Heaps Are Better than Buckets: Parallel Shortest Paths on Unbalanced Graphs*

Abstract. We propose a new parallel algorithm for the single-source shortest-path problem (SSSP). Its heap data structure is particularly advantageous on graphs with a moderate number of high degree nodes. On arbitrary directed graphs with n nodes, m edges and independent random edge weights uniformly distributed in the range $[0, 1]$ and maximum shortest path weight $\mathcal{L}$ the PRAM version of our algorithm runs in $\mathcal{O}(\log^2 n \cdot \min_i\{2^i \cdot \mathcal{L} \cdot \log n + |V_i|\})$ average-case time using $\mathcal{O}(n \cdot \log n + m)$ operations where $|V_i|$ is the number of graph vertices with degree at least 2^i. For power-law graph models of the Internet or call graphs this results in the first work-efficient $o(n^{1/4})$ average-case time algorithm.

1 Introduction

The *single-source shortest-path problem* (SSSP) is a fundamental and well-studied combinatorial optimization problem with many practical and theoretical applications. However, the fast and efficient SSSP computation still constitutes a major bottleneck in parallel computing.

Let $G = (V, E)$ be a directed graph with $|V| = n$ nodes and $|E| = m$ edges, let s be a distinguished vertex of the graph, and c be a function assigning a non-negative real-valued *weight* to each edge of G. The objective of the SSSP is to compute, for each vertex v reachable from s, the weight of a minimum-weight ("shortest distance") path from s to v, denoted by $\text{dist}(s, v)$, abbreviated $\text{dist}(v)$; the weight of a path is the sum of the weights of its edges. We are particularly interested in graphs with unbalanced node degrees, i.e., the maximum node degree d is by orders of magnitude bigger than the average node degree in G.

The parallel random access machine (PRAM) [10] is one of the most widely studied abstract models of a parallel computer. A PRAM consists of P independent processors (processing units, PUs) and a shared memory, which these processors can synchronously access in unit time. We assume the *arbitrary* CRCW (concurrent read concurrent write) PRAM, i.e., in case of conflicting write accesses to the same memory cell, an adversary can choose which access is successful.

A fast and efficient parallel algorithm minimizes both *time* and *work* (product of time and number of processors). Ideally, the work bound matches the complexity of the best (known) sequential algorithm. Dijkstra's sequential approach [8] with Fibonacci heaps [11] solves SSSP on arbitrary directed graphs with non-negative edge weights in $\mathcal{O}(n \log n + m)$ time. It maintains a partition of V into *settled*, *queued*, and *unreached* nodes, and for each node v a *tentative distance* $\text{tent}(v)$; In each iteration, the queued node v with smallest tentative distance is removed from the queue, and all edges (v, w) are *relaxed*, i.e., $\text{tent}(w)$ is set to $\min\{\text{tent}(w), \text{tent}(v) + c(v, w)\}$. It is well known that $\text{tent}(v) = \text{dist}(v)$, when v is selected from the queue, hence v is settled and will never re-enter the queue. Therefore, Dijkstra's approach is a so called *label-setting* method.

Label-correcting variants may remove nodes from the queue for which $\text{tent}(v) > \text{dist}(v)$ and hence have to *re-insert* those nodes until they are finally settled. Linear average-case time for *directed* SSSP can be achieved with a sequential label-correcting approach [17], too. Label-correcting SSSP algorithms are natural candidates for parallelization: using a number of sequential priority queues, several nodes are removed concurrently in one round. A key problem is the efficient selection of a large "provably good" node set for removal.

