### Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

# High-Pressure Limit Rate Rules for $\alpha$ -H Isomerization of Hydroperoxyalkylperoxy Radicals

## ABSTRACT

Hydroperoxyalkylperoxy (OOQOOH) radical isomerization is an important low-temperature chain branching reaction within the mechanism of hydrocarbon oxidation. This isomerization may proceed via the migration of the  $\alpha$ -hydrogen to the hydroperoxide group. In this work, a combination of high level composite methods - CBS-QB3, G3 and G4 - is used to determine the high-pressure-limit rate parameters for the title reaction. Rate rules for H-migration reactions proceeding through 5-, 6-, 7- and 8-membered ring transition states are determined. Migrations from primary, secondary and tertiary carbon sites to the peroxy group are considered. Chirality is

1  
2  
3 also investigated by considering two diastereomers for reactants and transition states with two  
4  
5 chiral centers. This is important since chirality may influence the energy barrier of the reaction as  
6  
7 well as the rotational energy barriers of hindered rotors in chemical species and transition states.  
8  
9 The effect of chirality and hydrogen bonding interactions in the investigated energies and rate  
10  
11 constants is studied. The results show that while the energy difference between two  
12  
13 diastereomers ranges from 0.1 - 3.2 kcal/mol, chirality hardly affects the kinetics, except at low  
14  
15 temperatures (atmospheric conditions) or when two chiral centers are present in the reactant.  
16  
17 Regarding the effects of the peroxy group position and the H-migration ring size, it is found that  
18  
19 in most cases, the 1,5 and 1,6 H-migration reactions have similar rates at low temperatures  
20  
21 (below ~830K) since the 1,6 H-migration proceeds via a cyclohexane-like transition state similar  
22  
23 to that of the 1,5 H-migration.

## 30 1. Introduction

31  
32 Hydrocarbon auto-oxidation chemistry is important in fuel combustion and atmospheric  
33  
34 processes<sup>1</sup>. At low temperatures, the oxidation chemistry of hydrocarbon fuels has been detailed  
35  
36 previously<sup>2-4</sup> and is shown in Figure 1; it is initiated by H-abstraction from the fuel to form  
37  
38 radicals, which undergo a series of O<sub>2</sub> additions (1st and 2nd O<sub>2</sub> additions) and isomerizations  
39  
40 that eventually form hydroperoxyalkylperoxy radicals (OOQOOH). OOQOOH can isomerize via  
41  
42 the intramolecular migration of a hydrogen atom from the  $\alpha$ -carbon to the hydroperoxide group  
43  
44 (i.e.,  $\alpha$ -H isomerization), ultimately leading to a ketohydroperoxide (KHP) and an OH radical.  
45  
46 The weak O–OH bond in the ketohydroperoxide then breaks to form OH and a ketoalkoxy  
47  
48 radical. This sequence of chain branching reactions is the reason for low-temperature reactivity  
49  
50 leading to chemical and thermal runaway. This work focuses on the low temperature oxidation  
51

chemistry of *n*-<sup>5-6</sup> and iso-alkanes<sup>7-10</sup>, which are important components in diesel<sup>11</sup> and gasoline<sup>12</sup> fuels; however, similar pathways are also important in cycloalkanes<sup>13-14</sup>.

**Figure 1.** Low temperature oxidation scheme of alkyl radical

OOQOOH radicals are important intermediates in low temperature oxidation chemistry for most conventional fuels<sup>1, 15</sup>. The  $\alpha$ -H isomerization reactions of OOQOOH to KHP and hydroxyl radicals have previously been studied<sup>16-20</sup>. However, only Miyoshi<sup>17</sup> considered the rates where the peroxy is positioned at a tertiary site, and none of these studies investigated the effect of chirality on the calculated rates. Previous work has shown that the competition between standard  $\alpha$ -H isomerization reactions and alternative isomerizations determines if molecules can undergo extensive auto-oxidation leading to highly oxygenated intermediates<sup>1, 21-24</sup>.

Curran et al.<sup>25-26</sup> assigned the rates for the OOQOOH isomerization by analogy to RO<sub>2</sub> isomerization. A correction factor of -3 kcal/mol was added to the activation energy in order to account for the weakness of the C-H bond at the  $\alpha$ -site. Moreover, the pre-exponential factor is multiplied by a factor of 0.5 to account for the OOH steric hindrance. However, Sharma et al.<sup>16</sup> calculated the rates of RO<sub>2</sub> and OOQOOH isomerization pathways and showed that the difference in the activation energy between the two channels ranged from 0 to 8.6 kcal/mol for different reactions and thus, the 3 kcal/mol reduction in activation energy was not a valid assumption. Meanwhile, Miyoshi<sup>17</sup> proposed rate rules, calculated at the CBS-QB3 level of theory, for the unimolecular reactions of RO<sub>2</sub>, QOOH, and OOQOOH radicals with different possible alkyl substitutions. Miyoshi<sup>17</sup> considered the OOQOOH site specific isomerization

1  
2  
3 rates based on the nature of both the abstracted hydrogen and the abstracting peroxy group. A  
4 recent study by Yao et al.<sup>18</sup> suggested that rate rules calculated based on the minimum-sized  
5 representative OOQOOH radical as previously considered<sup>16-17</sup> might be inaccurate, thus, they  
6 provided rate rules obtained by averaging the rates of a few representative reactions calculated  
7 using a non-standard CBS-QB3 method modified with MP2 for geometry optimization. They  
8 calculated the high-pressure-limit and pressure dependent rate rules for both standard and  
9 alternative OOQOOH isomerization, where the former abstracts the hydrogen at the  $\alpha$ -site to the  
10 OOH group, leading to KHP+OH, and the latter abstracts any other hydrogen.

OOQOOH isomerization was also considered by Goldsmith et al.<sup>19</sup> and Asatryan et al.<sup>20</sup>,  
where they studied the potential energy surface of R+O<sub>2</sub> and QOOH+O<sub>2</sub> for n,i-propyl and 2-  
pentyl radicals, respectively. They thoroughly discussed the potential energy surface and showed  
that the OOQOOH isomerization to KHP+OH is the dominant chain branching reaction at low  
temperatures (below 1000 K)<sup>19-20</sup>.

