associated with cardiomyopathies in 145 unrelated Finnish patients with DCM. We developed effective bioinformatic variant filtering strategy and implemented strict variant classification scheme to reveal diagnostic yield and genotype–phenotype correlations. Implemented OS-Seq technology provided high coverage of the target region (median coverage 410× and 99.42% of the nucleotides were sequenced at least 15× read depth). Diagnostic yield was 35.2% (familial 47.6% and sporadic 25.6%, $P = 0.004$) when both pathogenic and likely pathogenic variants are considered as disease causing. Of these, 20 (53%) were titin (*TTN*) truncations (non-sense and frameshift) affecting all *TTN* transcripts. *TTN* truncations accounted for 20.6% and 14.6% of the familial and sporadic DCM cases, respectively.

Conclusion

Panel-based, high-quality NGS enables high diagnostic yield especially in the familial form of DCM, and bioinformatic variant filtering is a reliable step in the process of interpretation of genomic data in a clinical setting.

Translational perspective

Genetic analysis among patients with dilated cardiomyopathy (DCM) is becoming an important part of clinical assessment, as it is in hypertrophic cardiomyopathy (HCM). The genetics of DCM is complex and therefore next-generation sequencing strategies are essential when providing genetic diagnostics. To achieve maximum yield, the diagnostic approach should include comprehensive clinical phenotyping combined with high-quality, high-coverage deep sequencing of DCM-associated genes and clinical variant classification as a basis for defining true yield in genetic testing. Our study has combined a novel sequencing strategy and clinical interpretation to analyse the yield and genotype–phenotype correlations among well-phenotyped Finnish DCM patients.

Introduction

According to the position statement of the European Society of Cardiology (ESC), DCM is defined as left ventricular dilatation and dysfunction in the absence of abnormal loading conditions or coronary artery disease sufficient to cause global systolic impairment. Furthermore, DCM can be divided into familial and non-familial forms.¹ Prevalence of DCM is at least 1:2500 and up to 30–50% of DCM cases are familial.² Dilated cardiomyopathy is the leading cause for heart transplantation and a relatively common cause for heart failure and sudden cardiac death.^{3,4}

In 2012, Herman and colleagues⁵ published a study showing truncating titin (*TTN*) mutations in 25% of familial and 18% of sporadic DCM patients. This index report has triggered more thorough and ambitious DCM research by next-generation sequencing (NGS) approaches that enable analysis at a scale once considered impossible. By now DCM-associated mutations have been found in >50 genes.⁶ Most identified mutations, often unique to families, are inherited in an autosomal dominant fashion, although some can be autosomal recessive, X-linked, or mitochondrial. These genes encode components of the sarcomere, desmosome, cytoskeleton, nuclear lamina, mitochondria, and calcium-handling proteins.^{7,8} However, many of the genes associated with cardiomyopathies are not specific to a particular type of cardiomyopathy, and it has been suggested that 9.0–12.6% of the patients carry at least two potentially disease-causing mutations.^{9,10} Penetrance of cardiomyopathies is clearly age and gene dependent but so far poorly understood.^{5,11} Though whole exome- and genome-level sequencing are required for DCM gene discovery, targeted high-quality NGS strategies are evolving as the primary diagnostic tool in clinical setting.

Fast accumulation of knowledge on cardiomyopathy genetics has started to reshape clinical practices as identification of causative mutation enables effective differential diagnostics and facilitates screening of the family members, but may also help in driving treatment decisions. Evolvement of open-access large reference databases such as the ExAC (<http://exac.broadinstitute.org>) together with diagnostic and research laboratories sharing variant information with classification into public databases such as ClinVar is already improving the interpretation and utility of genetic data. Due to this development, genetic diagnostics in cardiomyopathies is recommended in international guidelines.^{12,13} Moreover, genetic screening has shown to be cost-effective in hypertrophic cardiomyopathy,¹⁴ but the evaluation of the clinical utility and cost-effectiveness of genetic screening in DCM is still on the way.

Our goal was to investigate the genetic landscape of DCM in Finnish population and to evaluate associations between genotype and phenotype. Furthermore, our goal was to evaluate the utility of OS-Seq technology as a novel comprehensive diagnostic tool.