Previous Work on Parallel SSSP. So far there is no parallel $\mathcal{O}(n \cdot \log n + m)$ work PRAM SSSP algorithm with sublinear running time for arbitrary digraphs with non-negative edge weights. The $\mathcal{O}(n \cdot \log n + m)$ work solution by Driscoll et. al. [9] has running time $\mathcal{O}(n \cdot \log n)$. An $\mathcal{O}(n)$ time algorithm requiring $\mathcal{O}(m \cdot \log n)$ work was presented by Brodal et. al. [5]. Faster algorithms require more work, e.g., the approach by Han et. al. [12] needs $\mathcal{O}(\log^2 n)$ time and $\mathcal{O}(n^3 \cdot (\log\log n / \log n)^{1/3})$ work. The algorithm of Klein and Subramanian [14] takes $\mathcal{O}(\sqrt{n} \cdot \log \mathcal{L} \cdot \log n \cdot \log^* n)$ time and $\mathcal{O}(\sqrt{n} \cdot m \cdot \log \mathcal{L} \cdot \log n)$ work where $\mathcal{L}$ is the maximum shortest path weight. Similar results have been obtained by Cohen [6] and Shi and Spencer [20].

Further work-efficient SSSP algorithms exist for random graphs [4] where each of the n^2 possible edges is present with a certain probability. Under the assumption of independent random edge weights uniformly distributed in the interval $[0, 1]$ the fastest work-efficient label-correcting approach for random graphs [18,19] requires $\mathcal{O}(\log^2 n)$ time and linear work on average; additionally, $\mathcal{O}(d \cdot \mathcal{L} \cdot \log n + \log^2 n)$ time and $\mathcal{O}(n + m + d \cdot \mathcal{L} \cdot \log n)$ work on average is achieved for arbitrary graphs with random edge weights where d denotes the maximum node degree in the graph and $\mathcal{L}$ denotes the maximum weight of a shortest path to a node reachable from s, i.e., $\mathcal{L} = \max_{v \in G, \text{dist}(v) < \infty} \text{dist}(v)$. The algorithms fail for large d. Crauser et. al. [7] gave general criteria that divide Dijkstra's label-setting algorithm into a number of phases, such that the operations within a phase can be done in parallel. The efficiency of the criteria was shown for random graphs where sublinear average-case running time can be obtained.

New Results. We propose a new parallel label-correcting SSSP approach that is particularly suited for graphs with unbalanced node degrees and an-

alyze its average-case performance on arbitrary directed graphs: Let $|V_i|$ denote the number of graph vertices with degree at least 2^i. Assuming independent random edge weights uniformly distributed in $[0,1]$, our algorithm runs in $\mathcal{O}(\log^2 n \cdot \min_i\{2^i \cdot \mathcal{L} \cdot \log n + |V_i|\})$ time on average using $\mathcal{O}(n \cdot \log n + m)$ operations. This significantly extends the class of inputs for which parallel SSSP can be solved in sublinear average-case time using only $\mathcal{O}(n \cdot \log n + m)$ work. In particular, for some random power-law graph classes which are widely considered to be appropriate models of the Internet or telephone call graphs [1,16] our algorithm is the first to achieve $o(n^{1/4})$ average-case time while still remaining work efficient. Furthermore, we sketch how to extend the average-case analysis of the parallel label-setting approach with heaps [7] from random graphs to arbitrary graphs and compare its performance with our new algorithm.

2 Preliminaries

The parallel SSSP algorithm of [18], called Δ-stepping, and its improved version [19] are label-correcting approaches that work in phases: if M denotes the smallest tentative distance in the queue data structure Q at the beginning of a phase, then they remove all nodes v with tentative distance $\text{tent}(v) < M + \Delta$ in parallel. The parameter Δ is called the *step-width*. Those nodes which are removed with non-final distance values are eventually *re-inserted* into Q. In order to bound the number of re-insertions and hence the total work, Δ must not be chosen too big. On the other hand, taking Δ too small can result in many phases, i.e., poor running times:

Lemma 1 ([18]) *Under the assumption of independent random edge weights uniformly drawn from* $[0,1]$*, the average-case number of re-insertions for an arbitrary node* v_0 *in the* Δ*-stepping algorithm is bounded by* $\mathcal{O}(1)$ *provided that* $\Delta \leq 1/d$ *for maximum node degree* d*.*