Bugler et al.<sup>27</sup> evaluated the effect of OOQOOH isomerization rate constants calculated by  
Miyoshi<sup>17</sup> and Sharma et al.<sup>16</sup> on the ignition delay times of pentane isomers. They showed that  
Sharma's rate coefficients yield better agreement with experimental ignition delay data. Bugler  
et al.<sup>27</sup> attributed this to the coupled hindered rotor treatment implemented by Sharma et al.<sup>16</sup> in  
order to account for hydrogen bonding (HB) conformers, which may present in the OOQOOH  
radicals. However, Davis et al.<sup>28</sup> showed that the HB conformer, in structurally similar  
hydroxyalkoxy radicals, is not always the most favorable structure, particularly when the  
destabilizing effect of the ring strain imposed by hydrogen bonding is greater than the stabilizing  
effect resulting from the hydrogen bond. Chirality further complicates the effect of hydrogen  
bonding on OOQOOH stability.

1  
2  
3 For stable molecules with two chiral centers, four diastereomers can be formed, which can be  
4 separated into two groups: *mixed* chirality (RS, SR), and *same* chirality (RR, SS). For structures  
5 with two or more chiral centers, chirality affects the number and type of dihedral interactions,  
6 which in turn can affect the rotational barrier, and therefore the calculated A-factor. Moreover,  
7 the gauche/anti interactions between the substituents of the chiral center can affect the barrier  
8 heights<sup>29</sup>.

9  
10  
11  
12  
13  
14  
15  
16  
17 In transition states, chirality exists when abstracting from secondary sites of OOQOOH  
18 radicals when abstracting from  $\alpha$ -site to the OOH group. Additionally, H-migration from a  
19 primary carbon (C-OOH) can create a pseudo-chiral center, since abstracting either of the two  
20 primary hydrogens yields different axial/equatorial arrangements in the transition state. Chirality  
21 in transition states can be described by the configuration of the substituent, or the remaining  
22 alkyl chain, which is not involved in the migration ring (alkyl group, hydroperoxide group or  
23 hydrogen). For non-planar ring structures, this substituent can either be in the axial or equatorial  
24 position relative to the transition state ring, as illustrated in Figure 2.

40 **Figure 2.** Chirality in transition states

41  
42  
43 Davis and Francisco<sup>30</sup> showed that chirality can result in as much as a 1.8 kcal/mol difference  
44 in activation energies for 1,5 and 1,6 H-migration in alkyl radicals. They also studied in detail<sup>29</sup>  
45 the effect of the branched methyl group on the rate coefficients and enthalpies of H-migration  
46 reactions for a series of methylalkyl radicals from C3 to C7. They found that for the 1,5 and 1,6  
47 H-migration transition states the barrier for the equatorial configuration was lower than the axial  
48 configuration. This is because the axial position of the alkyl group results in gauche interaction  
49  
50  
51  
52  
53  
54  
55

1  
2  
3 with the transition state ring while the equatorial was anti. The axial configuration destabilized  
4 the transition state by 0.8 kcal/mol and resulted in a higher energy barrier.  
5  
6

7  
8 In their study, Davis and Francisco <sup>29</sup> found that the rates of alkyl isomerization reactions  
9 proceed via transition states wherein the alkyl groups in an equatorial position are 2-6 times (and  
10 sometimes an order of magnitude) faster than those where the alkyl group is in an axial position.  
11  
12 If such differences are not taken into consideration, the rate rule estimates will be inaccurate.  
13  
14  
15

16  
17 Chirality also has an effect on OOQOOH isomerization; however, this effect has not been  
18 previously reported in the literature. In the case of OOQOOH isomerization, the terminal  
19 substituent is a hydroperoxide (OOH) group. For isomerization transition states, the axial  
20 position of the OOH group may result in HB, which stabilizes the transition state and potentially  
21 lowers the barrier. This could lead to faster rates for the axial rather than the equatorial  
22 configuration. Therefore, it is important to study the effect of chirality on OOQOOH  
23 isomerization.

32  
33 This work aims to determine the rate parameters for OOQOOH radical isomerization reactions.  
34 Detailed conformational analysis is conducted, and the effects of chirality and hydrogen bonding  
35 on the calculated rates are assessed. Isomerization via five-, six-, seven- and eight-membered  
36 ring transition states, with all possible positions of the peroxy and the H-abstraction sites  
37 (primary, secondary or tertiary), are considered and tunneling corrections are applied. The  
38 obtained results are compared to the rates available in the literature for similar reactions.

## 46 2. Methods

47  
48  
49 Geometry optimization and frequency calculations of all reactants, products and transition  
50 states were performed using the Gaussian09 <sup>31</sup> suite of programs. Two diastereomers were  
51 considered for species with two chiral centers: one with mixed chirality (RS or SR), and another  
52  
53  
54  
55

1  
2  
3 with the same chirality (RR or SS) at both centers. All possible conformations of all species and  
4 transition states were determined using the B3LYP/6-31+G(d,p) method. Additional geometry  
5 optimizations at the B3LYP/6-311++G(2df,2pd) were carried out for all conformations that are  
6 within 0.5 kcal/mol of the minimum conformer. Frequency calculations were carried out at the  
7 same level of theory, and a scaling factor of 0.9679 was applied<sup>32</sup>. More accurate energies of the  
8 optimized lowest energy conformers were calculated using the CBS-QB3, G3 and G4 composite  
9 methods<sup>33-35</sup>. The reported enthalpies of formation are the average of six values calculated at the  
10 CBS-QB3, G3 and G4 levels of theory using two sets of isodesmic reactions<sup>36-38</sup> for each  
11 species where the auxiliary thermochemistry is adopted from ATcT tables<sup>39</sup> and NIST  
12 WebBook<sup>40</sup> (further details in supplementary material). Somers and Simmie<sup>41</sup> reported a two  
13 times root mean squared deviation (an approximate 95% confidence interval) of 1.2 kcal/mol,  
14 compared to ATcT values, for the average of CBS-QB3, G3 and G4 atomization values for  
15 radicals. The use of isodesmic reactions can reasonably be expected to further improve this  
16 value. Transition states were confirmed by the presence of a single imaginary frequency  
17 corresponding to the reaction path, as well as IRC calculations performed at the B3LYP/6-  
18 31+G(d,p) level of theory. The 1D hindered rotor treatment was applied using the Pitzer and  
19 Gwinn method<sup>42</sup>. Relaxed scans in 10° increments of all hindered rotors were calculated at the  
20 B3LYP/6-31+G(d,p) level of theory (further details in supplementary material). Tunneling  
21 corrections were included using the Eckart method and barrier width values from IRC  
22 calculations. Rate parameters were determined using classical transition state theory (CTST),  
23 which overestimates rate constants compared to variational transition state theory (VTST)<sup>43</sup>. The  
24 latter is up to three times more accurate at high temperatures (1000-1500K)<sup>44-45</sup>. However,  
25 VTST is computationally expensive for the relatively large systems considered in this study, and