Methods

Subjects and clinical evaluation

The Finn-DCM study cohort comprised 145 unrelated DCM patients (63 familial and 82 sporadic) of Finnish origin. The patients were recruited between 1999 and 2013 from Helsinki University Hospital, the only tertiary centre in the country to perform cardiac

transplantations. All patients fulfilled the following diagnostic criteria: left ventricular (LV) end-diastolic diameter (LVEDD) >27 mm/m² [modified from original criteria of >117% of the predicted value corrected for age and body surface area (BSA)] and LV systolic dysfunction (LVEF < 45%) in the absence of abnormal loading conditions such as hypertensive heart disease, primary valve disease, or significant coronary artery disease.¹⁵ Definition of familial cardiomyopathy was family history of hypertrophic cardiomyopathy (HCM), DCM, or arrhythmogenic right ventricular cardiomyopathy (ARVC), or two or more patients with atrial fibrillation before age 40 or rhythm/conduction disturbances requiring pacemakers in the family. Detailed clinical information was obtained at multiple time points for each subject including family history, anthropometrics, age at presentation, age at death due to cardiomyopathy, symptoms, blood pressure, electrocardiograms, echocardiograms, pacemaker implantation, transplantation, and resuscitation. Written informed consent was obtained from all patients, and the institutional ethical committee of the University of Helsinki approved the study (Dnro 307/13/03/01/11).

ExAC reference population

Exome Aggregation Consortium (<http://exac.broadinstitute.org>) is an international collaborative effort to aggregate and harmonize exome-sequencing data from a variety of large-scale sequencing projects. It consists of >60 000 individuals including Finnish SISu (Sequencing Initiative Suomi Project) Control Cohorts. To filter common polymorphisms in the Finnish population, identified candidate variants were queried for overlap against the available variants reported in the ExAC and SISu project databases.

Oligonucleotide-selective targeted sequencing of 101 cardiomyopathy-related genes

Genomic DNA was extracted from blood samples and sequenced using OS-Seq. One hundred and one-gene OS-Seq-based targeted sequencing panel with automated target DNA capture and sequencing was applied in the MiSeq sequencer.¹⁶ The gene panel (Pan Cardiomyopathy Panel, Blueprint Genetics v.1.0) was designed to screen 2515 consensus coding sequence (CCDS) regions and splice junctions of 51 known genes and 50 candidate genes associated with DCM and implicated in other inherited cardiomyopathies based on Online Mendelian Inheritance in Man database annotations and literature.^{17,18} Analytic validation of the Pan Cardiomyopathy Panel has been submitted elsewhere. Shortly, the panel had sensitivity of 99.0%, specificity of 100.0%, and positive predictive value of 99.0% to detect single-nucleotide polymorphisms (SNPs) and sensitivity of 100% for indels ranged 1–19 bp.

Bioinformatic data analyses and variant filtering

Raw paired-end sequence reads quality trimming and adapter sequence removal were carried out using Trimmomatic in paired-end mode.¹⁹ High-quality reads were mapped to human genome reference sequence (hg19) using Burrows–Wheeler Algorithm (BWA).²⁰ After excluding PCR duplicates, we applied GATK (V.3.1–1)²¹ base quality score recalibration, indel realignment, and performed SNP and insertion-deletion (INDEL) discovery and genotyping across all samples simultaneously using standard hard filtering parameters (Phred-scaled genotype quality score threshold of 30) according to GATK Best Practices recommendations.²² Identified variants were annotated using Ensembl's Variant Effects Predictor (VEP) tool,²³ and the pathogenicity of missense variants was predicted *in silico* using two ensemble scores from dbNSFP (RadialSVM and LR) based on 10 component scores (SIFT, PolyPhen-2

HDIV, PolyPhen-2 HVAR, GERP++, MutationTaster, Mutation Assessor, FATHMM, LRT, SiPhy, PhyloP) and the maximum frequency observed in the 1000 genomes populations.²⁴ Variant filtering was done using an in-house variant filtering and prioritization strategy (Figure 1). We adopted Blueprint Genetics' variant classification scheme (see Supplementary material online, Table S1), and a team of clinicians and geneticists evaluated and classified all rare variants as 'pathogenic', 'likely pathogenic', 'variant of unknown significance', 'likely benign', or 'benign'. For a detailed description of the data analysis and variant filtering strategy, refer to the Supplementary material online.