Proof: If a node v_0 was removed from Q for the first time in phase i, then a re-insertion of v_0 in phase $i+j$ can be mapped on a simple path $\langle v_j, \ldots, v_0\rangle$ such that v_k was removed in phase $i+j-k$ and the tentative distance of v_k was improved by relaxing the edge (v_{k+1}, v_k). In any case, the total weight of the path $\langle v_j, \ldots, v_0\rangle$ must be smaller than the step-width. If d denotes the maximum degree in the graph then there are at most d^l simple paths of l edges into v_0. For l independent random edge weights uniformly distributed in $[0,1]$, the probability that their sum is at most $\Delta \leq 1$ is bound by $\Delta^l/l!$. Hence, the average-case number of re-insertions for v_0 can be bounded by $\sum_1^\infty (d \cdot \Delta)^l/l! = \mathcal{O}(1)$ for $\Delta \leq 1/d$. □

Parallel node-removal is realized by using a random mapping π of node indices to a number of P sequential priority queues Q_j. Load-balancing for node removals is guaranteed with high probability (whp)[1] by the random distribution

[1] *with high probability* (*whp*) means that the probability for some event is at least $1 - n^{-\beta}$ for any constant $\beta > 0$.

provided that sufficiently many nodes are removed in parallel. Load-balancing for relaxations is done as follows: all relaxations of a phase are first grouped according to their target nodes (semi-sorting with integer keys) and for each node only the relaxation resulting in the smallest tentative distance is forwarded to its priority queue in charge [19].

The sequential priority structure for processor PU_j can be implemented by linear arrays B_j of buckets such a queued node v is kept in $B_{\pi(v)}[i]$ for tentative distances in the range $[i \cdot \Delta, (i+1) \cdot \Delta)$. Let k denote the biggest bucket index such that $B_j[0], \ldots, B_j[k-1]$ are empty for all j. Then a phase removes all nodes from $B_0[k], \ldots, B_{P-1}[k]$. After $\mathcal{O}(\log n)$ phases the smallest tentative distance in the queue has increased by at least Δ whp. This is a simple consequence of the observation that in a graph with maximum degree d and random edge weights there are no simple paths of $\Omega(\log n)$ edges and total weight at most $1/d$ whp [18]. Hence, each bucket is expanded during at most $\mathcal{O}(\log n)$ subsequent phases until it finally remains empty whp. Finding the next bucket index for deletion is done in a sequential fashion, i.e., testing k buckets takes k phases. Thus, for maximum shortest path weight $\mathcal{L}$, at least $\mathcal{L} \cdot d$ phases and at most $\mathcal{O}(\mathcal{L} \cdot d \cdot \log n)$ phases are required whp.

Based on the Δ-stepping algorithm sketched above, a sequential SSSP algorithm with average-case running time $\mathcal{O}(n+m)$ was developed [17]. Starting with buckets of width $\Delta = 1$, it builds a bucket hierarchy in the following way: before the algorithm removes all nodes from the current bucket B_{cur} of width Δ_{cur} it checks the maximum node degree d^* in B_{cur}. If $\Delta_{\text{cur}} > 1/d^*$ then it splits B_{cur} into smaller buckets of size $2^{-\lceil \log_2 d^* \rceil}$ each and continues with the leftmost non-empty bucket among those just generated. Thus, on the one hand, the average-case number of re-insertions and re-relaxations can be bounded by $\mathcal{O}(n+m)$ since nodes with high degree are exclusively expanded from buckets with sufficiently small widths; on the other hand, the number of buckets is bounded by $\mathcal{O}(n+m)$, as well, independent of the maximum shortest path weight $\mathcal{L}$. However, even though the nodes within a bucket can still be expanded in parallel, $\Omega(\mathcal{L} + \max_{v \in V} \text{ degree}(v))$ phases are required just to visit all buckets.

3 Degree Heaps

In the following we will use the idea of an adaptive step-width for an alternative data structure that avoids scanning lots of small distance intervals at little extra cost. Our new label-correcting algorithm (called Parallel Degree SSSP) uses a number of sequential priority queues and a simple method to compute an appropriate current step width. Opposite to the algorithm of [17] changing the step-width does not require restructuring of the priority queues themselves.