1  
2  
3 the OOQOOH isomerization reaction is more prone to occur at low temperatures (below 900K).  
4  
5 Therefore, we used CTST, as implemented in ChemRate<sup>46</sup>. The optimized geometries and scaled  
6  
7 frequencies calculated at the B3YLP/6-311++G(2df,2pd) were used as input for ChemRate,  
8  
9 along with the averaged energies (averages of values calculated at the CBS-QB3,G3, and G4  
10  
11 levels of theory). The rotational energy barriers for every hindered rotor were also used as input  
12  
13 for ChemRate. These values, along with the Eckart tunneling factors, were obtained from  
14  
15 calculations conducted at the B3LYP/6-31+G(d,p) level of theory. The resulting rates were fit to  
16  
17 a three parameter modified Arrhenius equation over the temperature range of 300-1500 K. These  
18  
19 calculations were performed for the species shown in Figure 3.  
20  
21  
22  
23

24 Hydrogen migration can be described as *a,b* H-migration, where *a* is the location of the  
25  
26 migrated hydrogen and *b* is the location of the abstracting peroxy radical. Alternatively, the  
27  
28 migration can be described as *NCD*, where *N* is the number of components or atoms in the  
29  
30 transition state ring, including the hydrogen. *C* and *D* represent the chemical nature (*P* = primary,  
31  
32 *S* = secondary, and *T* = tertiary) of the carbon sites of the OOH and OO group, respectively. *R*  
33  
34 and *S* subscripts will be added to the *C* and/or *D* to indicate the chiral nature of the carbon sites.  
35  
36 Where applicable, transition state chirality will also be indicated by the superscript *A* or *E* to  
37  
38 signify axial or equatorial substitution, respectively. Both the *a,b* H-migration and *NCD*  
39  
40 notations will be used to highlight different aspects of the reactions.

### 3. Results and discussion

#### 3.1 Lowest energy conformers:

The most stable conformers of reactants, transition states and products for hydroperoxyalkylperoxy reactions must be selected carefully due to the presence of the oxygenated sites that might introduce HB interactions. The minimum energy conformers were explored by rotating all dihedrals of the molecule by  $120^\circ$  at the same time, which leads to  $3^n$  conformers, where  $n$  is the number of rotors. For transition states where less rotors are available, smaller increments were used for the C-OOH and O-OH bonds (eg.  $60^\circ$ ) to capture different possibilities of HB or NHB conformers. The effect of chirality in the minimum energy conformer was also investigated. In this section, the energy values reported to compare HB and NHB structures are calculated at the B3YLP/6-311++G(2df,2pd) level of theory while the values of the heat of formation of axial and equatorial transition states are calculated using an average of isodesmic reactions for energies calculated at the CBS-QB3/G3/G4 composite methods.

For the reactant of 5CD, where the oxygenated sites are in alpha positions to each other and either C or D is on a primary carbon, the molecule forms HB where the hydrogen in the

1  
2  
3 hydroperoxide group interacts with an oxygen in the peroxy group and stabilizes the molecule.  
4  
5 Previous studies reported that decreases in energy resulting from HB can range from 1.5-4 kcal  
6  
7<sup>28, 47</sup>. The effect of this energy stabilization on the kinetics will be discussed in a separate study.  
8  
9

10 NSS reactants have two chiral centers, resulting in four different stereoisomers (RR, RS, SR  
11 and SS). Due to symmetry, the conformer and its mirror image (RR and SS) or (RS and SR) have  
12  
13 the same kinetic and thermodynamic properties. Therefore, the most stable diastereomers were  
14  
15 used: one with mixed chirality (RS or SR) and the other with the same chirality (RR or SS) at  
16  
17 both centers. In the text to follow, the terms *mixed* and *same* chirality will refer to RS (or SR)  
18  
19 and RR (or SS) conformers, respectively. In *5SS* the mixed chirality diastereomer,  $5S_S S_R$ , forms  
20  
21 HB, while the same chirality diastereomer,  $5S_R S_R$  does not, as seen in Figure 4,a and 4.b. The HB  
22  
23 conformer of  $5S_R S_R$  (Figure 4,b) is 0.1 kcal/mol less stable than the NHB conformer. For  
24  
25 reactants with one chiral center, such as *5ST*, each conformer is a mirror image of its  
26  
27 stereoisomer. *5ST* favors the NHB conformer, which is only 0.1 kcal/mol more stable than its HB  
28  
29 counterpart.  
30  
31  
32  
33  
34

35 As the oxygenated sites *C* and *D* are further separated (e.g. beta, gamma or delta to each  
36  
37 other), there is a rising steric cost for forming HB ring structures, due to the increasing number  
38  
39 of gauche interactions inside the ring. The energy cost of this steric effect may be greater than  
40  
41 the stabilizing effect of the HB, resulting in lower energy for the NHB conformer, except in the  
42  
43 case of  $6S_R S_S$  and *6PT* as in Figure 4,c and 4,d.  
44  
45  
46

47 HB is the most stable conformer for the products when the carbonyl and the hydroperoxide  
48  
49 groups are alpha, beta, gamma and delta position relative to each other. Special cases are *5ST*,  
50  
51 *6PP*, *6SP*, and *6SS* where the NHB is the most stable structure by 1.6, 2.4, 1.0 and 2.4 kcal/mol,  
52  
53 respectively. The HB conformer of the *5ST* comprises two alkyl gauche interactions compared to  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 one gauche interaction for the NHB, making the latter more favorable. For *6PP* and *6SP*, primary  
4  
5 OOH prefers to be in anti instead of gauche position in the HB conformer. In *6SS*, the HB  
6  
7 structure is less favorable due to the high steric effect resulting from the gauche interaction  
8  
9 between C1 and C4, which makes the NHB structure, where C1 and C4 are in the anti position  
10  
11 the most stable conformer, as seen in Figure 4,e and 4,f.  
12  
13