Statistical analyses

The Shapiro–Wilk test was applied to determine whether data are normally distributed. Normally distributed, continuous variables were expressed as mean \pm SD and non-parametric as median, and lower and upper quartiles. All categorical variables were depicted using relative frequency distributions. Characteristics of different groups such as patients with or without disease-causing mutation were compared using the χ^2 test for categorical variables if appropriate; otherwise, Fisher's exact test was used. Independent samples t-tests combined with Levene's tests were used for comparison between the groups for all continuous

variables, and Mann–Whitney *U* tests were used for non-parametric variables. Differences were considered significant if the two-sided *P*-value was <0.05 . All statistical analyses were done using *R* statistical software.

Results

Study population

The Finn-DCM cohort consisted of 145 unrelated DCM patients. The mean age at diagnosis was 44.3 ± 12.2 years in familial DCM [$n = 63, 44$ (69.8%) men] and 46.8 ± 11.7 years in sporadic disease [$n = 82, 63$ (77.0%) men]. The mean follow-up time was 6.2 years. In 83.9% cases of the familial and 28.9% cases of sporadic DCM at least one family member was studied by echocardiography. Endomyocardial biopsy or pathology report from the explanted heart was available from 50.3% of the patients. Angiography was performed on 78.6% ($n = 114$) of the patients, and 29.7% ($n = 43$) have undergone heart transplantation. Details on study population are presented in Table 1.

Table 1 Distribution of pathogenic and likely pathogenic variants among tested genes in patients with familial or sporadic dilated cardiomyopathy in the Finnish dilated cardiomyopathy study

Patients	All (N = 145)	Familial (N = 63)	Sporadic (N = 82)
Males	107 (73.8%)	44 (69.8%)	63 (76.8%)
Females	38 (26.2%)	19 (30.2%)	19 (23.2%)
Diagnostic yield			
Mutation positive, n (%)	51 (35.2)	30 (47.6)	21 (25.6)
Mutation negative, n (%)	94 (64.8)	33 (52.4)	61 (74.4)
Causative gene in Finnish dilated cardiomyopathy cohort, N (%)			
Sarcomere genes			
Titin (<i>TTN</i>)	25 (17.2%)	13 (20.6%)	12 (14.6%)
β -myosin heavy chain 7 (<i>MYH7</i>)	1 (0.7%)	1 (1.6%)	—
Troponin T type 2 (<i>TNNT2</i>)	1 (0.7%)	1 (1.6%)	—
Nuclear lamina			
Lamin A/C (<i>LMNA</i>)	12 (8.3%)	9 (14.3%)	3 (3.7%)
Z-disc/related, desmosomal, Ca ²⁺ handling			
Desmoplakin (<i>DSP</i>)	8 (5.5%)	4 (6.3%)	4 (4.9%)
RNA-binding motif protein 20 (<i>RBM20</i>)	2 (1.4%)	1 (1.6%)	1 (1.2%)
Dystrophin (<i>DMD</i>)	1 (0.7%)	—	1 (1.2%)
Titin-cap; telethonin (<i>TCAP</i>)	1 (0.7%)	1 (1.6%)	—
Total	51 (35.2%)	30 (47.6%)	21 (25.6%)

Sequencing quality

Using genomic DNA isolated from 145 subjects with DCM, we captured and performed oligonucleotide-selective sequencing of 667 kb of genomic region covering the CCDS coding regions and splice junctions of 101 genes. Sequencing depth was evaluated in each target base to demonstrate the efficiency of sequencing. Results from the sequencing coverage analyses are shown as percentage of targeted bases with $>1\times$, $>5\times$, $>10\times$, $>15\times$, $>25\times$, $>50\times$, $>100\times$, and until $>500\times$ depth in 145 subjects in the Supplementary material online, Figure S1. The median read depth in the target region across the samples was $410\times$, and 99.42% of the nucleotides had over $15\times$ read depth. Individual gene-specific sequencing coverage plot is shown in the Supplementary material online, Figure S2.