For a graph with n nodes we define a *sequential Degree Heap* D to be a collection of $h = \lceil \log_2 n \rceil$ *relaxed heaps* $D_1, \ldots, D_h$ such that D_i is in charge of tentative distances for nodes having in-degree in $[2^{i-1}+1, 2^i]$. A relaxed heap allows insertions and decrease_key operations in worst-case constant time, deletions of the minimum in worst-case logarithmic time [9]. There is no heap for

nodes with degree zero as they are never reached in the SSSP algorithm anyway. Let M_i be the smallest tentative distance in D_i ($M_i = \infty$ for empty D_i) and let $M = \min_i M_i$. Then we compute

$$\Delta_{\max} := \min_i \{\max\{2^{-i-1}, M_i - M\}\}. \quad (1)$$

Subsequently, for each D_i, the SSSP algorithm removes all nodes $v \in D_i$ satisfying $\text{tent}(v) < M + \Delta_{\max}$.

Property 1 *Up to a multiplicative factor of two, Δ_{max} is maximal such that for any queued node v with $\text{tent}(v) < M + \Delta_{max}$, we have degree$(v) \leq 1/(2 \cdot \Delta_{max})$.*

Proof: Consider the index i^* that minimizes (1), i.e., $\Delta_{\max} = \max\{2^{-i^*-1}, M_{i^*} - M\} < \infty$. If $M_{i^*} - M > 2^{-i^*-1}$, then $\Delta_{\max}$ was just chosen small enough in order not to remove any node from D_{i^*} for the current phase. Taking another step-width $\Delta \geq 2 \cdot \Delta_{\max} > 2^{-i^*}$ there is a node $v \in D_{i^*}$ having degree at least $2^{i^*-1} + 1$ and $\text{tent}(v) < M + \Delta$, hence $\text{degree}(v) > 1/(2 \cdot \Delta)$. Similarly, if $M_{i^*} - M \leq 2^{-i^*-1}$, then there is already a node $v \in D_{i^*}$ having degree at least $2^{i^*-1} + 1$ and $\text{tent}(v) < M + 2^{-i^*-1}$. Enlarging $\Delta_{\max}$ by a factor of two leads to the same kind of contradiction. □

Corollary 1 *Nodes of degree d are removed using step-width at most $2^{-\lceil \log_2 d \rceil - 1}$.*

Parallel Degree Heaps are obtained by having a sequential Degree Heap D^j for each processor PU_j. Again, a random mapping π is used to distribute the nodes over the sequential Degree Heaps, i.e., node v with in-degree d, $2^{i-1}+1 \leq d \leq 2^i$, is kept in the i-th heap of $PU_{\pi(v)}$, $D_i^{\pi(v)}$. The step-width computation is adapted in the obvious way by setting $M_i = \min_j M_i^j$ where M_i^j denotes the smallest tentative distance in the i-th heap of PU_j. The minimum of a relaxed heap can be determined in $\mathcal{O}(\log n)$ time, hence each PU can compute its local minima in $\mathcal{O}(\log^2 n)$ time. After that, the global minima M_i and M can be computed by standard pipelined tree-reductions in $\mathcal{O}(\log n)$ time. Finally, the new largest possible step-width is computed as the minimum of $\lceil \log_2 n \rceil$ expressions.

Lemma 2 *Each step-width computation for Parallel Degree Heaps with $P \leq n$ processors can be performed in $\mathcal{O}(\log^2 n)$ time and $\mathcal{O}(P \cdot \log^2 n)$ work.*

4 Average-Case Analysis of Parallel Degree Heaps SSSP

We exploit the correlation between the maximum degree among the nodes concurrently deleted in a phase and the applied step-width to show:

Lemma 3 *Using Parallel Degree Heaps SSSP for graphs with random edge weights uniformly drawn from $[0, 1]$, each node is re-inserted at most $\mathcal{O}(1)$ times on the average.*

Proof: Consider an arbitrary node v_0 with in-degree d_0. Let M be the minimum of all tentative distances for queued nodes in the Degree Heaps when v_0 is removed for the first time. By then, $\text{tent}(v_0) \leq M + 2^{-\lceil \log_2 d_0 \rceil - 1}$ (Corollary 1). As in the proof of Lemma 1, re-insertions of v_0 can be mapped to appropriate paths $P = \langle v_j, \ldots, v_0 \rangle$ of total weight at most $2^{-\lceil \log_2 d_0 \rceil - 1}$ such that the nodes $v_j, \ldots, v_0$ are subsequently removed from the Degree Heaps and the relaxation of their edges lead to an improvement for $\text{tent}(v_0)$.