14  
15 As mentioned previously, all transition states contain at least one chiral center. Both  
16  
17 diastereomers (R and S/mixed and same chirality) are considered. Chirality in the transition  
18  
19 states will be differentiated by whether the terminal chain, or substituents (which are not  
20  
21 involved in the transition state), are axial  $N^A CD$ , or equatorial  $N^E CD$ , to the transition state ring  
22  
23 structure. In 1,4 H-migration, the cyclopentane transition state structure is close to planar and  
24  
25 less puckered, which makes chirality less defined by axial and equatorial configuration. For  
26  
27  $5^E CD$ , the OOH is sterically unable to form HB. In  $5^A SP$ ,  $5^A SS$  and  $5^A ST$ , where the C-OOH is a  
28  
29 secondary carbon, HB conformers are lower in energy than the NHB ones, while in primary C-  
30  
31 OOH ( $5^A PP$ ,  $5^A PS$ ,  $5^A PT$ ), the OOH group is not sufficiently axial to form an HB conformer.  
32  
33 This is because the co-substituent (hydrogen) is not strong enough to push the OOH to a full  
34  
35 axial position; therefore the NHB conformer is more stable.  
36  
37  
38

39  
40 For  $N^A CD$  and  $N^E CD$ , where N=6 and 7, the NHB is the minimum energy conformer. In  
41  
42  $N^A CD$ , the high strain imposed by bringing the OOH and the OO groups close enough to form  
43  
44 HB, as well as the great distance between the H and O (3-3.7 Å) makes NHB the more stable  
45  
46 conformer. On the other hand,  $8^A CD$  transition states tend to form HB conformers that comprise  
47  
48 a flexible cycloheptane-like ring, in which the C-H..O angle is approximately  $180^\circ$  where H is  
49  
50 the migrating hydrogen, as shown in Figure 4,g. The flexibility of the cycloheptane ring structure  
51  
52 overcomes its high ring strain and favors the HB structure<sup>28</sup>.  
53  
54  
55

1  
2  
3 In terms of chirality, Table 1 shows that the difference in heat of formation between the  
4 diastereomers of 1,4 and 1,5 H-migration ranges from 0.1 to 0.9 kcal/mol. This difference  
5 increases up to 1.7 and 2.8 kcal/mol for 1,6 and 1,7 H-migration, respectively. Negative values  
6 indicate that the axial substituent (OOH group) is more stable than the equatorial conformer. In  
7 most cases, where the axial forms a HB, the axial is expected to be more stable. Exceptions are  
8 the *5PP*, *5PS*, *5PT*, *7PS* and *8PS*, where the axial primary OOH group is unable to form HB,  
9 making the equatorial a more stable conformer. In *8SS*, the mixed and same chirality transition  
10 states are *8S<sub>R</sub>S<sub>S</sub>* and *8S<sub>R</sub>S<sub>R</sub>*, where the OOH group is in axial configuration (R) in both transition  
11 states. Therefore, the most stable conformer in this case, will be determined based on the chiral  
12 nature of the peroxy site, or the configuration (axial or equatorial) of the CH<sub>3</sub> substituent. In  
13 *8S<sub>R</sub>S<sub>S</sub>*, the terminal CH<sub>3</sub> is axial to the transition state, forming a gauche interaction with the  
14 remaining alkyl chain and destabilizing the transition state, while the terminal CH<sub>3</sub> in *8S<sub>R</sub>S<sub>R</sub>* is  
15 equatorial and in an anti-position to the transition state backbone, which makes the equatorial  
16 *8S<sub>R</sub>S<sub>R</sub>* more stable. In *5SS*, the *5<sup>E</sup>SS* is the more stable conformer due to the less strained  
17 transition state ring, in addition to the absence of the gauche interaction between the peroxy and  
18 the hydroperoxide groups compared to *5<sup>A</sup>SS*. The effect of this difference in the rate constant is  
19 discussed in a subsequent section (3.3.4).

<sup>1</sup> In *NPD*, primary C-OOH is not a chiral center. R and S reflect the chirality of the transition state where two migrated hydrogens are distinguishable, resulting in a pseudo chiral center at the primary site.

2 A and E refer to a methyl group substituent of C-OO.

### 3.2 Energy calculations

The reported energies are averages of the values calculated using CBS-QB3, G3 and G4 methods, as recommended by Somers and Simmie<sup>41</sup>. Table 2 summarizes the energy barriers,  $\Delta H^\ddagger$ , of the investigated reactions. The enthalpies of formation of all species and transition states are estimated using an average of two sets of isodesmic reactions, as detailed in Supplementary Material. Somers and Simmie<sup>41</sup> showed that the CBS-QB3 and G3 methods tend to underestimate the enthalpy of formation compared to experimental values with a wider error distribution for the former; whereas G4 overestimates the predicted values compared to the experimental values. They showed that averaging the three methods results in better agreement with the experimental values. Table 2 shows that CBS-QB3 underestimated the energy compared to the averaged value, where G3 and G4 methods overestimated the enthalpy and the barrier.

Table 2 shows that the energy barriers of the investigated reactions decrease with increasing ring size. The 1,4 H-migration proceeds via a strained cyclopentane-like ring, which leads to a high energy barrier. The seven-member ring transition state of the 1,6 H-migration is expected to be higher in energy than that of the 1,5 H-migration, due to higher ring strain. However, the two values are similar, with the energy barrier of 1,6 H-migration being slightly lower than that of 1,5 H-migration. This is because the migrating hydrogen in the 1,6 H-migration is located between the abstracting oxygen and the abstraction carbon site (C-H...O~180°), which leads to a cyclohexane-like transition state. For the 1,7 H-migration, as mentioned earlier, the flexibility of the cycloheptane-like transition state ring allows for rearrangement to lower energy conformers. This flexibility will result in a more stable transition state due to the induced HB interaction and therefore, a low barrier for the 1,7 H-migration.

**Table 2.** Reaction barriers ( $\Delta H^\ddagger$ ) calculated at CBS-QB3, G3, G4 and the averaged value.

### 3.3 High pressure rate rules:

#### 3.3.1 Rate constants of OOQOOH isomerization to KHP+OH

High pressure limit rate constants are fitted to the single modified Arrhenius equation, over the temperature range of 300–1500 K, using the transition state theory

$$k(T) = \kappa(T)AT^n e^{-E_a/RT}$$

where A is the frequency factor, n is the temperature fitting parameter, T is temperature,  $E_a$  is the activation energy and  $\kappa(T)$  is the transmission coefficient used to correct for tunneling. The frequency factor A, is an indication of the entropic difference between the transition state and the reactant  $\Delta S^\ddagger$ . The rate constants are calculated for a minimum-sized representative reaction, and are detailed in Table 3 on a per hydrogen basis.

**Table 3.** High pressure limit rate parameters for OOQOOH isomerization reaction fit between 300 K and 1500 K, per hydrogen basis.