Variant filtering to identify clinically significant variants

Genotyping with GATK Unified Genotyper multi-sample mode generated a total of 1513 variants present in 145 subjects (234 variants/patient). Excluding synonymous single-nucleotide substitutions, we found 658 exonic and splice-site variants called with phred-scaled quality of ≥ 400 . After excluding common polymorphisms based on variants reported in 1000 Genomes and ESP databases, we obtained 167 rare exonic (131 missense, 13 non-sense, 17 frameshift-indel, and 6 in-frame indel) and 2 splice-site variants as candidates for further analysis (see Supplementary material online, Table S2). In total, 119 patients (82.1%) carried at least one rare variant in the target genes. Sixty-eight patients (46.9%) carried multiple rare variants (see Supplementary material online, Tables S2

and S4). *In silico* analysis predicted 32.8% (43/131) of the rare missense variants as deleterious. Of the rare variants, 79.2% (134/169) were private. In total, 38 variants were classified as pathogenic or likely pathogenic (see Supplementary material online, Table S3).

Diagnostic yield

Our diagnostic yield in whole Finn-DCM cohort was 35.2% when both pathogenic and likely pathogenic are considered as disease-causing variants. Diagnostic yield was significantly higher in familial vs. sporadic cases (47.6 vs. 25.6%, $P = 0.004$, Table 1). Based on our classification scheme, 8.3% of the rare variants were pathogenic, 26.2% likely pathogenic, 27.6% variant of unknown significance, 20.0% likely benign, and 17.9% benign. Disease-causing genes included *TTN* (17.2%); lamin A/C (*LMNA*) (8.3%); desmoplakin (*DSP*) (5.5%); RNA-binding motif protein 20 (*RBM20*) (1.4%); myosin, heavy chain 7 (*MYH7*), troponin T type 2 (*TNNT2*), dystrophin (*DMD*), and titin-cap (*TCAP*) (0.7%). Distribution of the disease-causing mutations within these genes in Finn-DCM cohort is presented in Table 1.

In total, 64 unique rare *TTN* variants were found in 48% (71/145) of Finn-DCM cohort. Of the rare *TTN* variants, 70% (38/64) were missense variants with 11 variants being novel based on ExAC database. As *TTN* missense variants were considered variants of unknown significance, we focused on truncating mutations. Twenty-one truncating *TTN* variants were predicted to cause loss of function in 25 patients (17.2%): 11 non-sense variants in 16 patients; 9 frameshift variants in 10 patients; and 1 consensus splice-site variant in one patient (see Supplementary material online, Table S3). Of note, one additional truncating *TTN* variant (p.Glu4647Lysfs*54) was graded as variant of unknown significance (VUS), because it is quite

common and affects only ENST00000360870 (TTN-010) transcript encoding a 5604 amino acid protein. Notably, 67% (14/21) of the truncating *TTN* mutations were private and not reported in the ExAC database. Truncating *TTN* mutations in the Finn-DCM cohort were not randomly distributed along the gene; instead, the majority 62% (13/21) of the mutations were located in the large A band region of titin that associates with the thick filament (Figure 2). In addition, 95% (20/21) of the truncating *TTN* mutations affected all transcripts of *TTN* gene. Family segregation analysis was performed in five families with truncating *TTN* mutations, and it revealed positive segregation with the disease in all cases (Figure 3). Disease penetrance increased from 53.8% at age 50 to 84.6% at age 60 and 100.0% at age 70.

Recurrent variants in multiple dilated cardiomyopathy patients

To further elucidate the role of the disease-causing variants identified in more than one Finn-DCM family, the allele frequencies were compared with the largest available genetically matched control population (Finnish controls in the ExAC study) using Fishers' exact test. All of the identified four variants were significantly enriched in the Finn-DCM cohort (Table 3).

Clinical characteristics and genotype–phenotype correlations

The clinical characteristics of the patients with vs. without a mutation were not statistically different (Table 1). Male patients had larger LVEDD (72 ± 10 vs. 64 ± 8 mm, $P < 0.001$) and lower EF (23 ± 8 vs. $28 \pm 9\%$, $P = 0.003$) than females and a trend of more frequent cardiac transplantation (33 vs. 16%, $P = 0.10$). Otherwise, gender had no significant effect on age at onset, arrhythmias, resuscitation, and use of pacemakers.

