

Hoare Logic and VDM: Machine-Checked Soundness and Completeness Proofs

Thomas Kleymann (formerly Schreiber)

Doctor of Philosophy
University of Edinburgh
1998

Abstract

Investigating soundness and completeness of verification calculi for imperative programming languages is a challenging task. Many incorrect results have been published in the past. We take advantage of the computer-aided proof tool LEGO to interactively establish soundness and completeness of both Hoare Logic and the operation decomposition rules of the Vienna Development Method (VDM) with respect to operational semantics. We deal with parameterless recursive procedures and local variables in the context of total correctness. As a case study, we use LEGO to verify the correctness of Quicksort in Hoare Logic.

As our main contribution, we illuminate the rôle of auxiliary variables in Hoare Logic. They are required to relate the value of program variables in the final state with the value of program variables in the initial state. In our formalisation, we reflect their purpose by interpreting assertions as relations on states and a domain of auxiliary variables. Furthermore, we propose a new structural rule for adjusting auxiliary variables when strengthening preconditions and weakening postconditions. This rule is stronger than all previously suggested structural rules, including rules of adaptation.

With the new treatment, we are able to show that, contrary to common belief, Hoare Logic subsumes VDM in that every derivation in VDM can be naturally embedded in Hoare Logic. Moreover, we establish completeness results uniformly as corollaries of Most General Formula theorems which remove the need to reason about arbitrary assertions.

Acknowledgements

Working towards a thesis is much more demanding than I had initially anticipated. I am grateful to my colleagues and friends who have succeeded in providing a pleasant environment to work and live in. Special thanks go to my wife Beate for her patience and support.

I would like to thank my supervisors Rod Burstall and Paul Jackson. Rod's advice has been invaluable in many respects. I have been very much enjoying discussions with him and have always left his office in good spirit. Paul has very much influenced the presentation of the thesis. He has also done a good job in pressuring me to finish.

Discussions with Healf Goguen, Martin Hofmann, Zhaohui Luo and James McKinna have been very stimulating. In fact, a remark by Healf has inspired me to investigate soundness and completeness in the first place. I would also like to thank the departmental computing support staff for providing a friendly and effective service.

I am in debt to Peter Otto for his generous support in the initial stage of this thesis. I would also like to acknowledge the financial support of the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 182, Mutliprozessor- und Netzwerkkonfigurationen), EPSRC, the British Council (ARC Project Co-Development of Object-Oriented Programs in LEGO) and the European Commission (Marie Curie Fellowship).

Declaration

I declare that this thesis was composed by myself and that the work contained therein is my own, except where explicitly stated otherwise in the text. Some of this work has been published previously (Schreiber 1997).

(Thomas Kleymann)

Chapter 1

Introduction

The correctness of software is an important issue in software engineering. In particular, in safety-critical applications e.g., controlling chemical plants, it must be ensured that the implementation satisfies the required specification. Often, it is insufficient to validate the correctness of a complex software system by relying merely on test data. Delivering the program together with a formal proof of its correctness with respect to some specification guarantees a correct program, whereas tests can only reduce errors.

In 1969, Hoare introduced a formal system, now referred to as Hoare Logic, relating imperative programs with two assertions, both first-order logical formulae. The purpose of Hoare Logic was twofold. On the one hand, it axiomatised the semantics of the programming language. Occasionally, one therefore finds *axiomatic semantics* as a synonym for Hoare Logic. On the other hand, objects of the formal system correspond to correctness formulae describing properties of programs. Thus, derivations in Hoare Logic are verification proofs. Nowadays, taking Hoare Logic rules as axiomatic definitions of programming languages is no longer seen as being adequate. Instead, one investigates soundness and completeness with respect to a simpler semantics, such as operational semantics.

Much attention was devoted to this line of research in the 70s and early 80s. However, the field appeared to run into insurmountable problems. Incompleteness results seemed to indicate that it would be impossible to design *any* verification calculus in the style of Hoare Logic as soon as one combines more complex language features. Moreover, conducting soundness and completeness proofs for more interesting programming languages turned out to be highly error-prone and laborious. Many of the proposed verification calculi were unsound or incomplete *despite* being backed up by “proofs” to the contrary.

For example, Sokołowski’s (1977) presentation for recursive procedures is incomplete. Apt’s (1981) extension yields a complete but, unfortunately, unsound calculus. The first sound and complete verification calculus in the style of Hoare Logic for re-

cursive procedures and total correctness was published in 1990 by America & de Boer.

1.1 Soundness and Completeness

Soundness is essential. If a system is unsound, deriving a property for a particular program within the formal system does not guarantee that the program actually fulfils the property.

In an incomplete formal system, one may only verify a strict subset of all true formulae. A naïve definition of completeness is bound to fail in the context of verification calculi. On the one hand, if the chosen underlying logical language is too weak, e.g., pure first-order logic together with the boolean constants **false** and **true**, some intermediate assertions cannot be expressed. Hence, derivations cannot be completed. On the other hand, if the logical language is too strong, e.g. Peano Arithmetic, it itself is already incomplete and the verification calculus inherits incompleteness.

To circumvent this dilemma, Cook (1978) proposed that instead one should investigate *relative completeness*. One merely considers sufficiently expressive underlying logical languages. Furthermore, the formal system is augmented by a theory¹ of first-order logic. Whenever a rule is protected by a first-order logic side-condition, the rule is already applicable when the side-condition is an element of the theory, and not only when the side-condition is itself *derivable*.

In practice, achieving relative completeness of verification calculi is highly desirable. In logic, finding valid formulae which cannot be derived is often somewhat esoteric. A different story has to be told for the notion of relative completeness in verification calculi e.g., in Sokołowski's (1977) calculus, it is very difficult to come up with any non-contrived correctness formula of a recursive procedure which can be derived!

1.2 Main Outcome

We have produced machine-checked soundness and completeness proofs for Hoare Logic and the operation decomposition rules of the Vienna Development Method (VDM). Our imperative programming language includes (parameterless) recursive procedures and local variables. We consider static binding and total correctness. Previously, machine-checked completeness results have only been available for simple imperative programs (and partial correctness).

¹the set of all valid as opposed to derivable formulae

Our message to the designers and researchers of verification calculi is that conducting computer-aided soundness and completeness proofs is both a feasible and profitable task. We are confident that when investigating further language features, the overhead caused by mechanisation is tolerable. Today's modern proof tools are sufficiently advanced. Besides LEGO, one could for example, also resort to the systems Coq (1998), HOL (1998), Isabelle (Paulson & Nipkow 1998) or PVS (Rushby 1998).

Conducting formal proofs at a level that they can be checked by a machine requires that all aspects and all details must be thoroughly investigated. To be a feasible task, it is often necessary to first simplify the concepts themselves, before establishing the desired properties. Hence, in addition to more confidence in the mechanised proofs, one can often contribute by simplifying or illuminating some aspects of the area investigated.

Our fundamental contribution has been to highlight the rôle of auxiliary variables in Hoare Logic. Usually, assertions are interpreted as *predicates on states* where free variables denote the value of program variables in a specific state. Variables for which no counterpart appears as a program variable in the program under consideration then take on the rôle of auxiliary variables. They are required to relate the value of program variables in *different* states.

Our view of assertions emphasises the pragmatic importance of auxiliary variables. We have followed a proposal by Apt & Meertens (1980) to consider assertions as *relations on states and auxiliary variables*. Furthermore, we stipulate a new structural rule to adjust auxiliary variables when strengthening preconditions and weakening postconditions. This rule is stronger than all previously suggested structural rules, including Hoare's (1969) consequence rule and rules of adaptation. As a direct consequence of the new treatment of auxiliary variables,

- we were able to show that Sokołowski's (1977) calculus is sound and complete if one replaces Hoare's rule of consequence with ours. In particular, none of the other structural rules introduced by Apt (1981) are required.
- We have clarified the relationship between Hoare Logic and its variant VDM. We were able to show that, contrary to common belief, VDM is more restrictive than Hoare Logic in that every derivation in VDM can be naturally embedded in Hoare Logic. Intuitively, in Hoare Logic, auxiliary variables record the value of variables at an *arbitrary* reference point. In VDM, the reference point corresponds to the state of the precondition and must therefore be constantly adjusted during a derivation.
- Completeness is established by induction on the structure of programs. How-

ever, in the presence of recursive procedures, a direct proof does not go through, because the induction hypothesis is then too weak. Instead one first establishes, also by induction, that a particular correctness formula, the Most General Formula (MGF), can be derived. This obliterates the problems of having to cater for arbitrary assertions. Completeness follows as a corollary by appealing to structural rules.

This technique had previously only been applied to Hoare Logic dealing with recursive procedures. We have conducted *all* completeness proofs with the help of the MGF property, because, with our new rule of consequence, completeness follows *directly* from the MGF theorem.

The new approach has already been taught to undergraduate students as part of Hofmann's (1997) course on semantics and verification at the University of Marburg.

1.3 The Logical Framework

We have employed the computer-aided proof tool LEGO (1998) to investigate soundness and completeness for Hoare Logic and the operation decomposition rules of VDM. LEGO is a proof assistant based on type theory which provides a higher-order (intuitionistic) logic. The system supports dependent types, inductively defined data types and inductively defined relations. The underlying type theory is UTT (Luo 1994). It is not necessary to be familiar with any proof assistant or type theory in order to read this thesis.

In our formalisation, programs may contain variables with *arbitrary* sorts. This leads to a more complex model of the state space. We have found it helpful to employ dependent function types in order to model the state space.

We define the syntax of programs as an inductive data type. We capture operational semantics and the notion of derivability of correctness formulae in a verification calculus as an inductive relation. This allows us to conduct (completeness) proofs by induction on the structure of programs and (soundness) proofs by induction on the derivation of correctness formulae.

We now introduce dependent function types, inductively defined data types and inductively defined relations in more detail.

1.3.1 Dependent Function Types

In type theory, every term is annotated by its type. Only well-typed terms are well-formed e.g., $f : T \rightarrow U$ is a function which, given $x : T$ yields $f(x) : U$. We may

only apply f to elements of type T . We will however omit such annotations in our presentation when the typing discipline is evident from the context.

UTT also provides dependent types in which types themselves are functions $\text{sort} : T \rightarrow \text{Type}$. One writes $\prod x : T \cdot \text{sort}(x)$ rather than $T \rightarrow \text{sort}$ to denote a dependent function space. Let $f : \prod x : T \cdot \text{sort}(x)$. Given an argument $x : T$, the function f returns a value of type $\text{sort}(x)$. Dependent function types are particularly useful when one wants to specify a function in which the type of some arguments depends on the value of previous arguments.

Example 1.1 (Scalar Product on Reals) *With dependent functions, one can implement a single function*

$$f(n)(\vec{x}, \vec{y}) = \sum_{1 \leq i \leq n} x_i \times y_i$$

to compute the scalar product of two vectors $\vec{x}, \vec{y} : \mathbb{R}^n$ of arbitrary but identical dimension $n : \text{nat}$. Its type is

$$f : \prod n : \text{nat} \cdot (\mathbb{R}^n \times \mathbb{R}^n) \rightarrow \mathbb{R} .$$

1.3.2 Inductively Defined Data Types

Consider the BNF grammar

$$S ::= x := t \mid \text{while } b \text{ do } S$$

of a (very) simple imperative programming language. This is an inductive definition. We may prove properties about arbitrary programs by considering its two constructors for assignments and loops. Formally, we may appeal to the induction principle

$$\frac{\forall x \cdot \forall t \cdot \Phi(x := t) \quad \forall b \cdot \forall S \cdot \Phi(S) \Rightarrow \Phi(\text{while } b \text{ do } S)}{\forall S \cdot \Phi(S)}$$

for an arbitrary predicate Φ on programs.

1.3.3 Inductively Defined Relations

Let $\sigma \xrightarrow{S} \tau$ be a new relation to describe the operational semantics of the above programming language. Intuitively, it denotes that the program S when invoked

in the state σ will terminate in the state τ . We define it by the least relation satisfying

$$\sigma \xrightarrow{x:=t} \sigma[x \mapsto \text{eval}(\sigma)(t)] \quad (1.1)$$

$$\sigma \xrightarrow{\text{while } b \text{ do } S} \sigma \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{false} . \quad (1.2)$$

$$\frac{\sigma \xrightarrow{S} \eta \quad \eta \xrightarrow{\text{while } b \text{ do } S} \tau}{\sigma \xrightarrow{\text{while } b \text{ do } S} \tau} \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{true} . \quad (1.3)$$

This is an example of an inductively defined relation. Given a proof obligation of the form

$$\forall \sigma \cdot \forall S \cdot \forall \tau \cdot \sigma \xrightarrow{S} \tau \Rightarrow \Phi(\sigma, S, \tau) \quad (1.4)$$

we may pursue induction by considering all (three) possible derivations². Formally, the induction principle is

$$\frac{\begin{array}{l} \forall \sigma \cdot \forall x \cdot \forall t \cdot \Phi(\sigma, x:=t, \sigma[x \mapsto \text{eval}(\sigma)(t)]) \\ \forall \sigma \cdot \forall b \cdot \forall S \cdot \text{eval}(\sigma)(b) = \mathbf{false} \Rightarrow \Phi(\sigma, \text{while } b \text{ do } S, \sigma) \\ \forall \sigma \cdot \forall b \cdot \forall S \cdot \forall \eta, \tau \cdot (\text{eval}(\sigma)(b) = \mathbf{true} \wedge \\ \sigma \xrightarrow{S} \eta \wedge \eta \xrightarrow{\text{while } b \text{ do } S} \tau \wedge \Phi(\sigma, S, \eta) \wedge \Phi(\eta, \text{while } b \text{ do } S, \tau)) \Rightarrow \\ \Phi(\sigma, \text{while } b \text{ do } S, \tau) \end{array}}{\forall \sigma \cdot \forall S \cdot \forall \tau \cdot \sigma \xrightarrow{S} \tau \Rightarrow \Phi(\sigma, S, \tau)} \quad (1.5)$$

Computer-aided tools are very helpful in formally dealing with such induction principles. The LEGO system generates induction principles automatically from the set of defining constructors, such as (1.1)–(1.3). It also provides an `Induction` tactic to bring the proof obligation into the shape of (1.4) before breaking it down into the cases according to the induction principle.