<sup>1</sup> E<sub>a</sub> is in kcal/mol

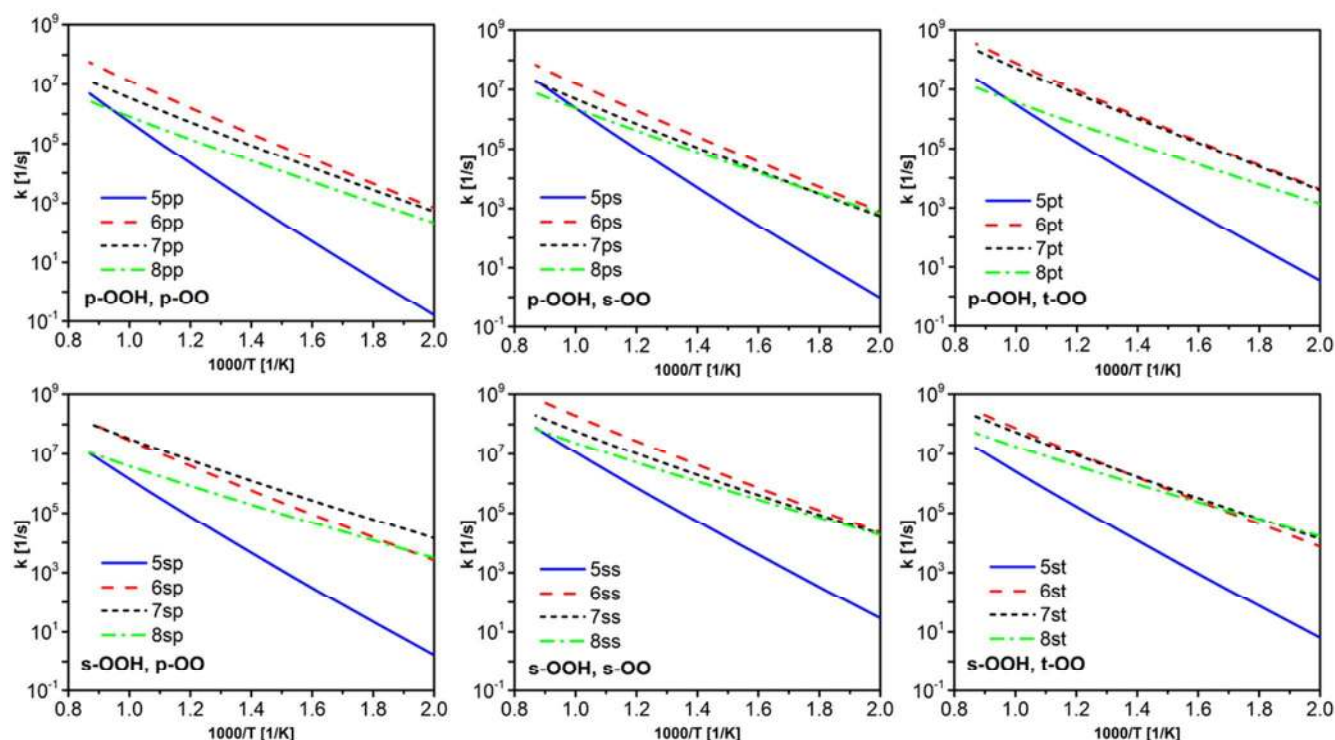

<sup>2</sup> The rates are an average of the rates with same and mixed chirality of the transition states (N-PS/N-SS) and reactant (N-SS). The mixed and same chirality rates are detailed in the Supplementary Material.

### 3.3.2 Effect of the transition state ring size:

The temperature dependence of the calculated rate constants is shown in Figure 5. Although the barrier heights of 1,5 H-migration are greater than or equal to the those of 1,6 H-migration, as shown in Table 1, the rate constants of these reactions do not always follow the same trend. This indicates the importance of the A-factor or the entropic term, which is a function of the number of rigid rotors in the transition state ring. The rate constants of 1,5 H-migration reactions are almost of the same magnitude or slightly lower than their 1,6 H-migration counterparts. As mentioned earlier, both six- and seven-member rings proceed via a cyclohexane-like transition state ring, and thus, they have similar rate constants. However, at high temperatures, six-

membered ring reactions are faster than its seven-membered ring counterpart, due to the fact that more rotors are locked to form the seven-membered ring transition state, which reduces the entropy and thus, the A-factor for the seven-membered ring reaction. 1,4 H-migration reactions proceeds via the slowest rates due to the relatively high ring strain in the corresponding five-membered ring transition states. Moreover, the rate constants of 1,4 H-migration exhibit stronger temperature dependence than either 1,5 or 1,6 H-migration. The rates for 1,7 H-migration are slower than the 1,5 and 1,6 H-migration, although they have the lowest barrier. This is likely due to the 1,7 H-migrations tying up more rotors in their eight-member ring transition states.

### 3.3.3 Effect of the peroxy position

The kinetics of H-migration in OOQOOH depend on the chemical nature of the abstraction site (H being abstracted from primary or secondary carbon) as well as that of the peroxy group. Moreover, the stability of the transition states depends on the substituents at both reacting carbon centers that may introduce gauche interactions. Figure 6 shows the effect of different peroxy position where it can be *P*, *S* or *T*. When the peroxy group is in a primary site (Blue solid lines), the rates are generally up to an order of magnitude slower due to the absence of gauche interactions in the reactant molecules, which renders them more stable. When the peroxy group is in a secondary or tertiary position, the rates depend on the chemical nature of the OOH site. For example, *6PT* is faster than *6PS*; although the reaction barrier of the latter is 0.9 kcal/mol lower. This is attributed to the HB nature of the *6PT* reactant, which increases the rotational barrier and the entropy, thus yielding faster rates for *6PT* relative to *6PS*. On the other hand, *5SS* is faster than *5ST*. This refers to the two gauche interactions present between the terminals for *5ST*, compared to zero or one gauche interaction in *5SS*. These gauche interactions alter the rotational barrier which affects the A-factor. The directionality of the substituents in the transition state also affects the A-factor, where axial and equatorial result in different interactions and rotational hindrance. This will be discussed in more detail in the section that follows.