We compared clinical characteristics between different mutation groups: *TTN*, *LMNA*, *DSP*, and others. Other mutation group

included two cases with *RBM20* mutations, one mutation in each of *MYH7*, *TNNT2*, *TCAP*, and *DMD*. Left ventricular end-diastolic diameter was larger in patients with *TTN* vs. *LMNA* mutations (70 ± 8 vs. 60 ± 10 , $P = 0.03$) (Table 1). In the *LMNA* group, pacemaker implantation, history of resuscitation (resuscitation or appropriate ICD shock), and atrial fibrillation were more frequent than in some of the other groups (Table 2). Age of disease onset (fulfilling DCM diagnostic criteria) seemed lower in the other mutation group compared with the *LMNA* ($P = 0.04$), *DSP* ($P = 0.03$), and *TTN* groups ($P = 0.10$) (Table 2), but it should be noted that especially in *LMNA* cardiomyopathy disease manifestation such as conduction abnormalities and arrhythmias exist commonly before LV dilatation and impaired systolic function. There was no significant difference in reaching the composite end point (cardiac transplantation and death from cardiac causes) among mutation positive vs. negative patients ($P = 0.34$, Figure 4A) or patients with disease-causing mutations in *TTN* vs. *LMNA* genes ($P = 0.58$, Figure 4B).

Discussion

Multiple genes can cause inherited DCM. Due to incomplete knowledge of the genes involved in DCM coupled with variation in population structure and genetics, genetic characterization of DCM has been a challenging task. This becomes more challenging in a bottlenecked population like the Finnish population, as such populations have a smaller spectrum of rare variation. To investigate the genetic landscape of DCM in the Finnish population, to evaluate associations between genotype and phenotype, and to evaluate the utility of OS-Seq technology as a novel comprehensive diagnostic tool, we developed and utilized a high-quality 101-gene OS-Seq-based targeted resequencing panel. In this study, we show excellent sequencing performance and clinical utility of a large cardiomyopathy targeted sequencing panel in genetic diagnosis of patients with DCM. Using rigorous clinically oriented variant classification and interpretation strategy, we obtained an unmatched diagnostic yield of

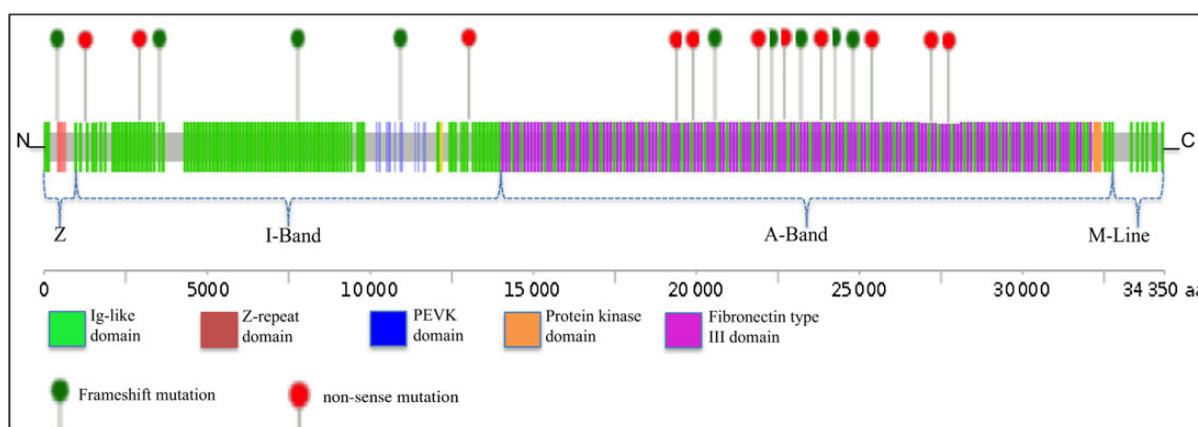

Figure 2 Spatial distribution of titin frameshift and non-sense mutations in Finnish dilated cardiomyopathy cohort. Titin is linearly depicted with its 152 Immunoglobulin-like domains in green and 132 fibronectin type III domains in purple. *TTN* mutations are shown as lollipops. Depicted are non-sense (red) and frameshift (green) mutations in subjects with dilated cardiomyopathy. Variants are shown relative to the titin Uniprot Sequence identifier Q8WZ42. The dashed lines below the protein schematic indicate the location of variants within the sarcomere.

DCM, dilated cardiomyopathy.