In practice, inversion is an important proof technique for dealing with inductively defined relations. Consider the proof of determinism. We want to show

$$\forall \sigma \cdot \forall S \cdot \forall \tau \cdot \sigma \xrightarrow{S} \tau \Rightarrow \forall \eta \cdot \sigma \xrightarrow{S} \eta \Rightarrow \tau = \eta .$$

The `Induction` tactic splits the proof obligation into the three cases corresponding to the induction principle (1.5). We only consider the base case where we have to establish

$$\forall \eta \cdot \sigma \xrightarrow{x:=t} \eta \Rightarrow \sigma[x \mapsto \text{eval}(\sigma)(t)] = \eta .$$

²On paper, such proofs sometimes appeal to induction on the *length* of a derivation. In a rigorous formal proof, it is (technically) more elegant to inductively analyse the derivation itself.

Rather than general induction, it suffices to consider the last step of the derivation of

$$\sigma \xrightarrow{x:=t} \eta \quad (1.6)$$

In other words, we want to *invert* the derivation. Intuitively, (1.6) can only be derived from the axiom (1.1). Hence, the state η must coincide with $\sigma[x \mapsto \text{eval}(\sigma)(t)]$. LEGO provides state of the art support for inverting inductively defined relations (McBride 1998).

1.4 Notation

We refrain from exposing the reader to the (rather unreadable) LEGO scripts in the main body of this thesis. Instead, we adopt a more traditional informal presentation with more flexible notation. We include sufficient details to facilitate encoding our results with different proof tools. We have decorated machine-checked developments with the symbol . An outline of the LEGO scripts can be found in Appendix B. All scripts are also available on-line and can be accessed from Lego's (1998) World Wide Web page.

The reader is encouraged to compare definitions in the text with the actual LEGO scripts (Pollack 1998). Machine-checked developments are not exempt from mistakes e.g., Homeier & Martin (1996) erroneously claim

“ The correctness of these VCG functions is established by proving the following theorems from the axioms and rules of inference of the axiomatic semantics ”

But the actual encodings in HOL reveal that correctness has instead been established by appealing to the definition of *operational* semantics.

1.4.1 Implicit Quantification

An important convention is that all free identifiers in a rule (or axiom) are implicitly universally quantified at the level of the rule. For example, the rule

$$\frac{\forall t : W \cdot \{p \wedge b \wedge u = t\} S \{p \wedge u < t\}}{\{p\} \text{ while } b \text{ do } S \{p \wedge \neg b\}}$$

is merely a convenient short cut for

$$\forall p \cdot \forall u \cdot \forall b \cdot \forall S \cdot \frac{\forall t : W \cdot \{p \wedge b \wedge u = t\} S \{p \wedge u < t\}}{\{p\} \text{ while } b \text{ do } S \{p \wedge \neg b\}}$$

where the order of the top-level universal quantifiers does not matter. In particular, scoping guarantees³ that the variable t can not occur freely in p , u , b and S .

³The rule would be unsound otherwise.

1.5 Overview of Thesis

In **Chapter 2**, restricting our attention to simple imperative programs, we consider fundamental aspects of verification calculi such as Hoare Logic and VDM. We axiomatise the meaning of programs via a structural operational semantics. We then demonstrate that reasoning based directly on this semantic account is tedious. A more abstract approach leads naturally to the operation decomposition rules of VDM.

Turning our attention to Hoare Logic, we discuss the rôle of auxiliary variables in detail. Based on this analysis, we interpret assertions as relations on the state space and a domain of auxiliary variables. Moreover, we introduce a new structural rule to adjust auxiliary variables when strengthening preconditions and weakening postconditions.

We mechanically establish soundness and completeness for both Hoare Logic and VDM. We also show that Hoare Logic subsumes VDM and take a closer look at the definition of (relative) completeness. At the end of this chapter, we compare our approach to related work.

Chapter 2 exposes the main ideas of this thesis. In **Chapter 3**, we apply the techniques to more intricate settings. America & de Boer (1990) presented the first sound and complete formal system for recursive procedures dealing with termination in the style of Hoare Logic. We show that after replacing Hoare’s (1969) rule with our new consequence rule, a third of their rules are not required; neither pragmatically, nor to achieve completeness. Furthermore, we extend our results to imperative programs supporting local variables (with static scoping) in the presence of recursive procedures.

Our meta-theoretical investigations of Hoare Logic and VDM are complemented by a case-study in **Chapter 4**. Focussing on the well-understood Quicksort algorithm, we hope to clarify how our new Hoare Logic rules may be used in practice.

In **Chapter 5**, we conclude and outline future work. All of our results have been developed using the LEGO proof tool. We comment on the feasibility of this project and on the strengths and weaknesses of the LEGO system.

Appendix A contains some further remarks on working with the LEGO system. In particular, we document how to encode a notion of well-founded relations and extensional equality. We also show how to update dependent functions and hence machine states; this requires quite sophisticated type theory. In **Appendix B**, we have collected an outline of the actual LEGO scripts.

Chapter 2

Fundamental Aspects of Hoare Logic and VDM

In this chapter, we introduce syntax and an operational semantics for a simple imperative programming language with assignments, conditionals and loops. We then present two verification calculi, VDM and Hoare Logic, and show that they are sound and complete with respect to the operational semantics. We consider total correctness i.e., besides input/output specifications, the verification calculi also deal with termination of programs.

The outline of the chapter is as follows. Having built up sufficient background theory, we consider the correctness proof of an imperative program realising the exponential function. This proof is based directly on the definition of the operational semantics. As this is rather cumbersome, we motivate a more abstract framework, VDM. We then carefully introduce the issues of soundness and completeness. We prove soundness, as usual, by induction on the derivation of the correctness formula. In our completeness proof, we are able to demonstrate that one may factor out details of assertions and adapt Gorelick's (1975) Most General Formula (MGF) theorem to the VDM setting.

Turning our attention to Hoare Logic, we discuss the rôle of auxiliary variables and propose to interpret assertions as relations on the state space and additionally a domain of auxiliary variables. Furthermore, we present a new rule of consequence. It is strictly stronger than Hoare's (1969) version and allows us to prove completeness as a trivial corollary of the MGF theorem. With the new treatment, we are able to show that derivations in VDM can be embedded in Hoare Logic.

We conclude with a summary of related work.

2.1 Deep and Shallow Embedding Techniques

Our main objective of this thesis is to mechanically establish meta-theorems such as soundness and completeness of verification calculi. It is **not** our aim to show that a proof tool such as the LEGO system is suitable to verify concrete programs relative to concrete specifications.

Traditionally, one defines syntax for expressions and relative to this setup, one characterises syntax of a programming language and syntax of an assertion language. Then, one describes the meaning of every syntactic construct. This approach is known as *deep embedding*. Alternatively one may shortcut this process and identify the syntactic representation with its denotation. This technique is known as *shallow embedding*.

The drawbacks of shallow embeddings are that

- one cannot exploit the inductive (syntactic) structure to prove properties
- the representation of concrete examples is often more difficult to comprehend

However, omitting syntactic representation cuts down the work load and is therefore often the preferred technique.

We will present a shallow embedding of expressions. Based on this definition, we will give a deep embedding of the programming language and a shallow embedding of the assertion language. A shallow embedding of the imperative programming language is inappropriate for our project, because the completeness proofs inherently rely on proofs by induction on the structure of programs.

A shallow embedding of Hoare Logic and VDM suffices to mechanically investigate soundness (Gordon 1989). However, to formalise the statement of completeness, one needs to explicitly refer to a notion of derivability. Thus, we give a deep embedding of Hoare Logic and VDM.

The main benefit of shallow embedding for our project has been that one does not have to worry about substitutions in assertions.

2.2 Program Variables

In practice, program variables are strings, sometimes restricted to a particular length. Strings are not directly supported in our logical framework. Instead of adopting an isomorphic structure e.g., lists over the finite set $0 - 255$, we chose the most general structure. Any type will do as long as equality is decidable.

→ p. 236  **Definition 2.1 (Program Variables)** *The syntactic class of program variables VAR may be an arbitrary type, provided it supports an associated decidable equality i.e., a*

boolean relation $eq : (\mathbf{VAR} \times \mathbf{VAR}) \rightarrow \text{bool}$ which reflects equality

$$\forall x, y : \mathbf{VAR} \cdot x = y \Leftrightarrow eq(x, y) = \text{true} .$$

We will investigate soundness and completeness relative to such a general notion of program variables. In logical frameworks supporting classical logic, the restriction to decidable equalities can be dropped. For concrete examples, we employ (finite) enumeration types $\mathbf{VAR} = (x, y, \dots)$.

Previous mechanisations only consider the case of a single data type, namely natural numbers. In a type-theoretic setting, it seems natural to investigate multiple sorts. For most data types present in imperative programming languages, we can immediately provide type-theoretic representations.

- Sum types yield finite data types e.g., booleans and characters.
- Inductive types yield data types such as natural numbers and lists.
- Employing quotients, we can construct integers from natural numbers and rationals from integers.
- Record types subsume records in programming languages.
- Using functions we may represent arrays. In particular, following the views of Dahl, Dijkstra & Hoare (1972) and Gries & Levin (1980), an assignment of an array element is regarded as functional updating.
- The type of program variables \mathbf{VAR} can be used to represent pointers.

We identify the universe of data types with the universe of all types expressible in our logical framework. Conceptually, results in the sequel are therefore independent of the actual available data types. Pragmatically, we can study more interesting programming examples involving different data types. The type of variables can be declared by providing a function

$$\text{sort} : \mathbf{VAR} \rightarrow \text{Type} .$$

2.3 The State Space

The state space records the value of every program variable. In the simple scenario of this chapter, there is exactly one entry for every program variable. We will encounter more interesting state spaces in the next chapter when dealing with local variables.

The state space is one of the major ingredients to deal with semantical aspects of imperative programs. When one encounters an assignment $x := t$, the semantics of the expression t depends on the value of all program variables occurring in t as recorded by the current state σ . Moreover, executing the assignment leads to a new state in which the entry for the program variable x in the state space has been updated. It suffices to consider *first-order substitutions* (Trakhtenbrot, Halpern & Meyer 1984) which restrict updating of an entry for $x : \mathbf{VAR}$ to values of type $\text{sort}(x)$ which cannot refer to values of variables.

As we have seen, a type environment is a function from program variables to types. A state σ for a type environment sort is a function mapping program variables x to values of type $\text{sort}(x)$. The state space itself is therefore a dependent function space:

↳ p. 140  **Definition 2.2 (State Space)** $\Sigma \stackrel{\text{def}}{=} \prod x : \mathbf{VAR} \cdot \text{sort}(x)$

Updating (dependent) functions $\sigma[x \mapsto v]$ then corresponds to first-order substitution with $x : \mathbf{VAR}$, $v : \text{sort}(x)$ and $\sigma : \Sigma$. Notice that a syntactic substitution such as

$$\sigma[x \mapsto x + 1]$$

is not well-typed. Instead, one needs to specify

$$\sigma[x \mapsto \sigma(x) + 1] \text{ .}$$

In LEGO, all functions are total. Thus, our model of the state space has no *undefined* values. At least for simple data types, such as integers, this is an adequate assumption, since, in the real world, one may access any entry in the memory and interpret it as a value. If one were interested in modelling undefined values for a data type T , one could store values of the sum type $T + 1$ where the right injection characterises an undefined value.

2.4 Interpretations

An interpretation determines the value of

- constants such as $0, +, \wedge$
- and (free) variables

in expressions and logical formulae. In the context of program verification, logical variables are assumed to refer to program variables. Therefore, the interpretation I for variables depends on a particular state σ i.e., $\llbracket x \rrbracket (I(\sigma)) = I(\sigma(x))$. In the following

chapter, when considering local variables, scoping dictates which program variables in the state space are to be inspected and the interpretation depends additionally on a scoping environment.

In our formalisation, we are only interested in the standard interpretation of constants. This not only simplifies the encoding, it also avoids the problematic issue of how to axiomatise the class of acceptable interpretations, see Sect. 2.12 for further details.

2.5 Expressions

Boolean expressions occur in loops and conditional statements. Other types of expressions depend on the data types expressible in the language and occur both as subexpressions of boolean expressions and in the assignment statement. One may define the syntax of expressions by a BNF grammar.

Example 2.3 (Syntax of Expression) *Homeier & Martin (1996) define two classes of expressions*

$$e ::= n \mid x \mid ++x \mid e_1 + e_2 \mid e_1 - e_2$$

$$b ::= e_1 = e_2 \mid e_1 < e_2 \mid b_1 \wedge b_2 \mid b_1 \vee b_2 \mid \neg b$$

We will only consider expressions without side-effects¹ and do not deal with the expression $++x$. The semantics can thus be easily fixed denotationally and is determined by an interpretation function I and a state σ .

Example 2.4 (Semantics of Expressions)

- $\llbracket n \rrbracket(I(\sigma)) \stackrel{\text{def}}{=} I(n)$ $\llbracket x \rrbracket(I(\sigma)) \stackrel{\text{def}}{=} I(\sigma(x))$
- $\llbracket e_1 \text{ op } e_2 \rrbracket(I(\sigma)) \stackrel{\text{def}}{=} \llbracket e_1 \rrbracket(I(\sigma)) I(\text{op}) \llbracket e_2 \rrbracket(I(\sigma))$ for $\text{op} \in \{+, -, =, <\}$
- $\llbracket b_1 \text{ op } b_2 \rrbracket(I(\sigma)) \stackrel{\text{def}}{=} \llbracket b_1 \rrbracket(I(\sigma)) I(\text{op}) \llbracket b_2 \rrbracket(I(\sigma))$ for $\text{op} \in \{\wedge, \vee\}$
- $\llbracket \neg b \rrbracket(I(\sigma)) \stackrel{\text{def}}{=} I(\neg) \llbracket b \rrbracket(I(\sigma))$

Whenever we come across a boolean expression in a loop or a conditional statement, we are only interested in the value it evaluates to, **true** or **false**. Similarly, in an assignment, we treat evaluation of the expression as atomic, merely a value depending on the state space. We are not interested in syntactic properties such as whether one expression is a subterm of another expression. Ignoring the syntax of expressions paves the

¹Such a strict distinction between expressions and commands is one of the fundamental principles underlying idealised Algol (Reynolds 1982).

way towards a reasonable level of abstraction when investigating properties of verification calculi for imperative programs without side-effects.