**Figure 6.** Effect of peroxy position on rate constants. The legend in each plot follows the NCD nomenclature, where  $N$  is the ring size,  $C$  and  $D$  are the type of the C-OOH and C-OO respectively

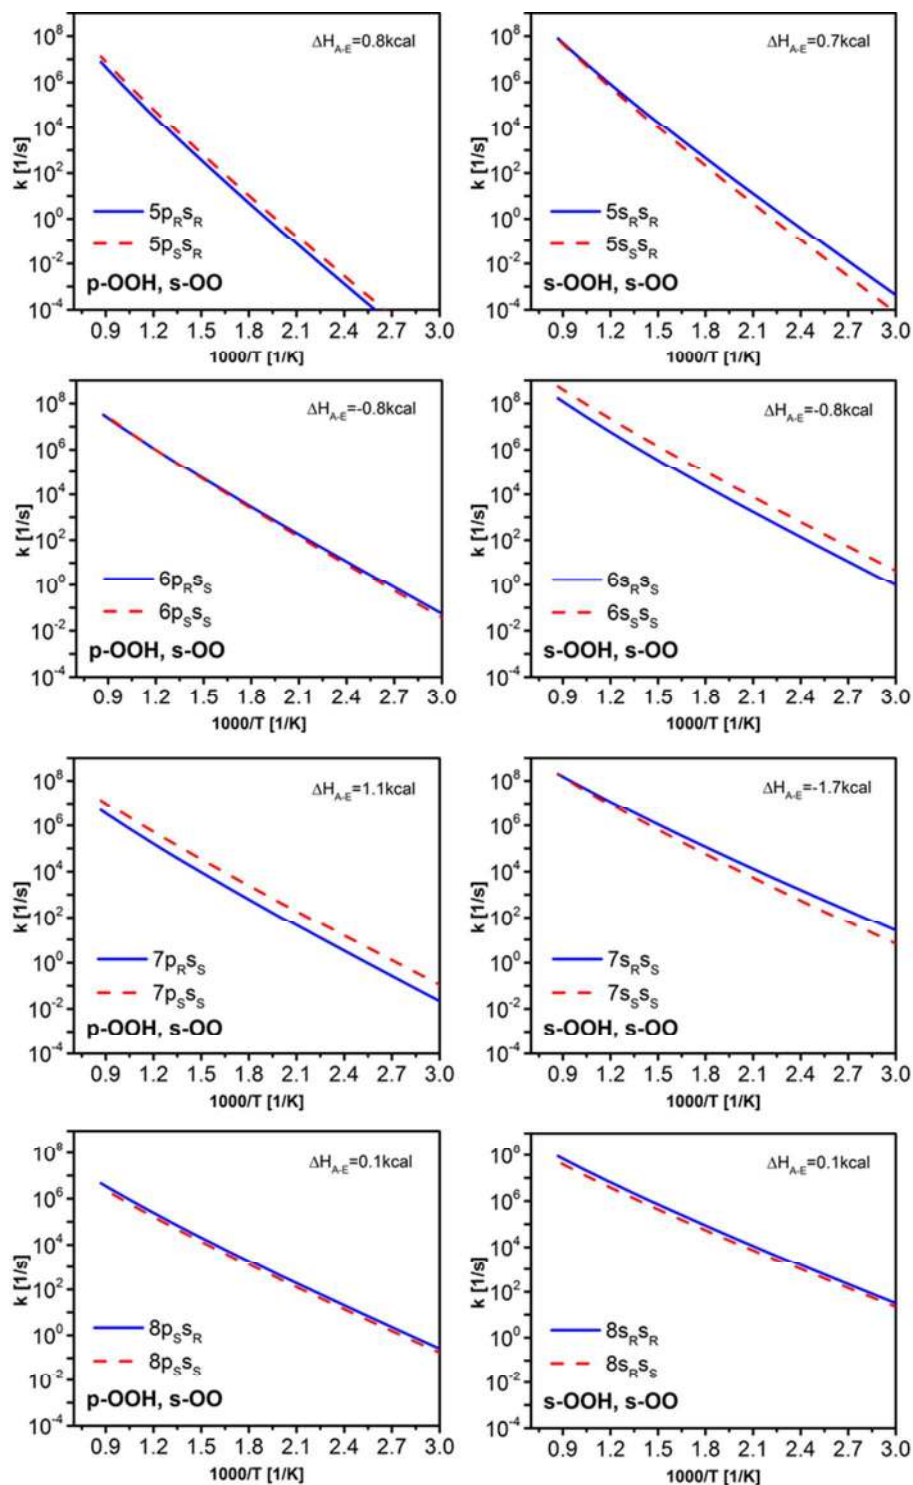

### 3.3.4 Effect of chirality

Chirality was observed for both reactants and transition states. In this study, only NSS reactants have two chiral centers. Meanwhile, transition states of the investigated reactions have only one chiral (or pseudo-chiral) center, except for those of NPS and NSS species, which have two chiral (or pseudo-chiral) centers. For transition states with one chiral center, the two conformers (R or S) are mirror images.

To study the effect of chirality on kinetics, only the reactants and transition states with two chiral centers (NPS and NSS) are investigated. As mentioned earlier, the two conformers of the same chirality (RR and SS) are mirror images to each other, as are the two mixed (RS and RS) conformers. Therefore, only one conformer of each pair is considered and used to obtain the specific rate constants, as in Figure 7. For NPS, the differences in rates are merely a function of the energy difference between the mixed and same chirality conformers of transition states. The

1  
2  
3 energy difference (shown in Table 1) is below 1 kcal/mol for 1,4, 1,5 and 1,7 H-migrations while  
4  
5 it is slightly higher (1.2 kcal/mol) for 1,6 H-migration. Therefore, in *NPS* the major difference in  
6  
7 rates is observed for the 1,6 H-migration. On the other hand, for *NSS*, two chiral centers exist in  
8  
9 the reactants and transition states. Thus, the rates are calculated for the mixed (or same) chirality  
10  
11 using matching mixed (or same) chirality conformers in both the reactant and the transition  
12  
13 states. This has resulted in a more pronounced effect of chirality on rate constants, which can be  
14  
15 as much as an order of magnitude under atmospheric conditions, especially for *6SS*.

**Figure 7.** Effect of chirality on rate constants. The legend in each plot follows the NCD nomenclature, where N is the ring size, C and D correspond to the type of C-OOH and C-OO, respectively. R and S subscripts indicate the chiral nature of the carbon.

### 3.4 Comparison with the literature

For the purpose of comparison to literature values, the rate constants calculated in this study for mixed and same chirality species and transition states are averaged. Our values are compared to those calculated at the CBS-QB3<sup>16-17</sup> and modified CBS-QB3(MP2)<sup>18</sup> levels of theory.