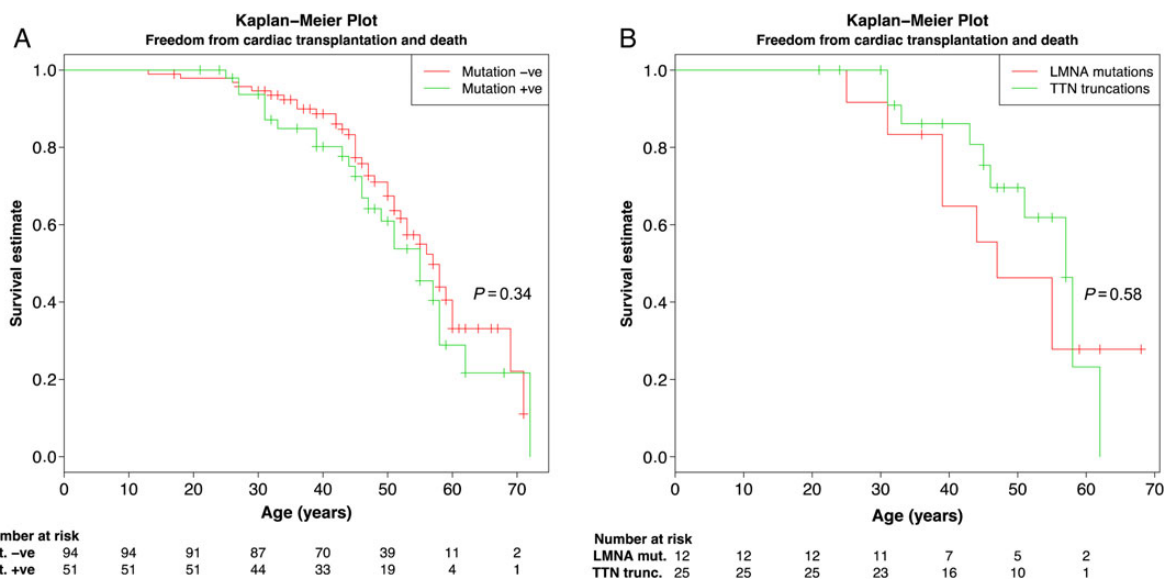

Figure 4 Kaplan-Meier curve demonstrating freedom from composite endpoint (cardiac transplantation and death from cardiac causes). Panel A shows Kaplan-Meier curve for patients with and without detected disease-causing mutation and Panel B shows comparison between patients with *TTN* vs. *LMNA* mutations. Importantly, many patients are 40–60 years old and have not reached any endpoint. Hatch marks indicate patient age at last follow-up date in Finnish dilated cardiomyopathy study.

role of *TTN* in DCM and genotype-phenotype association showed that *LMNA* cardiomyopathy is clinically distinct from DCM with other genetic origin.

In clinical diagnostic setting, sensitivity of the NGS panel is an important parameter affecting diagnostic yield. Haas et al. published recently an NGS cardiomyopathy panel with a median coverage of 2526×, which is higher than 410× in our study.¹⁰ Both panels have sensitivity of 99.0% in HapMap (NA12878) validation, but our accuracy was significantly better (100.00 vs. 91.3%). Most probably this reflects more uniform sequencing coverage in our study. Uniform sequencing depth is also an important element for affordable genetics diagnostics. Moreover, Haas et al. did not provide data of indel validation, which is critical as NGS strategies can have significant differences in specificity and sensitivity for indels. Indel detection efficiency is critical when aiming for high diagnostic yield in DCM as over 1000 cardiomyopathy-associated indel variants are listed in public and commercial databases such as ClinVar and Human Gene Mutation Database (HGMD).

In addition to sequencing quality, another equally important factor determining diagnostic hit rate is variant classification and interpretation. In many studies, relatively loose frequency criteria have been utilized to claim disease-associated variants.^{5,10} In Finn-DCM study, 89% (34/38) of the variants classified as pathogenic or likely pathogenic were not present in large control population (ExAC) and all except two patients carried only one known disease-causing variant, which is in-line with autosomal dominant inheritance pattern of familial DCM but opposite to that reported by Haas et al. In their DCM cohort, Haas et al. reported that 73.2% of the patients had 'known', 'likely', or 'potential' disease-causing mutation, and 46% of the patients were found to have 'known' disease-causing mutation in cardiomyopathy or chanellopathy genes, but only 16% of the patients had 'known' DCM mutation. Moreover, variant interpretation in the study by Haas et al. was based on variants reported in HMGD, which is known to contain variants classified as pathogenic, although some of them are increasingly being identified as benign polymorphisms with the advent of NGS. We randomly selected 10 variants