Let d_i be the in-degree of node v_i. We can confine our analysis to *degree-weight balanced* paths $\langle v_j, \ldots, v_0 \rangle$ where $c(v_{i+1}, v_i) \leq 2^{-\lceil \log_2 d_i \rceil - 1}$. In order to see this, let k be the smallest index such that $c(v_{k+1}, v_k) > 2^{-\lceil \log_2 d_k \rceil - 1}$ for the path P above. The value of $\text{tent}(v_k)$ is already correct up to at most $2^{-\lceil \log_2 d_k \rceil - 1}$ when v_k is removed for the first time. Either, $\text{dist}(v_{k+1}) < \text{dist}(v_k) - 2^{-\lceil \log_2 d_k \rceil - 1}$, then v_{k+1} must have been settled before v_k was removed, and the edge (v_{k+1}, v_k) will never be re-relaxed again to re-insert v_k (and v_0 in the end). Or $\text{dist}(v_{k+1}) \geq \text{dist}(v_k) - 2^{-\lceil \log_2 d_k \rceil - 1}$, but then after the first removal of v_k no improvement of $\text{tent}(v_k)$ can be obtained via a relaxation of (v_{k+1}, v_k). Hence, re-insertions for v_k that could trigger re-insertions of v_0 require edges into v_k of weight less than $2^{-\lceil \log_2 d_k \rceil - 1}$.

Therefore, in order to bound the number of re-insertions for node v_0 it is sufficient to consider all sub-paths $\langle v_l, \ldots, v_0 \rangle$ into v_0 that are degree-weight balanced and have total weight at most $2^{-\lceil \log_2 d_0 \rceil - 1}$: The expected number of edges with weight at most $\min\{2^{-\lceil \log_2 d_i \rceil - 1}, 2^{-\lceil \log_2 d_0 \rceil - 1}\}$ into node v_i is bounded by $1/2$. Therefore, using elementary results of branching processes [2,13] the expected number of relevant degree-weight balanced paths having l edges can be bounded by $(1/2)^l$. Thus, the expected number of re-insertions for v_0 can be bounded by $\mathcal{O}(\sum_{l \geq 1} (1/2)^l) = \mathcal{O}(1)$. □

Theorem 1 *For graphs with random edge weights uniformly drawn from* $[0, 1]$, *Parallel Degree Heap SSSP needs* $r = \mathcal{O}(\min_i\{2^i \cdot \mathcal{L} \cdot \log n + |V_i|\})$ *phases on the average where* $\mathcal{L}$ *denotes the maximum shortest path weight and* $|V_i|$ *is the number of graph vertices with in-degree at least* 2^i. *On a CRCW PRAM it can be implemented in* $\mathcal{O}(r \cdot \log^2 n)$ *time and* $\mathcal{O}(n \cdot \log n + m)$ *work on the average.*

Proof: We fix some arbitrary integer $x \geq 0$ and consider *B-phases* having step-width bigger or equal $\Delta_x := 2^{-x-1}$ and *S-phases* having step-width smaller than Δ_x. By Lemma 3, each node is re-inserted $\mathcal{O}(1)$ times on average, and by Property 1, S-phases do only occur when a node of in-degree at least $2^x + 1$ is deleted. Hence, the expected number of S-phases is bounded by $\mathcal{O}(|V_x|)$. After $\mathcal{O}(\log n)$ B-phases the smallest tentative distance among all queued nodes, M, has increased by Δ_x whp ([18], intermediate S-phases can only increase M). Therefore, the total number of B-phases is bounded by $\mathcal{O}(\frac{\mathcal{L} \cdot \log n}{\Delta_x}) = \mathcal{O}(2^x \cdot \mathcal{L} \cdot \log n)$ whp. Altogether we need $\mathcal{O}(2^x \cdot \mathcal{L} \cdot \log n + |V_x|)$ phases on average. Since we are free to choose x, the average-case bound for all phases can be improved to $\mathcal{O}(\min_i\{2^i \cdot \mathcal{L} \cdot \log n + |V_i|\})$.