Restricting our attention to the standard interpretation, the semantics of an expression is determined by the state space. We only consider expressions at this semantic level:

→ p. 140  **Definition 2.5 (Expressions)** *Given an arbitrary type T , we represent expressions by*

$$\text{expression}(T : \text{Type}) \stackrel{\text{def}}{=} \Sigma \rightarrow T .$$

Let $e : \text{expression}(T)$ be any expression. Its evaluation depends on a concrete snapshot of the state space $\sigma : \Sigma$. We define

$$\text{eval}(\sigma)(e) \stackrel{\text{def}}{=} e(\sigma) .$$

The main benefit of adopting shallow embedding is that we do not have to worry about formalising the syntax in a logical framework e.g., the expression $x * y$ where x and y are program variables with sort `nat` would be rendered as

$$\lambda \sigma . \sigma(x) * \sigma(y) : \text{expression}(\text{nat}) .$$

Moreover, substitutions are much easier to deal with at the semantic level. Consider the syntactic substitution $(x * y) [x \mapsto t]$. In the shallow embedding, this substitution can be realised by updating the state space i.e.

$$(\lambda \sigma . \sigma(x) * \sigma(y)) \circ (\lambda \sigma . \sigma[x \mapsto \text{eval}(\sigma)(t)]) \tag{2.1}$$

which, when applied to a concrete state σ , (β -)reduces to

$$(\sigma[x \mapsto \text{eval}(\sigma)(t)](x)) * (\sigma[x \mapsto \text{eval}(\sigma)(t)](y)) . \tag{2.2}$$

This is equivalent to

$$t' * \sigma(y) \tag{2.3}$$

where t' is a suitably reduced version of $\text{eval}(\sigma)(t)$. Employing a deep embedding, one would need to additionally check that the syntactic substitution function on expressions is correct e.g., $\llbracket (x * y) [x \mapsto t] \rrbracket$ must coincide with the term (2.1).

Unfortunately, the LEGO system offers no automatic support in reducing (2.2) to (2.3). In concrete examples, such as the Quicksort verification in Cha. 4, this leads to excessively large proof obligations. Moreover, examples are more difficult to read. To increase the readability of examples, we shall present the (manually translated) syntactic counterparts of expressions.

2.6 Imperative Programs

For representing statements of the imperative programming language, we resort to a deep embedding i.e., we first embed the syntax in the logical framework and then axiomatise the semantics by an analysis of the structure of programs. In this chapter, we restrict ourselves to basic language features:

→ p. 140  **Definition 2.6 (Abstract Syntax of Imperative Programs)**

Imperative programs $S : \text{prog}$ are defined by the BNF grammar

$$S ::= \mathbf{skip} \mid x := t \mid S_1; S_2 \mid \mathbf{if } b \mathbf{ then } S_1 \mathbf{ else } S_2 \mid \mathbf{while } b \mathbf{ do } S$$

where $x : \mathbf{VAR}$, $t : \text{expression}(\text{sort}(x))$ and $b : \text{expression}(\text{bool})$.

As LEGO supports definitions, we may define other, possibly generic, language constructs e.g., $\mathbf{if } b \mathbf{ then } S \stackrel{\text{def}}{=} \mathbf{if } b \mathbf{ then } S \mathbf{ else skip}$. However, any program $S : \text{prog}$ may be brought into normal form e.g., by expanding definitions, so that when pursuing induction on the structure of S , we only need to consider the primitive constructors given in Def. 2.6.

In examples, we assume that sequential composition is left-associative. Furthermore, we employ **begin** and **end** in our *concrete* syntax to clarify precedence.

Notice that LEGO actually needs to test equivalence of types to resolve the type dependency in the assignment constructor:

Example 2.7 *In the assignment $k := 1$, the principal type of 1 is nat . However, the typing discipline for the assignment constructor requires 1 to inhabit $\text{sort}(k)$. The typechecker thus needs to reduce $\text{sort}(k)$ to nat .*

2.6.1 Assignment and Arrays

Data types may be any type representable in type theory. This includes arrays which, following Dahl et al. (1972) and Gries & Levin (1980), one may consider as functions inhabiting $T \rightarrow U$, where U is an arbitrary type and T is any type where equality is decidable.

To represent the concrete statement $x[c] := x[d]$ for an array $x : \mathbf{VAR}$ with $\text{sort}(x) = T \rightarrow U$ and $\text{sort}(c) = \text{sort}(d) = T$, the assignment constructor expects a term inhabiting $(\prod x : \mathbf{VAR} \cdot \text{sort}(x)) \rightarrow T \rightarrow U$ as its second argument. Since x represents a function, the statement $x[c] := x[d]$ corresponds to updating the function x at position c i.e.,

$$x := \lambda \sigma : \Sigma \cdot (\sigma(x)) [\sigma(c) \mapsto \sigma(x)(\sigma(d))] \ .$$

2.7 Structural Operational Semantics

In this section, we axiomatise the semantics of the imperative programming language. We employ structural operational semantics (Plotkin 1981) which provides a clean way to specify the effect of each language constructor in an arbitrary state. It relates a program with its initial and final state.

→ p. 141  **Definition 2.8 (Semantics)** *The operational semantics is defined as the least relation*

$\cdot \longrightarrow \cdot \subseteq \Sigma \times \text{prog} \times \Sigma$ *satisfying*

$$\sigma \xrightarrow{\text{skip}} \sigma \quad (2.4)$$

$$\sigma \xrightarrow{x:=t} \sigma[x \mapsto \text{eval}(\sigma)(t)] \quad (2.5)$$

$$\frac{\sigma \xrightarrow{S_1} \eta \quad \eta \xrightarrow{S_2} \tau}{\sigma \xrightarrow{S_1; S_2} \tau} \quad (2.6)$$

$$\frac{\sigma \xrightarrow{S_1} \tau}{\sigma \xrightarrow{\text{if } b \text{ then } S_1 \text{ else } S_2} \tau} \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{true} . \quad (2.7)$$

$$\frac{\sigma \xrightarrow{S_2} \tau}{\sigma \xrightarrow{\text{if } b \text{ then } S_1 \text{ else } S_2} \tau} \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{false} . \quad (2.8)$$

$$\sigma \xrightarrow{\text{while } b \text{ do } S} \sigma \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{false} . \quad (2.9)$$

$$\frac{\sigma \xrightarrow{S} \eta \quad \eta \xrightarrow{\text{while } b \text{ do } S} \tau}{\sigma \xrightarrow{\text{while } b \text{ do } S} \tau} \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{true} . \quad (2.10)$$

Intuitively, $\sigma \xrightarrow{S} \tau$ denotes that the program S when invoked in the state σ will terminate in the state τ .

We can increase our confidence in the correctness of this axiomatisation by proving properties such as determinism.

→ p. 142  **Lemma 2.9 (Determinism)**

Program behaviour is deterministic i.e., for all programs S and states η , σ and τ , whenever $\sigma \xrightarrow{S} \tau$ and $\sigma \xrightarrow{S} \eta$, then $\tau = \eta$.

 **Proof** by induction on the derivation of $\sigma \xrightarrow{S} \tau$, followed by inverting $\sigma \xrightarrow{S} \eta$ in each case. □

However, being axiomatic, it is impossible to *prove* the correctness of the semantic description. We have to inspect each rule carefully.

We believe a denotational² semantics $M : (\text{prog} \times \Sigma) \rightarrow \Sigma$ is less suitable to *define* the behaviour of programs, because it involves more complicated mathematical constructs such as computing least fixed points e.g., Cousot (1990) argues that a denotational account should be justified with respect to an operational semantics. In our opinion, the induction principle triggered by the inductive definition of the operational semantics is sufficiently powerful to effectively investigate soundness and completeness. We do not see the need to deal with denotational semantics.

2.8 Low-Level Verification

Having integrated the semantics of a programming language in a logical framework, we can specify program behaviour and prove specifications correct. In this section, we employ the rules of the structural operational semantics to verify an imperative program implementing exponentiation. Analysing the proof, we uncover redundant steps which suggests that one might benefit from resorting to a set of higher-level proof rules.

As global program variables, we use **VAR** = $\{x, y, r\}$ and we assume that all program variables may also take on negative values. More precisely, we declare

$$\mathbf{fun} \text{sort}(-) = \text{int} \ .$$

An implementation then amounts to $S_{\text{exp}} \stackrel{\text{def}}{=} r := 1; \text{loop}_{\text{exp}}$ with

$\text{loop}_{\text{exp}} \stackrel{\text{def}}{=} \mathbf{while} \ y \neq 0 \ \mathbf{do} \ \mathbf{begin} \ r := r * x; \ y := y - 1 \ \mathbf{end}$

A possible specification in our current setup might be

$$\forall \sigma, \tau. (\sigma \xrightarrow{S_{\text{exp}}} \tau) \Rightarrow \tau(r) = \sigma(x)^{\sigma(y)} \quad (2.11)$$

This is a typical input/output specification (Liskov & Berzins 1986). The state σ captures the initial state, the state τ captures the final state of the program. The proposition $\tau(r) = \sigma(x)^{\sigma(y)}$ connects the *input* values of x and y with the *output* value of r . Notice that connecting the output value of r with the *output* values of x and y e.g., $\tau(r) = \tau(x)^{\tau(y)}$, would be an unwise requirement: If S_{exp} terminates, the output value of y amounts to 0 and thus, the program S_{exp} would only satisfy the specification for an initial value of 1 for x .

Specifications of the above shape trivially hold if programs do not terminate. In such a case, there are no states σ, τ satisfying $\sigma \xrightarrow{S_{\text{exp}}} \tau$. Hence, (2.11) only

²To avoid partiality, one may instead use a *relational* denotational semantics $M : \text{prog} \rightarrow 2^{\Sigma \times \Sigma}$.

specifies *partial correctness*. In this thesis, we consider *total correctness*. The proposition $\forall \sigma \cdot \exists \tau \cdot \sigma \xrightarrow{S} \tau$ characterises that S terminates on all inputs. In practice, we do not want to insist on termination for all initial states. In particular, we have designed our exponential program in such a way that it only terminates for positive values of y i.e., $\forall \sigma \cdot 0 \leq \sigma(y) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S_{\text{exp}}} \tau$. Combining the termination condition with (2.11) yields an adequate specification with respect to total correctness:

→ p. 144  **Lemma 2.10 (Correctness of Exponential Program)**

$$\forall \sigma \cdot 0 \leq \sigma(y) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S_{\text{exp}}} \tau \wedge \tau(r) = \sigma(x)^{\sigma(y)}$$

 **Proof**

Given a state σ such that

$$0 \leq \sigma(y) \quad , \quad (2.12)$$

we need to find a final state τ such that

$$\sigma \xrightarrow{S_{\text{exp}}} \tau \quad (2.13)$$

and $\tau(r) = \sigma(x)^{\sigma(y)}$ holds. Applying the rule for sequential composition (2.6), followed by the assignment axiom (2.5) simplifies the first proof obligation (2.13) to

$$\sigma[r \mapsto 1] \xrightarrow{\text{loop}_{\text{exp}}} \tau \quad . \quad (2.14)$$

We have thus reduced the original proof obligation to

$$\forall \sigma \cdot 0 \leq \sigma(y) \Rightarrow \exists \tau \cdot \sigma[r \mapsto 1] \xrightarrow{\text{loop}_{\text{exp}}} \tau \wedge \tau(r) = \sigma(x)^{\sigma(y)} \quad . \quad (2.15)$$

Since each execution of the loop body decreases the value of y until it is 0, we pursue *induction*. For the induction to go through, we have to strengthen the proof obligation (2.15) so that the state σ corresponds to an arbitrary intermediate state of the loop. In particular, it must not be restricted to the case where the value of r amounts to the initial 1. We choose

$$\forall \sigma \cdot 0 \leq \sigma(y) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{\text{loop}_{\text{exp}}} \tau \wedge \tau(y) = 0 \wedge \tau(r) = \sigma(r) * \sigma(x)^{\sigma(y)} \quad (2.16)$$

and pursue induction on $\sigma(y)$. Formally, we derive

$$\begin{aligned} \forall n \cdot \forall \sigma \cdot (0 \leq \sigma(y) \wedge \sigma(y) = n) \Rightarrow \\ \exists \tau \cdot \sigma \xrightarrow{\text{loop}_{\text{exp}}} \tau \wedge \tau(y) = 0 \wedge \tau(r) = \sigma(r) * \sigma(x)^{\sigma(y)} \end{aligned}$$

by induction on n .

In the base case, the axiom for loops (2.9) unifies σ with τ and we have to show

$$\sigma(r) = \sigma(r) * \sigma(r)^0 .$$

In the step case, for $\sigma(y) = n + 1$, we need to find a state τ which satisfies

$$\sigma \xrightarrow{\text{loop}_{\text{exp}}} \tau \quad (2.17)$$

and

$$\tau(y) = 0 \wedge \tau(r) = \sigma(r) * \sigma(x)^{\sigma(y)} . \quad (2.18)$$

Unwinding the loop once reduces the proof obligation (2.17) to

$$\eta \xrightarrow{\text{loop}_{\text{exp}}} \tau \quad \text{for } \eta = \sigma[r \mapsto \sigma(r) * \sigma(x)] [y \mapsto \sigma(y) - 1]. \quad (2.19)$$

We may now apply the induction hypothesis with η , because $n = \eta(y)$. This yields

$$\tau(y) = 0 \wedge \tau(r) = \sigma(r) * \sigma(x) * \sigma(x)^{\sigma(y)-1}$$

which is equivalent to the remaining proof obligation (2.18) for $\sigma(y) > 0$.