from Haas *et al.* study classified as potential disease causing (Classes 1a–III) variants and queried their frequency from the ExAC database. Interestingly, 80% of the variants were present in over 9 (allele frequency >0.015%) subjects in the ExAC database with an average of 263 carriers (allele frequency >0.44%) in the database. This prevalence in the population makes the variants highly unlikely to be disease causing.

Clinical exome sequencing strategies can also result in a false-negative test result meaning a known genetic cause was missed in the analysis. This is due to inadequate depth and breadth of sequencing coverage at clinically relevant locations. Recently, Park *et al.*²⁵ examined 57 exome sequencing data for adequacy in the detection of potentially pathogenic variant locations in the 56 genes described in the ACMG incidental findings recommendation. Despite high mean coverage between 74× and 120×, only 83–87% of the bases were covered at ≥20×. Of note, the clinical exome data had inadequate coverage for >50% of HGMD variant locations in 7/56 ACMG genes with a recommendation to report even as incidental findings.²⁶ This probably explains why targeted NGS panels outperform exome sequencing in clinical diagnostics.

Gudkova *et al.*²⁷ demonstrated a patient whose cardiomyopathy phenotype changed from HCM to restrictive and finally to DCM. Limited data exist on late-stage HCM developing to so call burnout physiology and resemblance to DCM.²⁸ Furthermore, the incidence of this phenomenon is unknown. Our study did not reveal any typical HCM-associated mutations, suggesting that at least in our DCM cohort the incidence of HCM with burnout physiology is extremely low. In addition to potential phenotypic overlap between HCM and DCM, there is increasing evidence of overlap between ARVC and DCM. Cardiac desmosomal genes such as desmoglein 2 (*DSG2*), desmocollin-2 (*DSC2*), junction plakoglobin (*JUP*), plakophilin-2 (*PKP2*), and *DSP* were originally reported in association with ARVC, but segregating mutations in these genes are increasingly found in patients with classical DCM.^{29,30} In one of these studies, 16% of DCM patients undergoing heart transplantation harboured known desmosomal ARVC mutations, and these patients were clinically and histologically indistinguishable from classical DCM.²⁹ In our study, we identified three likely pathogenic truncating *DSP* mutations in eight patients. These mutations were absent or extremely rare among controls. The truncating mutation p.Thr2104Glnfs*12 in *DSP* gene is especially interesting as we identified it in six DCM patients. Of note, three out of six patients harbouring this mutation have familial DCM, but no samples were available for segregation analysis. We have previously identified this mutation in a clinical setting in two other Finnish patients suffering either from DCM or ventricular fibrillation at childhood. In ExAC, the two out of four carriers of this mutation among over 60 000 individuals are Finnish. Originally this mutation has been described in two reports to cause early childhood-onset multiorgan disease with severe DCM combined with skin, hair, and tooth abnormalities.^{31,32} In both reports, the patients were compound heterozygous for two *DSP* mutations: both were carriers of the p.Thr2104Glnfs*12 mutation but harboured also another mutation in the *DSP* gene. Interestingly, in the study by Mahoney *et al.*³² the patient had a Finnish mother. In the other report, the family came from Swedish west coast, an area with large population of Finnish immigrants in the past. Based on previous reports, our experience from diagnostics and our

results in this study, the p.Thr2104Glnfs*12 in *DSP* could represent the first Finnish *DSP* founder mutation associated with DCM disease.