For the PRAM algorithm we use the load-balancing approach with semi-sorting from [19] where buckets are replaced by Degree Heaps: if r phases are

needed on the average then up to $\Theta(\frac{n}{r \cdot \log n})$ sequential Degree Heaps can be used in a load-balanced way. Hence, determining a new step-width takes $\mathcal{O}(\log^2 n)$ time and $\mathcal{O}(\frac{n \cdot \log n}{r})$ work for each phase by Lemma 2. Since node deletions in a Sequential Degree Heap require $\mathcal{O}(\log n)$ time (as compared to $\mathcal{O}(1)$ time for buckets), the algorithm needs altogether $\mathcal{O}(r \cdot \log^2 n)$ time and $\mathcal{O}(n \cdot \log n + m)$ work on the average. □

5 Parallel Label-Setting on Arbitrary Graphs

In this section we sketch how to improve the analysis of a previous parallel label-setting algorithm [7] that is also based on heaps. It applies an adaptive node-removal criterion, too: let $T = \min\{\text{tent}(u) + c(u,z) : u \text{ is queued and } (u,z) \in E\}$. The OUT-approach removes all queued nodes v with $\text{tent}(v) \leq T$ in one phase since these nodes cannot lead to further distance reductions.

The analysis for *random* graphs and random edge weights given in [7] is based on two observations: (1) random graphs are expanders, i.e., the priority queue is well-filled during most phases. (2) For q queued nodes, each of which having expected degree d, there is a constant probability that the $\sqrt{q/d}$ queued nodes with smallest tentative distance can be concurrently removed in one phase: Let $v_1, v_2, \ldots, v_q$ be the queued nodes in order of increasing tentative distances, and let T' be the value of T in the previous phase. The distance labels $\text{tent}(v_i)$ are random variables in $[T', T'+1]$. Their values are independent and their distributions are biased towards smaller values since they constitute the minimum of potentially many incoming path weights. The value of $\text{tent}(v_r)$ is therefore less than r/q with constant probability for arbitrary r, $1 \leq r \leq q$. The number of edges out of $v_1, \ldots, v_r$ is $\mathcal{O}(d \cdot r)$ with constant probability. Opposite to the tentative distances of queued nodes, the edge weights are not biased towards smaller values. Therefore, the shortest of these edges has length about $\frac{1}{rd}$. We remove $v_1, \ldots, v_r$ from the queue if $\text{tent}(v_r)$ is smaller than the length of the shortest edge out of $v_1, \ldots, v_r$. This is the case (with constant probability) if $r/q \leq \frac{1}{rd}$ or $r \leq \sqrt{q/d}$.

An improved analysis for arbitrary graphs with random edge weights can be based on "active edges" where all edges of a queued node are active. By the same argument as before, for k active edges, there is a constant probability that $\Omega(\sqrt{k})$ of them are concurrently removed in a single phase. Additionally, we use that $T - T' \geq \sqrt{1/k}$ with constant probability. Note that the smallest tentative distance kept in the queue, M, increases by the same amount as T. Therefore, looking at a number of consecutive phases, either M will significantly increase or many edges will be removed. Altogether, for maximum shortest path weight $\mathcal{L}$ there are at most $\mathcal{O}(\sqrt{\mathcal{L} \cdot m})$ phases that remove at least $\Omega(\sqrt{m/\mathcal{L}})$ edges each. For any of the other phases, there is a constant probability that T is increased by $\Omega(\sqrt{\mathcal{L}/m})$. However, there cannot be more than $\mathcal{O}(\sqrt{\mathcal{L} \cdot m})$ such phases because M will not exceed $\mathcal{L}$. Thus, on the average there are $\mathcal{O}(\sqrt{\mathcal{L} \cdot m})$ phases in total.