□

As part of the proof, given an initial state σ satisfying a particular precondition, we needed to find a final state τ such that, according to the rule of the operational semantics, we could derive $\sigma \xrightarrow{S} \tau$. Furthermore, we had to establish that the postcondition relating σ and τ held.

However, being deterministic, the operational semantics uniquely determines such a final state. In addition, the initial correctness formula, the proof obligation (2.19) and the crucial proof obligation (2.16) are all of the form

$$\forall \sigma \cdot p(\sigma) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S} \tau \wedge q(\tau, \sigma) \quad (2.20)$$

for particular instances of $p : \Sigma \rightarrow \text{Prop}$, $S : \text{prog}$ and $q : (\Sigma \times \Sigma) \rightarrow \text{Prop}$. Instead of resorting to inference steps preserving this structure, the above proof has unnecessarily employed introduction and elimination rules for the logical connectives \forall , \Rightarrow and \exists to destruct and reconstruct such forms.

In VDM, one focusses on deriving correctness formulae of the form (2.20). Hoare Logic is similar, but postconditions are restricted to predicates rather than binary relations on the state space. One can thus not directly specify input/output behaviour. To compensate for this deficiency, one needs to additionally deal with auxiliary variables. We therefore first consider VDM.

2.9 The Vienna Development Method

The Vienna Development Method (VDM) is a verification calculus which relates programs with pre- and postconditions (Jones 1990, Jones & Shaw 1990). We commence by introducing VDM, in particular its operation decomposition calculus, at an informal level. Employing a shallow embedding of assertions, we then show how one might represent such a verification calculus in a logical framework. Next, we reconsider the above verification proof in VDM before investigating soundness and completeness.

In VDM, assertions are objects of a logic of partial functions (LPF). In the postcondition one may employ *hooked* program variables \overleftarrow{x} to refer to the value of the program variable in the initial state. The meaning of a postcondition is determined by an interpretation $I(\tau, \sigma)$ relative to a final state τ and initial state σ . In particular, for a program variable x , we have

$$\begin{aligned} \llbracket x \rrbracket I(\tau, \sigma) &\stackrel{\text{def}}{=} I(\tau(x)) \\ \llbracket \overleftarrow{x} \rrbracket I(\tau, \sigma) &\stackrel{\text{def}}{=} I(\sigma(x)) \quad . \end{aligned}$$

Hooked notation is extended to expressions and preconditions. Hooked expressions and preconditions may only appear within postconditions. On a syntactic level, one has to hook all free occurring variables. Semantically, let t be an expression and p be a precondition. One then interprets

$$\begin{aligned} \llbracket \overleftarrow{t} \rrbracket I(\tau, \sigma) &\stackrel{\text{def}}{=} \llbracket t \rrbracket I(\sigma) \\ \llbracket \overleftarrow{p} \rrbracket I(\tau, \sigma) &\stackrel{\text{def}}{=} \llbracket p \rrbracket I(\sigma) \quad . \end{aligned}$$

VDM is a formal system for deriving correctness formulae $\{p\} S \{q\}$. Such a triple is interpreted as

$$\forall \sigma \cdot \llbracket p \rrbracket I(\sigma) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S} \tau \wedge \llbracket q \rrbracket I(\tau, \sigma)$$

and thus reflects the shape of correctness formulae as encountered in the above verification example. However, being a formal system which manipulates objects of the form $\{p\} S \{q\}$, VDM guides verification proofs at a more abstract level. Whereas in the above correctness proof, one was confronted with (higher-order) propositions built around a formal system relating programs with states, VDM is a formal system relating programs with *relations on states*. More precisely, VDM encompasses two orthogonal methods:

1. refining abstract objects into concrete data types available in the programming language, and

2. refining correctness formulae, which allows one to decompose programs.

We will only consider VDM's operation decomposition rules and, from now on, do no longer distinguish between them and VDM in general.

For every constructor of the imperative programming language, VDM provides a rule which allows one to decompose a program. In particular, the programs mentioned in the premisses are strict subprograms of the programs mentioned in the conclusions. Unlike the operational semantics, this also holds for loops where a well-founded induction argument has been built into the rule.

$$\frac{\frac{\{\mathbf{true}\} \mathbf{skip} \left\{ \bigwedge_{v \in \mathbf{VAR}} v = \overleftarrow{v} \right\}}{\{\mathbf{true}\} x := t \left\{ x = \overleftarrow{t} \wedge \bigwedge_{v \in \mathbf{VAR} \setminus \{x\}} v = \overleftarrow{v} \right\}}}{\frac{\{p_1\} S_1 \{p_2 \wedge r_1\} \quad \{p_2\} S_2 \{r_2\}}{\{p_1\} S_1; S_2 \{r_2 \circ r_1\}}}$$

Semantically, the postcondition in the conclusion corresponds to relational composition i.e., $\llbracket r_2 \circ r_1 \rrbracket I(\tau, \sigma) \stackrel{\text{def}}{=} \exists \eta. \llbracket r_1 \rrbracket I(\eta, \sigma) \wedge \llbracket r_2 \rrbracket I(\tau, \eta)$. Syntactically, it suffices to existentially quantify intermediate values for all free occurring program variables and substitute them for all free program variables in r_1 and all hooked program variables in r_2 .

Example 2.11 (VDM's Sequential Decomposition Rule) *Let*

$$\begin{aligned} r_1 &\stackrel{\text{def}}{=} r = 1 \wedge 0 \leq y \wedge x = \overleftarrow{x} \wedge y = \overleftarrow{y} \\ r_2 &\stackrel{\text{def}}{=} y = 0 \wedge \overleftarrow{r} * \overleftarrow{x} \overleftarrow{y} = r * x^y \wedge y \leq \overleftarrow{y} \end{aligned}$$

Then, $r_2 \circ r_1$ corresponds to

$$\begin{aligned} \exists x_i, y_i, r_i. r_i \cdot r_i = 1 \wedge 0 \leq y_i \wedge x_i = \overleftarrow{x} \wedge y_i = \overleftarrow{y} \wedge \\ y = 0 \wedge r_i * x_i^{y_i} = r * x^y \wedge y \leq y_i \end{aligned}$$

which is equivalent to $0 \leq \overleftarrow{y} \wedge y = 0 \wedge r = \overleftarrow{x} \overleftarrow{y}$.

$$\frac{\{p \wedge b\} S_1 \{q\} \quad \{p \wedge \neg b\} S_2 \{q\}}{\{p\} \mathbf{if } b \mathbf{ then } S_1 \mathbf{ else } S_2 \{q\}}$$

$$\frac{\{p \wedge b\} S \{p \wedge \textit{sofar}\}}{\{p\} \mathbf{while} \ b \ \mathbf{do} \ S \ \{p \wedge \neg b \wedge (\textit{sofar} \vee \bigwedge_{v \in \mathbf{VAR}} v = \overleftarrow{v})\}}$$

where *sofar* is³ transitive and well-founded.

As Jones (1990) points out, it suffices to ensure that the relation *sofar* is well-founded on the set of states *satisfying the invariant p*. It would thus suffice, if the relation $\lambda(\tau, \sigma) \cdot \llbracket \textit{sofar} \rrbracket I(\tau, \sigma) \wedge \llbracket p \rrbracket I(\tau)$ was well-founded.

One also needs the structural rule

$$\frac{\{p_1\} S \{q_1\}}{\{p\} S \{q\}} \quad \text{provided } p \Rightarrow p_1 \text{ and } \overleftarrow{p} \Rightarrow q_1 \Rightarrow q$$

which allows one to weaken the precondition and strengthen the postcondition in a proof obligation. This is particularly useful when one wants to apply the rule for loops as the precondition must remain invariant with respect to the body of the loop, whereas the postcondition is expected to incorporate justification for termination.

2.9.1 Mechanisation

The above presentation of VDM is due to Aczel (1982a, 1982b). There, preconditions are treated as predicates on states, whereas postconditions are captured by binary relations on states. In particular, assertions are not considered at a syntactic level and there is no reference to LPF.

We follow Aczel's approach and employ a shallow embedding to represent assertions. In a logical framework supporting set theory, one might use sets to capture relations. Using LEGO, we only consider sets of the form $\{x \mid P(x)\}$ where $P : T \rightarrow \text{Prop}$ is a *function* mapping elements of an arbitrary type T to LEGO's internal logic. In other words, we represent sets by their characteristic functions. Thus, in VDM, preconditions inhabit $\Sigma \rightarrow \text{Prop}$ and postconditions inhabit $(\Sigma \times \Sigma) \rightarrow \text{Prop}$.

We are interested in the meta theory of VDM. We therefore need to capture both the semantics and the notion of deriving a VDM correctness formula.

↪ p. 144  **Definition 2.12 (Semantics of VDM)** *Let*

$$\models_{\text{VDM}} \{.\} \cdot \{.\} \subseteq (\Sigma \rightarrow \text{Prop}) \times \text{prog} \times ((\Sigma \times \Sigma) \rightarrow \text{Prop})$$

be a new judgement defined in terms of the operational semantics

$$\models_{\text{VDM}} \{p\} S \{q\} \stackrel{\text{def}}{=} \forall \sigma \cdot p(\sigma) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S} \tau \wedge q(\tau, \sigma)$$

³i.e., the relation $\lambda(\tau, \sigma) \cdot \llbracket \textit{sofar} \rrbracket(\tau, \sigma)$

→ p. 145  **Definition 2.13 (VDM)** *Let*

$$\vdash_{\text{VDM}} \{.\} \cdot \{.\} \subseteq (\Sigma \rightarrow \text{Prop}) \times \text{prog} \times ((\Sigma \times \Sigma) \rightarrow \text{Prop})$$

be the least relation satisfying

$$\vdash_{\text{VDM}} \{\lambda\sigma \cdot \mathbf{true}\} \mathbf{skip} \{\lambda(\tau, \sigma) \cdot \tau = \sigma\} \quad (2.21)$$

$$\vdash_{\text{VDM}} \{\lambda\sigma \cdot \mathbf{true}\} x := t \{\lambda(\tau, \sigma) \cdot \tau = \sigma[x \mapsto \text{eval}(\sigma)(t)]\} \quad (2.22)$$

$$\frac{\vdash_{\text{VDM}} \{p_1\} S_1 \{\lambda(\tau, \sigma) \cdot p_2(\tau) \wedge r_1(\tau, \sigma)\} \quad \vdash_{\text{VDM}} \{p_2\} S_2 \{r_2\}}{\vdash_{\text{VDM}} \{p_1\} S_1; S_2 \{r_2 \circ r_1\}} \quad (2.23)$$

$$\frac{\vdash_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \quad \vdash_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\}}{\vdash_{\text{VDM}} \{p\} \mathbf{if } b \mathbf{ then } S_1 \mathbf{ else } S_2 \{q\}} \quad (2.24)$$

$$\frac{\vdash_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S \{\lambda(\tau, \sigma) \cdot p(\tau) \wedge \text{sofar}(\tau, \sigma)\}}{\vdash_{\text{VDM}} \{p\} \mathbf{while } b \mathbf{ do } S \{q\}}$$

where sofar is any binary transitive relation on the state space Σ such that

$$\lambda(\tau, \sigma) \cdot \text{sofar}(\tau, \sigma) \wedge p(\tau) \text{ is well-founded}$$

$$\text{and } q(\tau, \sigma) \stackrel{\text{def}}{=} p(\tau) \wedge \text{eval}(\tau)(b) = \mathbf{false} \wedge (\text{sofar}(\tau, \sigma) \vee \tau = \sigma). \quad (2.25)$$

$$\frac{\vdash_{\text{VDM}} \{p_1\} S \{q_1\}}{\vdash_{\text{VDM}} \{p\} S \{q\}} \quad \text{provided } \forall \sigma \cdot p(\sigma) \Rightarrow p_1(\sigma) \text{ and } \forall (\tau, \sigma) \cdot p(\sigma) \Rightarrow q_1(\tau, \sigma) \Rightarrow q(\tau, \sigma). \quad (2.26)$$

2.9.2 High-Level Verification

We now revisit the verification of the exponential program within the VDM framework. To increase readability, we use syntactic representations for assertions. These have been manually translated from the shallow embedding used in the actual script.