General comparisons (Figure 8-11) show that better agreement is found for smaller ring size transition states than for larger ring sizes. This is due to larger systematic error associated with bigger molecules, especially when atomization reactions are used instead of isodesmic reactions. For the 1,4 H-migration, as shown in Figure 8, the calculated rates are in very good agreement with those of Sharma et al.<sup>16</sup> and Miyoshi<sup>17</sup>, with discrepancies up to one order of magnitude at high temperatures in the case of the *5PS* reaction. Disagreement at high temperatures is mainly due to the entropic effects resulting from the different HR treatment performed by Sharma et al.<sup>16</sup>. Yao et al.<sup>18</sup> reports site-specific rates for certain *NCD* reactions and an average rate rule intended for use in kinetic models. The site-specific rates reported by Yao et al.<sup>18</sup> are much faster (1 to 3 order of magnitude) than those calculated in this study, as well as those reported by Sharma et al.<sup>16</sup> and Miyoshi<sup>17</sup>. This may be attributed to the differences in activation energy resulting from the CBS-QB3(MP2) level of theory used for energy calculation. Yao et al.<sup>18</sup> suggested this method to optimize a di-hydroperoxidealkylradical  $P(OOH)_2$ , without considering the rapid decomposition to ketohydroperoxide and OH. Also, the enthalpy of formation was estimated using the atomization method. Discrepancies are also observed between A-factors calculated in this study and those reported by Yao et al.<sup>18</sup>. Such discrepancies are probably due to the fact that Yao et al.<sup>18</sup> did not calculate the energy barriers for all hindered rotors in the investigated species and transitions states. Instead, they calculated these barriers for representative rotors, and then used the same values for other rotors.

1  
2  
3 For the 1,5 H-migration, the calculated rates agree well with those of Miyoshi <sup>17</sup>, but not with  
4 those reported by Sharma et al. <sup>16</sup> as shown in Figure 9. The discrepancy is seen at low  
5 temperatures, suggesting that tunneling may be the cause. Sharma et al. <sup>16</sup> use the Wigner  
6 method that underestimates tunneling corrections, leading to lower rates compared to those  
7 calculated by Miyoshi <sup>17</sup> and in this study where the Eckart tunneling method is adopted.  
8  
9

10  
11  
12 For the 1,6 H-migration (Figure 10), good agreement with Miyoshi <sup>17</sup> is observed, except for  
13 *7PT*, *7SS* and *7ST*. Similar slopes suggest that the major source of discrepancy is not the  
14 activation energy, but the entropic term. Miyoshi <sup>17</sup> did not calculate the hindered rotor barriers  
15 for all rotors. Instead, they used a representative rotational barrier for some rotors. Yao et al. <sup>18</sup>  
16 followed the same procedure which, along with the invalidated CBS-QB3(MP2) method used for  
17 the energy calculations, resulted in the notable discrepancy. Also for 1,6 H-migration, the rates  
18 reported by Sharma et al. <sup>16</sup> are close to an order of magnitude slower than the calculated rates,  
19 especially at high temperatures, which might be attributed to the entropic effects and the coupled  
20 hindered rotor treatment adopted by Sharma et al. <sup>16</sup>. Furthermore, the transition states  
21 considered by Sharma for the 1,6 H-migration reactions (eg. *7PS*, *7SP* and *7SS*) are different than  
22 the most stable cyclohexane-like conformers determined this study. The greater ring strain of the  
23 transition states considered by Sharma results in higher barriers, and ultimately, slower rates  
24 compared to the ones obtained in this work.  
25  
26  
27

35  
36  
37  
38  
39  
40  
41  
42  
43

44  
45 The greatest discrepancy between the calculated rates and those available in the literature is  
46 observed for 1,7 H-migration site specific rates, except for *8SP* and *8PP*, where the calculated  
47 rate for the former is in very good agreement with those of Sharma et al. <sup>16</sup> and Miyoshi <sup>17</sup>. In the  
48 case of *8PP*, the rates are in a good agreement with Miyoshi <sup>17</sup>, while the disagreement with  
49 Sharma et al. <sup>16</sup> rates is mainly due to the entropic term (A factor), as evidenced by the identical  
50  
51  
52  
53  
54  
55