In 2012, Herman *et al.*⁵ identified *TTN* truncating mutations in 25% of familial DCM and 18% of sporadic DCM, whereas diagnostic hit rate was a bit lower (19 and 11%, respectively) in recently published European DCM cohort.¹⁰ Of note, the European DCM cohort in the study by Haas *et al.* does not include any Finnish DCM patients. In our Finn-DCM cohort, 17.2% of the patients had truncating *TTN* mutation. This accounts for 20.6 and 14.6% of the familial and sporadic DCM cases, respectively. This is slightly lower compared with the frequency reported by Herman *et al.* However, 95% of the truncating *TTN* mutations classified as disease causing in our study affect all transcripts of *TTN*, but this was not taken into consideration in the other index studies. Clinical practice has shown that co-segregation of truncating *TTN* variant is lower if it is present only in short *TTN* isoform/transcripts. Importantly, we performed family segregation analysis in five families with truncating *TTN* variants affecting all *TTN* transcripts (p.Trp29474*, p.Ser25617-Cysfs*18, p.Ala486Serfs*26, p.Gln25732*, and p.Ile20447*) and found complete segregation. Disease penetrance increased from 53.8% at age 50 to 84.6% at age 60 and 100.0% at age 70.

Patients with *TTN* truncating mutations had clinical manifestations, morbidity, and mortality that were indistinct from those with *DSP* and other gene mutation groups. In contrast, *TTN* truncating mutation carriers had clinically and statistically larger LVEDD but lower mortality, less pacemakers, resuscitation, and atrial fibrillation compared with *LMNA* mutation carriers.

Although recent studies have identified same disease-causing variants in multiple DCM families,^{33,34} majority of the disease-causing variants in our Finn-DCM cohort were unique to a family. We identified four variants present in multiple families (total 15 patients): Ser143Pro in *LMNA*, Thr2104Glnfs*12 in *DSP*, Trp20911* and Trp29474* in *TTN*; and absent or very rare in control populations (Table 3). Of note, 73% (11/15) of the patients with a recurrent variant carried no other disease-causing variant, 20% (3/15) carried a VUS, whereas only one patient had another likely pathogenic variant.

Our study demonstrates that comprehensive targeted sequencing can provide genetic diagnosis for a substantial proportion of DCM patients. The diagnostic yield is in our experience very similar to what is seen in practice with HCM patients. We suggest that the genetic aetiology of DCM patients should be sought for more vigorously. Despite the relatively high diagnostic yield, gene discovery with whole exome or genome is still needed as several families with DCM are still left without a diagnosis, suggesting that new genes are to be found. Several mutation-negative families from our cohort are already enrolled into exome sequencing to reveal novel genetic mechanisms underlying the pathogenesis of DCM.

Limitations

We were unable to perform comprehensive co-segregation analysis in many cases due to sporadic DCM and low number of family member samples in familial cases. We hope that future follow-ups and studies will bring light to this limitation.

A 35-year-old, previously healthy man, presented with a 6-month history of progressive exercise intolerance. Routine laboratory values and ECGs at rest and during exercise were inconspicuous. Transthoracic echocardiography hinted at moderate enlargement of right-sided cavities of the heart without apparent atrial septal defect (ASD).

Hence, cardiovascular magnetic resonance (CMR) imaging was performed to elucidate right-ventricular enlargement: on cine imaging right-ventricular end-diastolic volume amounted to 295 mL while regional and global RV-function were normal (*Panel B*, see Supplementary material online, *Movie S1*). Subsequent contrast-enhanced pulmonary CMR angiography revealed a partial anomalous pulmonary venous connection (PAPVC) of the right upper pulmonary vein with drainage into the superior vena cava (white arrows in *Panel A*, see Supplementary material online, *Movie S2*). Cardiovascular magnetic resonance determined left-to-right shunting yielded a $Q_p:Q_s = 1.89$ (shunt fraction, 47%). Consequently, surgical repair was recommended: an autologous pericardial patch was used to redirect the blood flow from the orifice of the anomalous pulmonary vein into the left atrium via a surgically created ASD (Warden procedure with intracardiac baffle; outlined arrow in *Panel C*, see Supplementary material online, *Movie S3*). At 3-month follow-up, the symptom-free patient presented with improved exercise capacity and CMR imaging highlighted already normalized right-ventricular dimensions (*Panel D*, see Supplementary material online, *Movie S1*).

Partial anomalous pulmonary venous connection as a rare congenital cardiac defect represents an uncommon cause of right-ventricular enlargement. While in most cases, PAPVC is associated with an ASD (sinus venosus type), an isolated PAPVC with an intact atrial septum is a very rare finding and difficult to detect on echocardiography. In order to clarify the diagnosis of patients with unexplained right-ventricular enlargement, CMR imaging consistently constitutes the method of choice.