→ p. 148  **Lemma 2.14 (VDM – Correctness of Exponential Function)**

$$\vdash_{\text{VDM}} \{0 \leq y\} S_{\text{exp}} \left\{ r = \overleftarrow{x} \overleftarrow{y} \right\}$$

 **Proof** According to the axiom for assignments (2.22), we may derive the correctness formula $\vdash_{\text{VDM}} \{\mathbf{true}\} r := 1 \{r = 1 \wedge x = \overleftarrow{x} \wedge y = \overleftarrow{y}\}$. Taking $0 \leq y$ into account, by the consequence rule (2.26) we may deduce

$$\vdash_{\text{VDM}} \{0 \leq y\} r := 1 \{r = 1 \wedge x = \overleftarrow{x} \wedge y = \overleftarrow{y} \wedge 0 \leq y\} \quad (2.27)$$

The challenge in the correctness proof stems from instantiating the loop rule (2.25) with an appropriate invariance predicate and termination measure. From the postcondition of (2.27), we adopt $0 \leq y$ as an invariant. In addition, the loop leaves $r * x^y$ invariant as decreases of y are compensated by increasing r appropriately:

$$\mathit{sofar} \stackrel{\text{def}}{=} \overleftarrow{r} * \overleftarrow{x}^{\overleftarrow{y}} = r * x^y \wedge y < \overleftarrow{y} .$$

We thus focus on deriving

$$\vdash_{\text{VDM}} \{0 \leq y\} \mathit{loop}_{\text{exp}} \{0 \leq y \wedge \neg(y \neq 0) \wedge \mathit{sofar}\} \quad (2.28)$$

which is semantically equivalent to the proof obligation (2.16). We may decompose (2.28) by the rule for loops (2.25) as sofar is clearly transitive and in the light of $0 \leq y$, there are only finitely many smaller \overleftarrow{y} . We now need to show

$$\vdash_{\text{VDM}} \{0 \leq y \wedge y \neq 0\} r := r * x; y := y - 1 \{0 \leq y \wedge \mathit{sofar}\} \quad (2.29)$$

According to the axiom (2.22), we may deduce

$$\vdash_{\text{VDM}} \{\mathbf{true}\} r := r * x \{r = \overleftarrow{r} * \overleftarrow{x} \wedge x = \overleftarrow{x} \wedge y = \overleftarrow{y}\} \quad (2.30)$$

$$\text{and } \vdash_{\text{VDM}} \{\mathbf{true}\} y := y - 1 \{y = \overleftarrow{y} - 1 \wedge x = \overleftarrow{x} \wedge r = \overleftarrow{r}\} \quad (2.31)$$

Connecting (2.30) with the precondition of (2.29), the rule of consequence (2.26) yields

$$\vdash_{\text{VDM}} \{0 \leq y \wedge y \neq 0\} r := r * x \{r = \overleftarrow{r} * \overleftarrow{x} \wedge x = \overleftarrow{x} \wedge 0 < y \wedge y = \overleftarrow{y}\} \quad (2.32)$$

We now derive

$$\vdash_{\text{VDM}} \{0 \leq y \wedge y \neq 0\} r := r * x; y := y - 1 \{\mathit{postbody}\} \quad (2.33)$$

with

$$\begin{aligned} \mathit{postbody} \stackrel{\text{def}}{=} \exists x_i, y_i, r_i \cdot r_i = \overleftarrow{r} * \overleftarrow{x} \wedge x_i = \overleftarrow{x} \wedge 0 < y_i \wedge y_i = \overleftarrow{y} \wedge \\ y = y_i - 1 \wedge x = x_i \wedge r = r_i \end{aligned}$$

by applying the sequential rule (2.23) to the correctness formulae (2.32) and (2.31). Appealing to the consequence rule (2.26), it suffices to show that the postcondition of (2.33) entails the postcondition of (2.29). The above postcondition is equivalent to

$$r = \overleftarrow{r} * \overleftarrow{x} \wedge x = \overleftarrow{x} \wedge 0 \leq y \wedge y = \overleftarrow{y} - 1 . \quad (2.34)$$

It is straightforward to check that $0 \leq y \wedge \mathit{sofar}$ follows from (2.34). Combining the initialisation (2.27) with the loop (2.28) via the rule of sequential composition (2.23) leads to

$$\vdash_{\text{VDM}} \{0 \leq y\} S_{\text{exp}} \left\{ 0 \leq \overleftarrow{y} \wedge y = 0 \wedge r = \overleftarrow{x}^{\overleftarrow{y}} \right\}$$

Appealing to the consequence rule (2.26), we may weaken the postcondition and derive the desired correctness formula. \square

2.9.3 Soundness

In this section, we justify the VDM rules and show that VDM is merely a more abstract calculus for verifying correctness formulae. In particular, any derivation in VDM corresponds to a proof based on the rules of the operational semantics.

→ p. 149  **Theorem 2.15 (Soundness of VDM)** *For any precondition p , program S and postcondition q , whenever $\vdash_{\text{VDM}} \{p\} S \{q\}$ is derivable, $\models_{\text{VDM}} \{p\} S \{q\}$ holds.*

 **Proof** by induction on the derivation of $\vdash_{\text{VDM}} \{p\} S \{q\}$. We consider the two cases where $\vdash_{\text{VDM}} \{p\} S \{q\}$ has been derived by the rule for conditionals or loops in more detail:

Conditional From the two induction hypotheses

$$\models_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \quad (2.35)$$

$$\models_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\} \quad (2.36)$$

we need to establish

$$\models_{\text{VDM}} \{p\} \mathbf{if } b \mathbf{ then } S_1 \mathbf{ else } S_2 \{q\} .$$

We show this by expanding the definition of \models_{VDM} and considering the cases for $\text{eval}(\sigma)(b) = \mathbf{true}$ and $\text{eval}(\sigma)(b) = \mathbf{false}$. The conclusion follows from (2.35) and (2.36) respectively.

Loop Given a state satisfying the predicate p , we need to find a final state τ such that

$$\sigma \xrightarrow{\mathbf{while } b \mathbf{ do } S} \tau , \quad (2.37)$$

$$p(\tau) , \quad (2.38)$$

$$\text{eval}(\tau)(b) = \mathbf{false} \quad (2.39)$$

and

$$\text{sofar}(\tau, \sigma) \vee \tau = \sigma . \quad (2.40)$$

We commence with a case analysis on the initial value of the guard b . If it is **false**, (2.9) is applicable. In particular, for $\tau = \sigma$, (2.38)–(2.40) trivially hold. Otherwise, we may exploit the induction hypothesis

$$\models_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S \{\lambda(\tau, \sigma) \cdot p(\tau) \wedge \text{sofar}(\tau, \sigma)\} .$$

There must be a state η such that

$$\sigma \xrightarrow{S} \eta , \quad (2.41)$$

$p(\eta)$ and

$$\text{sofar}(\eta, \sigma) . \quad (2.42)$$

Is the guard b satisfied in state η ?

No: From (2.41), we may conclude $\sigma \xrightarrow{\text{while } b \text{ do } S} \eta$. For $\tau = \eta$, (2.38)–(2.40) trivially hold.

Yes: The side-condition of the rule for loops guarantees that the relation

$$\lambda(\tau, \sigma) \cdot \text{sofar}(\tau, \sigma) \wedge p(\tau)$$

is well-founded. We know that η is less than σ with respect to this ordering and may thus exploit variants of (2.38)–(2.40) where σ has been substituted by η . In particular, there has to be a state τ satisfying (2.38), (2.39),

$$\eta \xrightarrow{\text{while } b \text{ do } S} \tau \quad (2.43)$$

and

$$\text{sofar}(\tau, \eta) \vee \tau = \eta . \quad (2.44)$$

In fact, τ is the desired final state. Applying the rule for loops (2.10) to (2.41) and (2.43) justifies (2.37), whereas transitivity of *sofar* leads from (2.44) and (2.42) to (2.40).

□

2.9.4 Completeness

If the VDM rules are to serve as the basis of a methodology for developing programs, completeness is an important issue i.e., given any derivable correctness formula of the form $\models_{\text{VDM}} \{p\} S \{q\}$, can we also justify it only employing the VDM rules? In other words, in moving from the level of states to the level of predicates and relations over states, have we actually achieved a more abstract perspective? Our objective is to show that whenever $\models_{\text{VDM}} \{p\} S \{q\}$ holds, the judgement $\vdash_{\text{VDM}} \{p\} S \{q\}$ is derivable.

One may prove completeness directly by induction on the structure of S e.g., Aczel (1982a) establishes soundness and completeness simultaneously by induction on the structure of programs. Instead, we follow an idea due to Gorelick (1975), which, previously, has only been applied to Hoare Logic dealing with recursive procedures :

1. By induction on the structure of an arbitrary program S , one establishes that a specific correctness formula $\text{MGF}_{\text{VDM}}(S)$, known as the *Most General Formula* (MGF), is derivable in the verification calculus.
2. Given the assumption $\models_{\text{VDM}} \{p\} S \{q\}$, one may derive $\vdash_{\text{VDM}} \{p\} S \{q\}$ by applying structural rules to $\vdash_{\text{VDM}} \text{MGF}_{\text{VDM}}(S)$. All side-conditions which arise will be dealt with by the assumption.

In other words, instead of directly deriving $\models_{\text{VDM}} \{p\} S \{q\} \Rightarrow \vdash_{\text{VDM}} \{p\} S \{q\}$, one considers the stronger property $\vdash_{\text{VDM}} \text{MGF}_{\text{VDM}}(S)$ for which induction goes through more easily. In particular, the direct proof cannot be applied when one considers recursive procedures, because the induction hypotheses are not strong enough.

The proposition $\vdash_{\text{VDM}} \text{MGF}_{\text{VDM}}(S)$ asserts that, provided that one only considers input states in which the program S terminates, one may *derive* a correctness formula in which the postcondition relates all inputs with the appropriate outputs according to the underlying operational semantics of the programming language. At the semantic level, $\models_{\text{VDM}} \text{MGF}_{\text{VDM}}(S)$ holds trivially.

→ p. 149  **Definition 2.16 (Termination)** For a deterministic programming language, commencing execution in a state σ , a program S terminates, if there is a final state τ according to the operational semantics, $S \downarrow(\sigma) \stackrel{\text{def}}{=} \exists \tau \cdot \sigma \xrightarrow{S} \tau$.

→ p. 149  **Definition 2.17 (MGF)** $\text{MGF}_{\text{VDM}}(S) \stackrel{\text{def}}{=} \{S \downarrow\} S \left\{ \lambda(\tau, \sigma) \cdot \sigma \xrightarrow{S} \tau \right\}$

Having chosen a shallow embedding, we can directly express the assertions of the MGF. If one also considers syntax of the assertion language, one needs to show that it is sufficiently *expressive*. We will return to this issue in more detail in Section 2.12.

→ p. 150  **Theorem 2.18 (MGF for VDM)** For an arbitrary program S , $\vdash_{\text{VDM}} \text{MGF}_{\text{VDM}}(S)$ is derivable.

 **Proof** The proof is by induction on the structure of S . Observe that this induction strategy affects both pre- and postcondition. In the case of a loop, from

$$\vdash_{\text{VDM}} \{S \downarrow\} S \left\{ \lambda(\tau, \sigma) \cdot \sigma \xrightarrow{S} \tau \right\} \quad (2.45)$$

we have to establish

$$\vdash_{\text{VDM}} \{\mathbf{while} \ b \ \mathbf{do} \ S \downarrow\} \mathbf{while} \ b \ \mathbf{do} \ S \left\{ \lambda(\tau, \sigma) \cdot \sigma \xrightarrow{\mathbf{while} \ b \ \mathbf{do} \ S} \tau \right\} . \quad (2.46)$$

We first apply the consequence rule (2.26) to the hypothesis (2.45) so that the precondition is of the form $\lambda \sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}$ and the postcondition matches

$\lambda(\tau, \sigma) \cdot p(\tau) \wedge \text{sofar}(\tau, \sigma)$ for some suitable invariant p and variant sofar . We then apply the rule for loops and, finally, employ again the consequence rule to transform the correctness formula into the desired (2.46).

These transformations trigger some side-conditions relative to the variant and invariant to be synthesised. Applying the consequence rule for the first time yields

$$\forall \sigma \cdot (p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}) \Rightarrow S \downarrow (\sigma) \quad (2.47)$$

$$\forall (\tau, \sigma) \cdot (p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}) \Rightarrow \sigma \xrightarrow{S} \tau \Rightarrow (p(\tau) \wedge \text{sofar}(\tau, \sigma)) \quad (2.48)$$

The rule for loops is concerned with $\lambda(\tau, \sigma) \cdot \text{sofar}(\tau, \sigma) \wedge p(\tau)$ being well-founded and the last appeal to the rule of consequence triggers

$$\forall \sigma \cdot \mathbf{while} \ b \ \mathbf{do} \ S \downarrow (\sigma) \Rightarrow p(\sigma) \quad (2.49)$$

$$\forall (\tau, \sigma) \cdot \mathbf{while} \ b \ \mathbf{do} \ S \downarrow (\sigma) \Rightarrow (p(\tau) \wedge \text{eval}(\tau)(b) = \mathbf{false} \wedge \text{sofar}^{\neq}(\tau, \sigma)) \Rightarrow \sigma \xrightarrow{\mathbf{while} \ b \ \mathbf{do} \ S} \tau \quad (2.50)$$

The termination condition for loops $p \stackrel{\text{def}}{=} \mathbf{while} \ b \ \mathbf{do} \ S \downarrow$ is an appropriate invariant.

A single step of the loop is captured by the relation

$$\lambda(\sigma, \tau) \cdot \text{eval}(\sigma)(b) = \mathbf{true} \wedge \sigma \xrightarrow{S} \tau .$$

Appealing to the operational semantics definition, it is easy to check that the transitive closure

$$\text{sofar}(\tau, \sigma) \stackrel{\text{def}}{=} (\lambda(\sigma, \tau) \cdot \text{eval}(\sigma)(b) = \mathbf{true} \wedge \sigma \xrightarrow{S} \tau)^+(\sigma, \tau)$$

approximates the loop. In particular, if τ is one of the intermediate states of the loop for which the loop guard does *not* hold, i.e., for some initial state σ , if $\text{sofar}^{\neq}(\tau, \sigma)$ and $\text{eval}(\tau)(b) = \mathbf{false}$ holds, we must have $\sigma \xrightarrow{\mathbf{while} \ b \ \mathbf{do} \ S} \tau$. \square

→ p. 150  **Corollary 2.19 (Completeness of VDM)** For any precondition p , program S and post-condition q , whenever $\models_{\text{VDM}} \{p\} S \{q\}$ holds, $\vdash_{\text{VDM}} \{p\} S \{q\}$ is derivable.

It is instructive to study the completeness proof in order to appreciate the rôle of the main theorem 2.18:

📖 **Proof** By Def. 2.12, the hypothesis is equivalent to

$$\forall \sigma \cdot p(\sigma) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S} \tau \wedge q(\tau, \sigma) . \quad (2.51)$$

Applying the consequence rule (2.26) to the MGF i.e.,

$$\vdash_{\text{VDM}} \{S\downarrow\} S \left\{ \lambda(\tau, \sigma) \cdot \sigma \xrightarrow{S} \tau \right\} ,$$

we may derive the desired $\vdash_{\text{VDM}} \{p\} S \{q\}$ provided we can satisfy the side conditions

$$\forall \sigma \cdot p(\sigma) \Rightarrow S\downarrow(\sigma) \quad (2.52)$$

and

$$\forall (\tau, \sigma) \cdot p(\sigma) \Rightarrow \sigma \xrightarrow{S} \tau \Rightarrow q(\tau, \sigma) . \quad (2.53)$$

Weakening the precondition (2.52) is a direct consequence of (2.51). We may strengthen the postcondition as suggested in (2.53) due to determinism. \square

2.10 Hoare Logic

Hoare Logic deviates from VDM in that the postcondition can only refer to the final and not to the initial state. We first present a set of rules for total correctness which reflects the traditional presentation. This includes a mechanised soundness and completeness result. Such meta-theoretical proofs are very similar to those in the VDM setting and we will merely highlight technical differences.