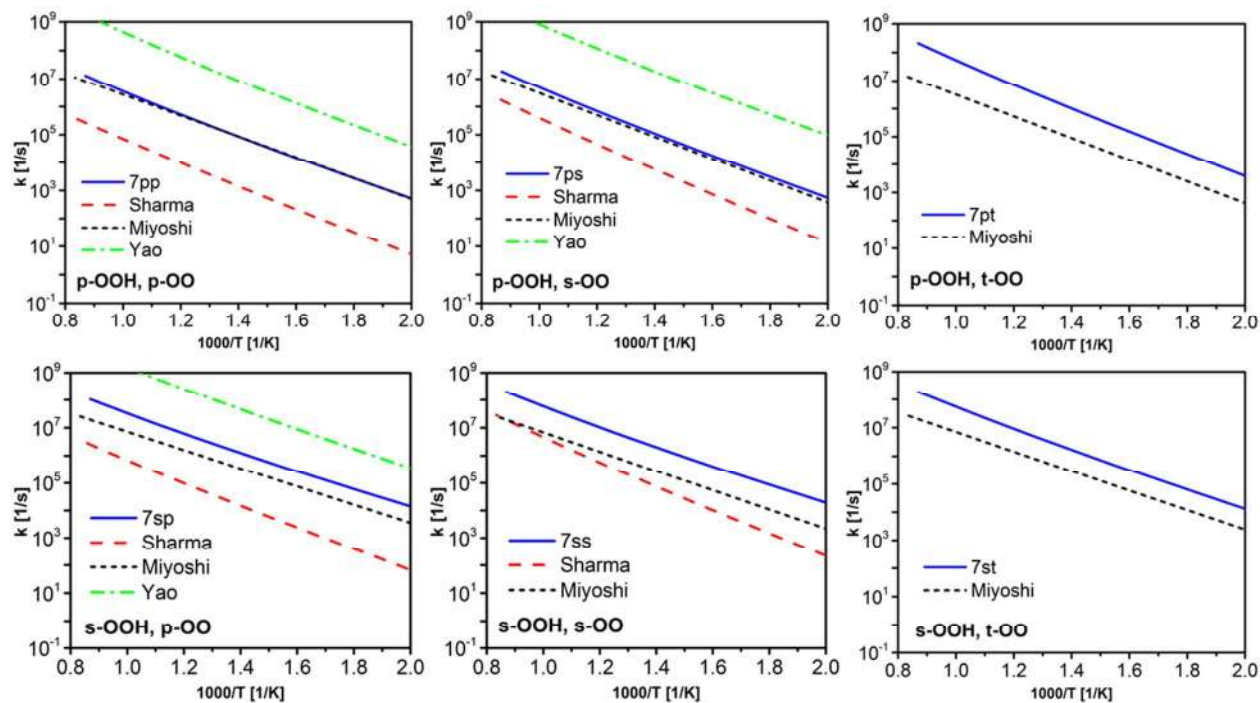

1  
2  
3 slopes observed in Figure 11 for this reaction. Meanwhile, the y-axis intercept obtained in this  
4  
5 study is ten times greater than that obtained by Sharma et al.<sup>16</sup>. Compared to Yao et al.<sup>18</sup>, our  
6  
7 rates of *8PP* are orders of magnitude slower. Again, the discrepancies are due to the fact that  
8  
9 Yao et al.<sup>18</sup> did not consider HR treatment for each rotor, and Sharma et al.<sup>16</sup> used the coupled  
10  
11 HR treatment. Also, Sharma's minimum energy conformer for the *8PP* reactant is an HB  
12  
13 structure, while the most stable conformer optimized in this work is an NHB structure.  
14  
15 Optimizing Sharma's conformer with the same level of theory adopted in this study resulted in  
16  
17 higher energy compared to the NHB conformer. For *8PS* and *8SP*, the same difference is  
18  
19 detected compared to Yao et al.<sup>18</sup>, whereas the major difference compared to Miyoshi<sup>17</sup> is  
20  
21 noticeable at low temperatures (below 715K). Although Miyoshi used the same Eckart tunneling  
22  
23 as in this study, he fitted the rates to a two parameter Arrhenius model, which will not show the  
24  
25 strong temperature dependence at low temperatures as found in this study.

#### 4. Implications for chemical kinetic modeling

To assess the implications of using the calculated rate constants in kinetic models, the site specific rate rules are implemented in models for 2-methylhexane<sup>9</sup> and iso-octane (2,2,4-trimethylpentane)<sup>10</sup>, which originally used Sharma et al.<sup>16</sup> rates as estimates. Since Sharma et al.<sup>16</sup> did not provide all site specific rate rules, analogies were adopted for some rate rules in the original 2-methylhexane<sup>9</sup> model. Ignition delay times were simulated in a closed homogenous batch reactor model in Chemkin-Pro<sup>48</sup> software using the updated model. The ignition delay times were compared to the original model behavior at equivalence ratio of 1 and 0.5, 20 and 40 atm. At the investigated conditions, the effect of the calculated rate constants for OOQOOH isomerization reactions on ignition delay times of 2-methylhexane was found to be minor (Figure 12). The updated model predicts shorter ignition delay times at low temperatures below 800 K, which can be attributed to the rates calculated herein being faster than those from Sharma et al.<sup>16</sup>. In the case of iso-octane, the new rates notably increased the reactivity for iso-octane, as shown in Figure 13. Ignition delay times at 40 atm are shorter below 900 K. The rates calculated herein have a notable effect on iso-octane ignition delay times because six-membered ring OOQOOH isomerizations are the primary chain branching pathway; the faster rates calculated here have a significant effect on increasing low temperature reactivity. Additional detailed theoretical calculations are needed for alternative isomerization pathways to improve the kinetic modeling predictions of experimental data.

**Figure 12.** Ignition delay time of 2-methylhexane at  $\phi=1$  and 0.5, 20 and 40 atm against experimental data from Mohamed et al.<sup>9</sup>. Solid lines are the simulations using the rate rules for OOQOOH isomerization calculated in this work, compared to dashed lines using Sharma et al.<sup>16</sup> rates.

**Figure 13.** Ignition delay time of iso-octane at  $\phi=1$  and 0.5, 40 atm against experimental data from Fieweger et al.<sup>49</sup> (squares) and Hartmann et al.<sup>50</sup> (circles). Solid lines are the simulations using the rate rules for OOQOOH isomerization calculated in this work, compared to dashed lines using Sharma et al.<sup>16</sup> rates.

## 5. Summary and conclusion

In this work, the kinetics of OOQOOH radical isomerization is investigated and the rate parameters calculated. Five-, six-, seven- and eight-membered ring transition states, with different combinations of carbon site types for the hydroperoxide and peroxy groups are considered. The rate constants are calculated using classical transition state theory and fitted to a modified three-parameter Arrhenius equation over the temperature range of 300-1500K. Energy calculations were performed using CBS-QB3, G3 and G4 composite methods for minimum energy conformers. The minimum energy conformers were determined by considering all possible configurations of the reactants, products and transition states. 1D Hindered rotor treatment and Eckart tunneling were also considered.

A detailed conformational analysis was conducted to investigate the effect of chirality and HB on minimum energy conformers. It was found that, depending on the steric cost imposed by the HB ring, HB conformers were not always lower in energy (more stable). Chirality was considered for all chiral centers in the investigated molecules and transition states. For reactants with two chiral centers, conformers with mixed or the same chirality at both centers were considered. Meanwhile, transition state conformers wherein the substituents were in the axial or equatorial position were considered. Transition states with an axial configuration were found to be lower in energy when HB existed, but in some cases equatorial was preferred, especially when the axial configuration exhibited additional unfavorable gauche interactions. The effect of chirality on the kinetics was also discussed. Although two chiral conformers can be up to 3 kcal/mol different in energy, a very minor effect was observed on rate constants, especially under atmospheric conditions.

1  
2  
3 In terms of ring size, 1,5 H-migration was found to proceed via the same, or slightly higher,  
4 barrier than the 1,6 H-migration, as both transition state rings are cyclohexane-like. Since  
5 previous studies have not given much attention to rates where the peroxy group is in the tertiary  
6 site, the effect of the peroxy position was also discussed, and differences of up to an order of  
7 magnitude were observed. The calculated rates showed good agreement with the literature rates  
8 from Miyoshi <sup>17</sup>; however, some discrepancy is observed when compared to Sharma et al. <sup>16</sup> and  
9 Yao et al. <sup>18</sup>. This demonstrates the importance of the selected levels of theory for calculations,  
10 and the methods used to account for tunneling and entropic corrections. Finally, the calculated  
11 rates were shown to alter chemical kinetic modeling predictions of ignition delay time, especially  
12 in highly branched molecules where ignition is very sensitive to the KHP formation rate.