Using the OUT-approach together with the load-balancing scheme of [19], SSSP can be solved in $\mathcal{O}(\sqrt{\mathcal{L} \cdot m} \cdot \log^3 n)$ average-case time and $\mathcal{O}(n \cdot \log n + m)$ work. Hence, label-correcting SSSP with Parallel Degree Heaps is faster than the OUT-approach unless the graph contains $\Omega(\sqrt{\mathcal{L} \cdot m})$ nodes of in-degree $\Omega(\sqrt{m/\mathcal{L}})$. In that case, the average-case time of both algorithms is bounded by $\mathcal{O}(\sqrt{\mathcal{L} \cdot m} \cdot \log^3 n)$. In fact, if $\mathcal{L} \cdot m$ is very big, both algorithms require at most n phases since each phase settles at least one node whereas the Δ-stepping may take $\Omega(n^2)$ phases. On the other hand, disregarding logarithmic factors, the OUT-approach (and therefore also the Parallel Degree Heap SSSP) is faster than the Δ-stepping whenever $d^2 \cdot \mathcal{L} > m$.

6 Performance on Power Law Graphs

Many massive graphs such as the WWW graph and telephone call graphs share universal characteristics which can be described by the so-called "power law": the number of nodes, y, of a given in-degree x is proportional to $x^{-\beta}$ for some constant $\beta > 0$. For most massive graphs, $\beta > 2$. Independently, Kumar et. al. [15] and Babarasi et. al. [3] reported $\beta \approx 2.1$ for the in-degrees of the WWW graph, and the same value was estimated for telephone call graphs [1].

Graph models where the targets of edges are drawn *randomly* and the *expected* number of nodes for a certain node degree follow a power-law are widely considered to be appropriate models of real massive graphs like the WWW. For $\beta > 2$, the diameter of such graphs was shown to be $\mathcal{O}(\log n)$ whp [16]. Furthermore, for $\beta \geq 2$, the expected maximum node degree is $\Theta(n^{1/\beta})$ and $m = \mathcal{O}(n)$. Hence, assuming independent random edge weights uniformly distributed in $[0, 1]$, SSSP on WWW-like graphs with Δ-stepping requires about $\mathcal{O}(n^{1/2.1} \cdot \log^2 n) = \mathcal{O}(n^{0.48})$ time and linear work on average. The average-case execution time of the OUT-approach is about the same, $\mathcal{O}(n^{0.5} \cdot \text{polylog}(n))$.

The expected number of nodes having in-degree at least d^* is bounded by $\mathcal{O}(n \cdot \sum_{x \geq d^*} x^{-\beta})$ which for constant $\beta \geq 2$ and arbitrary $d^* \geq \beta$ can be approximated by $\mathcal{O}(n \cdot \int_{d^*}^{\infty} x^{-\beta}\, dx) = \mathcal{O}(n \cdot {d^*}^{-\beta-1})$. Thus, taking $\beta = 2.1$ and $d^* = n^{10/41}$ one expects $\mathcal{O}(n \cdot n^{-3.1 \cdot 10/41}) = \mathcal{O}(n^{10/41})$ nodes of in-degree at least d^*. Therefore, with Parallel Degree Heaps, the average-case time for SSSP on WWW-like graphs drops to $\mathcal{O}(\log^2 n \cdot (n^{10/41} \cdot \log n \cdot \log n + n^{10/41})) = o(n^{1/4})$ using $\mathcal{O}(n \cdot \log n + m)$ work.

7 Conclusions

We have given a new parallel label-correcting SSSP approach together with a data structure that efficiently supports the required operations. The provable average-case performance depends on the node degree distribution. Improved running times while retaining work-efficiency could be shown for practically important inputs with unbalanced node degrees like the WWW graph. However, for the future it would be desirable to solve the SSSP on Web-like graphs in polylogarithmic time and $\mathcal{O}(n \cdot \log n + m)$ work. Furthermore, any work-efficient

algorithm with sublinear running time that is independent of the diameter would be of great interest.