Using Hoare Logic, one cannot directly specify input/output specifications. In Sect. 2.10.3, we discuss various approaches to overcome this problem. Amongst these, we favour a proposal by Apt & Meertens (1980) to semantically consider assertions as relations between states and a domain of auxiliary variables. This idea has not previously been applied to Hoare Logic. It is useful in mechanising soundness and completeness of Hoare Logic, because it more adequately reflects the rôle of auxiliary variables employed in practice to relate output and input.

As our main contribution, we have designed a rule of consequence for adjusting auxiliary variables while strengthening preconditions and weakening postconditions. The new consequence rule is strictly stronger than Hoare's (1969) version. It plays a crucial rôle in establishing completeness as a corollary of the MGF theorem. Furthermore, it obviates the need for any further structural rules when considering recursive procedures.

In the traditional understanding of Hoare Logic (Cousot 1990), both pre- and post-conditions are first-order logic formulae where free variables denote the value of *program variables*. In particular, the validity of a formulae depends on a state σ .

For the purpose of mechanising soundness and completeness, we ignore the syntactical aspect of assertions. Employing again a shallow embedding, assertions are to inhabit the function space $\Sigma \rightarrow \text{Prop}$ which, intuitively, characterises predicates on states.

→ p. 150  **Definition 2.20 (Semantics of Hoare Logic)** *Let*

$$\models_{\text{Hoare}} \{.\} . \{.\} \subseteq (\Sigma \rightarrow \text{Prop}) \times \text{prog} \times (\Sigma \rightarrow \text{Prop})$$

be a new judgement defined in terms of the operational semantics

$$\models_{\text{Hoare}} \{p\} S \{q\} \stackrel{\text{def}}{=} \forall \sigma . p(\sigma) \Rightarrow \exists \tau . \sigma \xrightarrow{S} \tau \wedge q(\tau) .$$

2.10.1 Verification Calculus

Based on work of Floyd (1967), Hoare (1969) proposed a verification calculus for partial correctness, now referred to as Hoare Logic, see Fig. 2.1. To ensure termination,

$\{p\} \text{ skip } \{p\}$	
$\{p[x \mapsto t]\} x := t \{p\} \tag{2.54}$	
$\frac{\{p\} S_1 \{r\} \quad \{r\} S_2 \{q\}}{\{p\} S_1; S_2 \{q\}}$	
$\frac{\{p \wedge b\} S_1 \{q\} \quad \{p \wedge \neg b\} S_2 \{q\}}{\{p\} \text{ if } b \text{ then } S_1 \text{ else } S_2 \{q\}}$	
$\frac{\{p \wedge b\} S \{p\}}{\{p\} \text{ while } b \text{ do } S \{p \wedge \neg b\}} \tag{2.55}$	
$\frac{\{p_1\} S \{q_1\}}{\{p\} S \{q\}} \quad \text{provided } p \Rightarrow p_1 \text{ and } q_1 \Rightarrow q.$	
<p>Figure 2.1: Hoare Logic for Partial Correctness – Syntactic Presentation</p>	

the rule for loops (2.55) needs to be modified. We introduce a termination measure u with $\llbracket u \rrbracket : \Sigma \rightarrow W$ rather than just $u : \text{expression}(W)$. It may inspect *all* of the state space for some well-founded⁴ domain $(W, <)$ which is decreased whenever the body

⁴As we have already observed in the case of VDM's rule for loops, for the special case of $W = \Sigma$, it suffices to show that the relation $\lambda(\tau, \sigma) . p(\tau) \wedge \tau < \sigma$ is well-founded.

is executed:

$$\frac{\forall t : W \cdot \{p \wedge b \wedge u = t\} S \{p \wedge u < t\}}{\{p\} \mathbf{while} \ b \ \mathbf{do} \ S \{p \wedge \neg b\}} \quad \text{where } (W, <) \text{ is well-founded.}$$

A similar rule for verification calculi where postconditions may explicitly refer to the value of program variables in the initial state e.g., VDM, has been put forward by Manna & Pnueli (1974). Variants of this rule tailored for $W = \text{nat}$ (Harel 1980) or $W = \text{int}$ (Apt & Olderog 1991) have also been published previously. We prefer the well-founded version, because it simplifies the completeness proof without any impact on the soundness proof. One may instantiate $W = \Sigma$ and $u = \lambda\sigma \cdot \sigma$, and encounters almost the same proof obligations as in the case of VDM. It is well known that in practice, it is often easier to reason about termination using well-founded sets rather than being restricted to natural numbers (Dershowitz & Manna 1979).

Formalising these rules in a logical framework is as easy as in the case of VDM. In particular, representing the axiom for assignments (2.54) requires little work, because we chose a shallow embedding of assertions. Syntactically, the precondition amounts to updating a formulae at position x . We do not need to worry about formalising the notion of updating *assertions*. It can be expressed straightforwardly in terms of updating the state space i.e.,

$$\llbracket p[x \mapsto t] \rrbracket I(\sigma) = \llbracket p \rrbracket (I(\sigma[x \mapsto \llbracket t \rrbracket I(\sigma)])) \quad (2.56)$$

Previous experiments (Mason 1987, Homeier 1995) have made it clear that a deep embedding of assertions requires much more work. In particular, one would have to *prove* the substitution lemma (2.56) (Sieber 1981).

→ p. 150  **Definition 2.21 (Hoare Logic)** A verification calculus for Hoare Logic is defined as the least relation $\vdash_{\text{Hoare}} \{.\} \cdot \{.\} \subseteq (\Sigma \rightarrow \text{Prop}) \times \text{prog} \times (\Sigma \rightarrow \text{Prop})$ satisfying

$$\begin{array}{c} \vdash_{\text{Hoare}} \{p\} \mathbf{skip} \{p\} \\ \vdash_{\text{Hoare}} \{\lambda\sigma \cdot p(\sigma[x \mapsto \text{eval}(\sigma)(t)])\} x := t \{p\} \\ \frac{\vdash_{\text{Hoare}} \{p\} S_1 \{r\} \quad \vdash_{\text{Hoare}} \{r\} S_2 \{q\}}{\vdash_{\text{Hoare}} \{p\} S_1; S_2 \{q\}} \\ \frac{\vdash_{\text{Hoare}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \\ \vdash_{\text{Hoare}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{if} \ b \ \mathbf{then} \ S_1 \ \mathbf{else} \ S_2 \ \{q\}} \end{array}$$

$$\frac{\forall t : W \cdot \vdash_{\text{Hoare}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true} \wedge u(\sigma) = t\} S \{\lambda\tau \cdot p(\tau) \wedge u(\tau) < t\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{while} \ b \ \mathbf{do} \ S \{\lambda\tau \cdot p(\tau) \wedge \text{eval}(\tau)(b) = \mathbf{false}\}} \quad \text{where } (W, <) \text{ is well-founded.} \quad (2.57)$$

$$\frac{\vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{\vdash_{\text{Hoare}} \{p\} S \{q\}} \quad \text{provided } \forall \sigma \cdot p(\sigma) \Rightarrow p_1(\sigma) \text{ and } \forall \tau \cdot q_1(\tau) \Rightarrow q(\tau). \quad (2.58)$$

2.10.2 Soundness and Completeness

→ p. 151  **Theorem 2.22 (Soundness of Hoare Logic)** *The above verification calculus is sound.*

 **Proof** by induction on the derivation of $\vdash_{\text{Hoare}} \{p\} S \{q\}$. □

→ p. 151  **Definition 2.23 (Completeness of Hoare Logic)**

The above verification calculus is complete.

 **Proof** by induction on the structure of programs. We concentrate on the case for loops. From the induction hypothesis

$$\forall p, q \cdot \models_{\text{Hoare}} \{p\} S \{q\} \Rightarrow \vdash_{\text{Hoare}} \{p\} S \{q\}$$

and the assumption

$$\vdash_{\text{Hoare}} \{p\} \mathbf{while} \ b \ \mathbf{do} \ S \ \{q\} \quad (2.59)$$

we have to establish

$$\vdash_{\text{Hoare}} \{p\} \mathbf{while} \ b \ \mathbf{do} \ S \ \{q\} \ . \quad (2.60)$$

Our strategy is to use the rule for loops to connect the induction hypothesis with the conclusion. In particular, we have to come up with a suitable invariant and a termination measure $u : \Sigma \rightarrow W$ for some well-founded domain $(W, <)$. The proof is more challenging than establishing the MGF theorem⁵, because one needs to worry about arbitrary assertions p and q . In general, the supplied precondition p cannot be expected to remain invariant. Instead, we choose

$$\mathit{inv} = \mathit{wp}(\mathbf{while} \ b \ \mathbf{do} \ S, q)$$

where, relative to a program and postcondition, the weakest precondition wp is defined as

$$\mathit{wp}(S, q)(\sigma) \stackrel{\text{def}}{=} \exists \tau \cdot \sigma \xrightarrow{S} \tau \wedge q(\tau) \ .$$

It is easy to see that, for a loop, the weakest precondition⁶ is bound to remain invariant.

⁵In the following section, we will strengthen the rule of consequence (2.58) so that one may establish completeness as a corollary of the MGF property.

⁶In verifying *concrete* programs, the problem of constructing suitable invariants stems from having to find syntactic representations of such predicates. It does not suffice to rely on a sufficiently expressive assertion language in which one may express weakest preconditions. Instead, one needs to find an invariant specific to the domain involved; otherwise the difficulty in verification of finding suitable invariants is merely propagated to proving more difficult side-conditions arising from applications of the consequence rule.

In finding a suitable termination measure, we borrow ideas from the corresponding proof in the context of VDM. We choose $W = \Sigma$, $u = \lambda\sigma \cdot \sigma$,

$$\tau < \sigma =$$

$$\mathbf{while } b \mathbf{ do } S \downarrow(\sigma) \wedge (\lambda(\sigma, \tau) \cdot \text{eval}(\sigma)(b) = \mathbf{true} \wedge \sigma \xrightarrow{S} \tau)^+(\sigma, \tau) \quad (2.61)$$

and aim to establish

$$\forall t : \Sigma \cdot \vdash_{\text{Hoare}} \{ \lambda\sigma \cdot \text{inv}(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true} \wedge \sigma = t \} S \{ \lambda\tau \cdot \text{inv}(\tau) \wedge \tau < t \} \quad (2.62)$$

Let t be an arbitrary state. Appealing to the induction hypothesis, it suffices to show the semantic counterpart

$$\models_{\text{Hoare}} \{ \lambda\sigma \cdot \text{inv}(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true} \wedge \sigma = t \} S \{ \lambda\tau \cdot \text{inv}(\tau) \wedge \tau < t \}$$

In other words, relative to an initial state σ , such that

$$\underbrace{\exists \tau \cdot \sigma \xrightarrow{\mathbf{while } b \mathbf{ do } S} \tau \wedge q(\tau)}_{\text{inv}(\sigma)} \quad \text{and} \quad \text{eval}(\sigma)(b) = \mathbf{true}$$

we have to find an intermediate state η such that

$$\begin{array}{c} \sigma \xrightarrow{S} \eta, \\ \underbrace{\exists \tau \cdot \eta \xrightarrow{\mathbf{while } b \mathbf{ do } S} \tau \wedge q(\tau)}_{\text{inv}(\eta)} \end{array}$$

$$\text{and} \quad \underbrace{\mathbf{while } b \mathbf{ do } S \downarrow(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true} \wedge \sigma \xrightarrow{S} \eta}_{\eta < \sigma}$$

These proof obligations can be resolved easily by appealing to the definition of the operational semantics. We may thus apply the rule for loops (2.57) to the correctness formula (2.62). This yields

$$\vdash_{\text{Hoare}} \left\{ \lambda\sigma \cdot \exists \tau \cdot \sigma \xrightarrow{\mathbf{while } b \mathbf{ do } S} \tau \wedge q(\tau) \right\} \cdot \left\{ \lambda\eta \cdot \exists \tau \cdot \eta \xrightarrow{\mathbf{while } b \mathbf{ do } S} \tau \wedge q(\tau) \wedge \text{eval}(\eta)(b) = \mathbf{false} \right\}$$

According to the rule of consequence, we may derive the desired (2.60), provided the two side-conditions

$$\forall \sigma \cdot p(\sigma) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{\mathbf{while } b \mathbf{ do } S} \tau \wedge q(\tau) \quad (2.63)$$

$$\forall \eta \cdot (\exists \tau \cdot \eta \xrightarrow{\mathbf{while } b \mathbf{ do } S} \tau \wedge q(\tau) \wedge \text{eval}(\eta)(b) = \mathbf{false}) \Rightarrow q(\eta) \quad (2.64)$$

hold. The first condition is identical to the assumption (2.59). In the second obligation, according to the definition of the operational semantics, the state τ must be equal to η in the case where the loop guard evaluates to **false**. \square

2.10.3 Auxiliary Variables

Recall the specification of the exponential function in VDM

$$\{0 \leq y\} S_{\text{exp}} \left\{ r = \overleftarrow{x}^{\overleftarrow{y}} \right\}, \quad (2.65)$$

where all variables hold integer values. In Hoare Logic, we cannot directly relate the value of variables in the final with values of variables in the initial state. To overcome this deficiency, one needs to introduce auxiliary variables. These are simply program variables which only occur in assertions. In the precondition they freeze the value of other program variables so that in the postcondition one may refer to the initial value of program variables.

Let X and Y be program variables with sort `int`. In Hoare Logic, we may paraphrase the above correctness formula (2.65) as

$$\{0 \leq y \wedge x = X \wedge y = Y\} S_{\text{exp}} \{r = X^Y\}$$

where X and Y must not occur free in S_{exp} . (2.66)

Notice that the side-condition is essential for the two correctness formulae (2.65) and (2.66) to be equivalent. However, in Hoare Logic, we may not derive correctness formulae with attached side conditions, because, formally, Hoare Logic is a calculus for deriving programs with pre- and postconditions only. Side-conditions may only appear within axioms and rules.

Strictly speaking, Hoare Logic is thus not adequate for verifying concrete programs with non-contrived specifications. Problems also arise when the program to be verified is not fully given. This is for example the case when one wants to

- develop programs hand-in-hand with their proofs of correctness (Gries 1981, Burstall & McKinna 1993)
- consider free procedures which are specified with respect to pre- and postcondition, but for which one does not consider a concrete implementation (Tarlecki 1985)
- verify programs invoking recursive procedures

Assume that S is a program about which we only know that the program variable X does not occur in it. Then, the two specifications

$$\{X = x\} S \{X = x\} \quad (2.67)$$

and

$$\{X = x + 1\} S \{X = x + 1\} \quad (2.68)$$

where all variables denote integer values both assert that the program S leaves x in-

variant. Whenever one can derive (2.67), one may derive (2.68) and vice versa. Nevertheless, the consequence rule (2.58) does not allow one to derive (2.68) from (2.67) or vice versa, as one would have to show $x = x + 1$.

Pragmatically, this is quite worrying. Taking software reuse seriously, imagine that (2.67) has been derived as part of the verification in a project. It is conceivable that in another project, one needs the equivalent correctness formula (2.68). Unfortunately, in such a situation, the formalism would force us to rebuild (2.68) from scratch. Of course in the new derivation one would benefit from analysing the first derivation, but such a methodology is nevertheless undesirable.

In Chapter 3, using recursive procedures, we show that precisely this problem occurs in trying to verify a program computing the factorial function. In a nutshell, similar to an inductive step, during the verification of a recursive procedure, one needs to unroll the recursive call and can exploit the correctness formula before unrolling. Unfortunately, the hypothesis only matches modulo shifts of auxiliary variables reminiscent of the difference between (2.67) and (2.68).

We need to strengthen the consequence rule and exploit the fact that some program variables are not affected by the program e.g.,

$$\frac{\{p_1\} S \{q_1\}}{\{p\} S \{q\}} \quad \text{provided } \forall X \cdot \exists t \cdot (\forall x \cdot p \Rightarrow (p_1 [X \mapsto t])) \wedge (\forall x \cdot (q_1 [X \mapsto t] \Rightarrow q)), \quad (2.69)$$

where x and X are two disjoint lists of all program variables occurring in any of the assertions and no variables from X appear in the program. Furthermore, t is a list of compatible expressions.

Such a consequence rule is strictly stronger than Hoare's (1969), which one might view as a special case of 2.69 in which the choice of t is confined to X . In particular, employing the new rule of consequence, the two correctness formulae (2.67) and (2.68) are interderivable e.g., (2.68) follows from (2.67), because one may choose $t = X - 1$.

It also highlights that auxiliary variables and program variables deserve to be treated differently e.g., in the above side-condition, one only substitutes *auxiliary* variables. We would like to reflect this intuition in our encoding. We see two alternatives to capture auxiliary variables

1. explicit quantification
2. implicit quantification

Following Sieber (1985), we could extend Hoare Logic by allowing quantifiers at the *object* level i.e., correctness formulae may also take on the form of

$$\vdash_{\text{Hoare}} \forall X \cdot \{p\} S \{q\}$$

where the value of X does not depend on a state⁷.

Universal quantification is one way to ensure that auxiliary variables are bound explicitly to a specific correctness formula. It binds all occurrences of auxiliary variables in the precondition, program and postcondition. We prefer an implicit quantification in which both pre- and postcondition characterise binary relations on states. The advantages over explicit quantification are that

- programs cannot mention auxiliary variables
- it reflects *current* software engineering practice and does not require a syntactic modification of correctness formulae
- it is easier to encode in a logical framework

At the syntactic level, one would need to (formally) distinguish between program variables and auxiliary variables⁸. One could for example enforce that program variables have to start with a lower-case letter, whereas auxiliary variables must start with an upper-case letter. To be well-formed, programs may only refer to program variables.

Semantically, program variables are, as before, interpreted according to the state space. However, auxiliary variables are interpreted freely. Let T be the domain of this interpretation. We revise our shallow embedding of assertions:

→ p. 152  **Definition 2.24 (Assertions)** $\text{Assertion}(T : \text{Type}) \stackrel{\text{def}}{=} (T \times \Sigma) \rightarrow \text{Prop}$

Example 2.25 Let $T = \{X, Y\} \rightarrow \text{int}$. Relative to an interpretation $Z : T$ and a state σ , we interpret

$$\llbracket [0 \leq y \wedge x = X \wedge y = Y] \rrbracket (Z, \sigma) = 0 \leq \sigma(y) \wedge \sigma(x) = Z(X) \wedge \sigma(y) = Z(Y) .$$

The universal quantification is then integrated into the semantics:

→ p. 152  **Definition 2.26 (Semantics of Hoare Logic)** Parametrised by an arbitrary type T , let $\models_{\text{Hoare}} \{.\} . \{.\} \subseteq \text{Assertion}(T) \times \text{prog} \times \text{Assertion}(T)$ be a new judgement defined in terms of the operational semantics

$$\models_{\text{Hoare}} \{p\} S \{q\} \stackrel{\text{def}}{=} \forall Z . \forall \sigma . p(Z, \sigma) \Rightarrow \exists \tau . \sigma \xrightarrow{S} \tau \wedge q(Z, \tau) .$$

⁷In Reynolds's (1982) specification logic, X may be an arbitrary *expression* and one needs to additionally assert that X is not affected by the program S .

⁸This has also been proposed by Homeier & Martin (1996).

The previous axioms and rules from Def. 2.21 can be reused without any syntactic changes when assertions are represented as relations rather than predicates. Furthermore, we can easily formally cater for the stronger rule of consequence (2.69):

$$\frac{\vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{\vdash_{\text{Hoare}} \{p\} S \{q\}} \quad \text{provided } \forall Z \cdot \exists Z_1 \cdot (\forall \sigma \cdot p(Z, \sigma) \Rightarrow p_1(Z_1, \sigma)) \wedge (\forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau))$$

where $p_1, q_1 : \text{Assertion}(T)$ and $p, q : \text{Assertion}(U)$ are assertions for not necessarily identical domains T and U . In deriving completeness as a corollary from the MGF property, besides being able to switch the domain of auxiliary variables, we also need a weaker side-condition in which the choice of Z_1 may additionally depend on the initial value of variables:

$$\frac{\vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{\vdash_{\text{Hoare}} \{p\} S \{q\}} \quad \text{where } p_1, q_1 : \text{Assertion}(U) \text{ and } p, q : \text{Assertion}(T) \text{ for arbitrary types } T \text{ and } U$$

$$\text{and } \forall Z \cdot \forall \sigma \cdot p(Z, \sigma) \Rightarrow \left(\exists Z_1 \cdot p_1(Z_1, \sigma) \wedge (\forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau)) \right). \quad (2.70)$$

In classical logic, $\forall Z \cdot \forall \sigma \cdot \exists Z_1 \cdot (p(Z, \sigma) \Rightarrow p_1(Z_1, \sigma)) \wedge (\forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau))$ is an equivalent side-condition. Constructively, it is stronger and not sufficient. We will present a further variant on page 71 in connection with the rule of adaptation. However, the above consequence rule (2.70) suffices for all examples and completeness proofs in this thesis. In moving from predicates to binary relations, we retain all other axioms and rules:

→ p. 152  **Definition 2.27 (Hoare Logic)** *A verification calculus for Hoare Logic which takes auxiliary variables seriously is defined as the least relation*

$$\vdash_{\text{Hoare}} \{.\} . \{.\} \subseteq \text{Assertion}(T) \times \text{prog} \times \text{Assertion}(T)$$

indexed by an arbitrary type T such that

$$\vdash_{\text{Hoare}} \{p\} \text{ skip } \{p\} \quad (2.71)$$

$$\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma[x \mapsto \text{eval}(\sigma)(t)])\} x := t \{p\} \quad (2.72)$$

$$\frac{\vdash_{\text{Hoare}} \{p\} S_1 \{r\} \quad \vdash_{\text{Hoare}} \{r\} S_2 \{q\}}{\vdash_{\text{Hoare}} \{p\} S_1; S_2 \{q\}}$$

$$\frac{\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \quad \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{if } b \mathbf{ then } S_1 \mathbf{ else } S_2 \{q\}}$$

$$\frac{\forall t : W \cdot \vdash_{\text{Hoare}} \{\hat{p}\} S \{\lambda(Z, \tau) \cdot p(Z, \tau) \wedge u(\tau) < t\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{while} \ b \ \mathbf{do} \ S \{\lambda(Z, \tau) \cdot p(Z, \tau) \wedge \text{eval}(\tau)(b) = \mathbf{false}\}}$$

where $\hat{p}(Z, \sigma) \stackrel{\text{def}}{=} p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true} \wedge u(\sigma) = t$

and $(W, <)$ is well-founded. (2.73)

$$\frac{\vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{\vdash_{\text{Hoare}} \{p\} S \{q\}}$$

where $p_1, q_1 : \text{Assertion}(U)$ and $p, q : \text{Assertion}(T)$ for arbitrary types T and U

and $\forall Z \cdot \forall \sigma \cdot p(Z, \sigma) \Rightarrow \left(\exists Z_1 \cdot p_1(Z_1, \sigma) \wedge (\forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau)) \right)$. (2.70)

2.10.3.1 Universal Quantification versus Auxiliary Variables

Notice that the universally quantified variable in the rule for loops (2.73) plays the same rôle as an auxiliary variable. It must not occur⁹ in the program S . In particular, the rule

$$\frac{\{\hat{p}\} S \{\lambda((Z, t), \tau) \cdot p(Z, \tau) \wedge u(\tau) < t\}}{\{p\} \mathbf{while} \ b \ \mathbf{do} \ S \{\lambda(Z, \tau) \cdot p(Z, \tau) \wedge \text{eval}(\tau)(b) = \mathbf{false}\}}$$

where $\hat{p}((Z, t), \sigma) \stackrel{\text{def}}{=} p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true} \wedge u(\sigma) = t$

and $(W, <)$ is well-founded.

is (semantically) equivalent.

We have chosen the version (2.73) with universal quantification to illuminate the similarities with the rule for procedure calls in the following chapter in which the universal quantification ranges over *two* correctness formulae and cannot be internalised as an auxiliary variable. Furthermore, the implicitly quantified version needs to extend the domain of auxiliary variables in the premiss to guarantee that t is fresh. Hence, one could not restrict the domain of auxiliary variables to the state space.

In practice, rules with universal quantifications in the *premiss* pose no problems. In a refinement proof, one continues deriving the pure Hoare triple in which the quantified variable is replaced by a constant.

2.10.3.2 Soundness

We refer the reader to Fig. 2.2 on the next page for a syntactic presentation of this calculus. There, the side condition of the rule of consequence is tailored to classical logic and x denotes the list of all program variables, whereas Z denotes the list of all auxiliary variables.

⁹in our formalisation in LEGO, S is universally quantified outside the scope of t .

$$\begin{array}{c}
\{p\} \text{ skip } \{p\} \\
\{p[x \mapsto t]\} x := t \{p\} \\
\frac{\{p\} S_1 \{r\} \quad \{r\} S_2 \{q\}}{\{p\} S_1; S_2 \{q\}} \\
\frac{\{p \wedge b\} S_1 \{q\} \quad \{p \wedge \neg b\} S_2 \{q\}}{\{p\} \text{ if } b \text{ then } S_1 \text{ else } S_2 \{q\}} \\
\frac{\forall t : W \cdot \{p \wedge b \wedge u = t\} S \{p \wedge u < t\}}{\{p\} \text{ while } b \text{ do } S \{p \wedge \neg b\}} \quad \text{where } (W, <) \text{ is well-founded.} \\
\\
\frac{\{p_1\} S \{q_1\}}{\{p\} S \{q\}} \\
\text{provided } \forall Z \cdot \forall x \cdot \exists Z_1 \cdot (p \Rightarrow (p_1[Z \mapsto Z_1])) \wedge (\forall x \cdot (q_1[Z \mapsto Z_1]) \Rightarrow q).
\end{array}$$

Figure 2.2: Hoare Logic for Total Correctness – Syntactic Presentation

→ p. 154  **Theorem 2.28 (Soundness of Hoare Logic)** *The above verification calculus is sound.*

 **Proof** by induction on the derivation of $\vdash_{\text{Hoare}} \{p\} S \{q\}$. If the rule of consequence (2.70) has been applied last, from the induction hypothesis $\models_{\text{Hoare}} \{p_1\} S \{q_1\}$ i.e.,

$$\forall Z_1 \cdot \forall \sigma \cdot p_1(Z_1, \sigma) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S} \tau \wedge q_1(Z_1, \tau) \quad (2.74)$$

and the side-condition

$$\forall Z \cdot \forall \sigma \cdot p(Z, \sigma) \Rightarrow \left(\exists Z_1 \cdot p_1(Z_1, \sigma) \wedge (\forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau)) \right) \quad (2.75)$$

we need to show that $\models_{\text{Hoare}} \{p\} S \{q\}$ holds.

Given an auxiliary variable Z and an initial state σ satisfying $p(Z, \sigma)$, we need to find a final state τ such that $\sigma \xrightarrow{S} \tau$ and $q(Z, \tau)$. Combining $p(Z, \sigma)$ and (2.75), we can extract a witness Z_1 such that $p_1(Z_1, \sigma)$ holds, and for any state τ , we may reduce the task of showing $q(Z, \tau)$ to $q_1(Z_1, \tau)$. Appealing to (2.74), from $p_1(Z_1, \sigma)$ we may infer that there is a state τ satisfying both $\sigma \xrightarrow{S} \tau$ and $q_1(Z_1, \tau)$. \square

2.10.3.3 Completeness

Having represented assertions as binary relations over an arbitrary domain and the state space, we can immediately formulate the MGF property for Hoare Logic. Picking the

state space as the domain of auxiliary variables, we could simulate

$$\vdash_{\text{VDM}} \{S\downarrow\} S \left\{ \lambda(\tau, \sigma) \cdot \sigma \xrightarrow{S} \tau \right\}$$

by

$$\vdash_{\text{Hoare}} \{ \lambda(Z, \sigma) \cdot \sigma = Z \wedge S\downarrow(\sigma) \} S \left\{ \lambda(Z, \tau) \cdot Z \xrightarrow{S} \tau \right\} .$$

However, if one exploits the auxiliary variable to capture the final rather than the initial state, one has the more elegant

→ p. 154  **Definition 2.29 (MGF)**

$$\text{MGF}_{\text{Hoare}}(S) \stackrel{\text{def}}{=} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{S} Z \right\} S \{ \lambda(Z, \tau) \cdot Z = \tau \}$$

Notice that the precondition coincides with the weakest precondition relative to the program S and postcondition $\lambda(Z, \tau) \cdot Z = \tau$.

→ p. 154  **Theorem 2.30 (MGF for Hoare Logic)** *For an arbitrary program S , one may derive*
 $\vdash_{\text{Hoare}} \text{MGF}_{\text{Hoare}}(S)$.

 **Proof** by induction on the structure of S . In the case of a loop, from the induction hypothesis

$$\vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{S} Z \right\} S \{ \lambda(Z, \tau) \cdot Z = \tau \} \quad (2.76)$$

we have to establish

$$\vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{\mathbf{while} \ b \ \mathbf{do} \ S} Z \right\} \mathbf{while} \ b \ \mathbf{do} \ S \{ \lambda(Z, \tau) \cdot Z = \tau \} . \quad (2.77)$$

The proof follows the structure of the same property for VDM on page 27. To exploit the rule for loops, we want to transform the hypothesis into the form

$$\vdash_{\text{Hoare}} \{ \hat{p} \} S \{ \lambda(Z, \tau) \cdot p(Z, \tau) \wedge u(\tau) < t \}$$

where $t : \Sigma$ is a constant and the termination measure $u = \lambda\sigma \cdot \sigma$ is the identity function. For the invariant, we choose

$$p(Z, \sigma) = \sigma \xrightarrow{\mathbf{while} \ b \ \mathbf{do} \ S} Z$$

and for the variant $<$, we reuse the well-founded relation (2.61) employed in the direct proof of completeness on page 33.

This transformation is sanctioned by the rule of consequence (2.70). As a side-condition, for arbitrary states σ and Z , given

$$\sigma \xrightarrow{\text{while } b \text{ do } S} Z \quad (2.78)$$

$$\text{eval}(\sigma)(b) = \mathbf{true} \quad (2.79)$$

we need to find a state Z_1 such that $\sigma \xrightarrow{S} Z_1$ and

$$\forall \tau. (Z_1 = \tau) \Rightarrow (\tau \xrightarrow{\text{while } b \text{ do } S} Z_1 \wedge \sigma < t) .$$

Inverting the derivation of (2.78) in the presence of (2.79), these obligations can be resolved easily.

To conclude the proof, we need to again apply the rule of consequence to mediate between the conclusion of the loop rule

$$\vdash_{\text{Hoare}} \{p\} \text{ while } b \text{ do } S \{ \lambda(Z, \tau) \cdot p(Z, \tau) \wedge \text{eval}(\tau)(b) = \mathbf{false} \}$$

and the desired correctness formula (2.77). In this case, for arbitrary states σ and Z such that $\sigma \xrightarrow{\text{while } b \text{ do } S} Z$, we have find a state Z_1 such that

$$\sigma \xrightarrow{\text{while } b \text{ do } S} Z_1 \quad (2.80)$$

$$\forall \tau. (\tau \xrightarrow{\text{while } b \text{ do } S} Z_1 \wedge \text{eval}(\tau)(b) = \mathbf{false}) \Rightarrow Z_1 = \tau \quad (2.81)$$

We resolve (2.80) by selecting $Z_1 = Z$, whereas (2.81) is a direct consequence of the operational semantics. \square

Having treated auxiliary variables in a rigorous manner, it is interesting to observe that the main Theorem 2.30 singles out *the set of all states* as the domain for auxiliary variables i.e., $T = \Sigma$. Intuitively, such a restriction ties the auxiliary variables together with the program variables. Let $\{x_1, \dots, x_n\}$ be the set of all program variables with corresponding types $\{T_1, \dots, T_n\}$ occurring in some program S . An assertion of the form

$$\lambda(Z : T_1 \times \dots \times T_n, \sigma : \Sigma) \cdot P(Z.1, \dots, Z.n, \sigma)$$

is equivalent to

$$\lambda(Z, \sigma : \Sigma) \cdot P(Z(x_1), \dots, Z(x_n), \sigma) .$$

➔ p. 154  **Corollary 2.31 (Completeness of Hoare Logic)** For any precondition p , program S and postcondition q , whenever $\models_{\text{Hoare}} \{p\} S \{q\}$ holds, then $\vdash_{\text{Hoare}} \{p\} S \{q\}$ is derivable.

☞ **Proof** Let S be a program and $p, q : \text{Assertion}(T)$ be assertions for an *arbitrary* domain T . Given $\models_{\text{Hoare}} \{p\} S \{q\}$ i.e.,

$$\forall Z \cdot \forall \sigma \cdot p(Z, \sigma) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S} \tau \wedge q(Z, \tau) \quad (2.82)$$

we need to establish $\vdash_{\text{Hoare}} \{p\} S \{q\}$.

By the consequence rule (2.70), we may directly infer $\vdash_{\text{Hoare}} \{p\} S \{q\}$ from the MGF, triggering the side condition

$$\forall Z \cdot \forall \sigma \cdot p(Z, \sigma) \Rightarrow \exists Z_1 \cdot \sigma \xrightarrow{S} Z_1 \wedge \forall \tau \cdot \tau = Z_1 \Rightarrow q(Z, \tau) . \quad (2.83)$$

Clearly, (2.82) implies (2.83). □

We learn from the proof that in order to derive the correctness of a specification using an arbitrary domain of free variables T , applying the new consequence rule will confine the domain of auxiliary variables to the state space Σ . In particular, notice that the consequence rule has mediated between the state space and the domain T as representing auxiliary variables. Implementors of computer-aided verification systems can employ this transformation and safely restrict the domain of auxiliary variables to the state space for all other rules. Alternatively, one might implement a system in which the user can only formulate specifications where auxiliary variables live in the state space. Again, the above proof suggests that this is a sensible approach. In fact, in the system VDM, such a restriction has essentially been made.

Furthermore, notice that in the completeness proof, we only needed to apply the consequence rule (2.70). Thus, completeness always follows as a corollary of the MGF theorem, irrespective of any programming language extensions.

2.11 Hoare Logic subsumes VDM

In the traditional understanding of Hoare Logic, assertions characterise *predicates* on states. VDM is more flexible in that postconditions may, in addition to the final state, also refer to the initial state. In that respect, one may argue that VDM subsumes Hoare Logic.

However, we question such a view, because, pragmatically, in Hoare Logic, one uses auxiliary variables to relate output with input. Thus, one may choose an *arbitrary* reference point. In particular, during a derivation of a correctness formula $\{p\} S \{q\}$ in Hoare Logic, both pre- and postcondition may refer to the value of program variables before executing S . VDM is more restrictive. In a derivation, the rule of sequential composition enforces that, in order to derive $\{p\} S_1; S_2 \{q\}$ one must adapt the point of reference so that the postcondition for S_2 is expressed relative to some intermediate

state. We should emphasise that this argument reflects the *intended* use of both systems. Of course, one could mirror Hoare Logic derivations in VDM by also employing auxiliary variables. But notice that one would then have to also improve VDM's rule of consequence to simulate our version for Hoare Logic.

As a novelty, we show that Hoare Logic subsumes VDM in the sense that an arbitrary derivation in VDM can be embedded in Hoare Logic. In particular, every correctness formulae in the VDM derivation is uniformly translated and every decomposition rule in VDM is simulated by the corresponding rule in Hoare Logic where both premiss and conclusion may have to be adjusted by our new rule of consequence.

This result hinges on a rigorous treatment of auxiliary variables in Hoare Logic and the new rule of consequence. In particular, VDM's consequence rule can be simulated by our rule of consequence, but not Hoare's (1969).

→ p. 155  **Theorem 2.32 (Embedding VDM Correctness Formulae in Hoare Logic)**

Let $p \subseteq \Sigma$ and $q \subseteq \Sigma \times \Sigma$ be assertions and S an arbitrary program. Whenever

$$\vdash_{\text{VDM}} \{p\} S \{q\}$$

is derivable, we may also establish

$$\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \sigma = Z \wedge p(\sigma)\} S \{\lambda(Z, \tau) \cdot q(\tau, Z)\} .$$

By appealing to soundness and completeness, it is evident that for every derivation in VDM, one can reconstruct a proof of the corresponding correctness formula in Hoare Logic:

Proof Assume $\vdash_{\text{VDM}} \{p\} S \{q\}$. By soundness of VDM, we have

$$\forall \sigma \cdot p(\sigma) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S} \tau \wedge q(\tau, \sigma)$$

which is equivalent to

$$\forall Z \cdot \forall \sigma \cdot (\sigma = Z \wedge p(\sigma)) \Rightarrow \exists \tau \cdot \sigma \xrightarrow{S} \tau \wedge q(\tau, Z) .$$

Hence, by completeness of Hoare Logic, we may derive

$$\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \sigma = Z \wedge p(\sigma)\} S \{\lambda(Z, \tau) \cdot q(\tau, Z)\} .$$

□

However, we are primarily interested in the *structure* of the translation. The following constructive proof shows explicitly how to transform VDM into Hoare Logic derivations. Notice that the proof transformation is compositional!

▣ **Proof** by induction on the derivation of $\vdash_{\text{VDM}} \{p\} S \{q\}$. We consider the interesting cases where the last rule applied has been the rule for sequential composition, loops, or the rule of consequence.

Sequential Composition From the induction hypotheses

$$\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \sigma = Z \wedge p_1(\sigma)\} S_1 \{\lambda(Z, \tau) \cdot p_2(\tau) \wedge r_1(\tau, Z)\} \quad (2.84)$$

and

$$\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \sigma = Z \wedge p_2(\sigma)\} S_2 \{\lambda(Z, \tau) \cdot r_2(\tau, Z)\} \quad (2.85)$$

we have to show

$$\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \sigma = Z \wedge p_1(\sigma)\} S_1; S_2 \{\lambda(Z, \tau) \cdot r_2 \circ r_1(\tau, Z)\} .$$

We employ the strengthened rule of consequence to shift the reference point of the second assumption (2.85) to the initial state of the *compound* statement, yielding

$$\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p_2(\sigma) \wedge r_1(\sigma, Z)\} S_2 \{\lambda(Z, \tau) \cdot r_2 \circ r_1(\tau, Z)\} \quad (2.86)$$

This transformation triggers the proof obligation

$$\begin{aligned} \forall Z, \sigma \cdot (p_2(\sigma) \wedge r_1(\sigma, Z)) \Rightarrow \\ \exists Z_1 \cdot (\sigma = Z_1 \wedge p_2(\sigma)) \wedge (\forall \tau \cdot r_2(\tau, Z_1) \Rightarrow (r_2 \circ r_1)(\tau, Z)) \end{aligned}$$

which can be resolved easily when choosing $Z_1 = \sigma$. Notice that Z_1 has to capture the value of all program variables in the initial state. In particular, neither Hoare's (1969) nor the draft rule of consequence (2.69) would have backed up the required transformation.

Finally, applying the rule of sequential composition to the correctness formulae (2.84) and (2.86) completes the case.

Loops From the induction hypothesis

$$\begin{aligned} \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \sigma = Z \wedge p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} \\ S \\ \{\lambda(Z, \tau) \cdot p(\tau) \wedge \text{sofar}(\tau, Z)\} \end{aligned} \quad (2.87)$$

we have to show

$$\begin{array}{c} \vdash_{\text{Hoare}} \\ \{ \lambda(Z, \sigma) \cdot \sigma = Z \wedge p(\sigma) \} \\ \mathbf{while } b \mathbf{ do } S \\ \{ \lambda(Z, \tau) \cdot p(\tau) \wedge \text{eval}(\tau)(b) = \mathbf{false} \wedge \text{sofar}^=(\tau, Z) \} \end{array} \quad (2.88)$$

where *sofar* is transitive and $\lambda(\tau, \sigma) \cdot \text{sofar}(\tau, \sigma) \wedge p(\tau)$ is well-founded.

VDM's rule for loops is stronger than the well-founded version (2.73), because in the postcondition of the conclusion, the rule for VDM additionally records information regarding the variant *sofar*. To compensate, instead of p , we use the weaker invariant

$$\text{inv}(Z, \sigma) = \text{sofar}^=(\sigma, Z) \wedge p(\sigma) .$$

Another difficulty arises because we have to express termination relative to a new constant t . Again, it is up to the strengthened rule of consequence to reconcile the differences between the hypothesis (2.87) and

$$\begin{array}{c} \vdash_{\text{Hoare}} \\ \{ \lambda(Z, \sigma) \cdot \text{inv}(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true} \wedge \sigma = t \} \\ S \\ \{ \lambda(Z, \tau) \cdot \text{inv}(Z, \tau) \wedge \text{sofar}(\tau, t) \} \end{array} . \quad (2.89)$$

We first deal with the proof obligation triggered by the side-condition of the rule of consequence. For arbitrary states Z, σ such that

$$\text{inv}(Z, \sigma) , \quad (2.90)$$

$\text{eval}(\sigma)(b) = \mathbf{true}$ and $\sigma = t$, we have to find a state Z_1 such that $\sigma = Z_1$, $p(\sigma)$, $\text{eval}(\sigma)(b) = \mathbf{true}$ and

$$\forall \tau \cdot (p(\tau) \wedge \text{sofar}(\tau, Z_1)) \Rightarrow (\text{inv}(Z, \tau) \wedge \text{sofar}(\tau, t) \wedge p(\tau)) \quad (2.91)$$

holds. Obviously, we have to chose $Z_1 = \sigma$. We consider (2.91) in more detail. Let τ be an arbitrary state such that $p(\tau)$ and

$$\text{sofar}(\tau, \sigma). \quad (2.92)$$

Besides $p(\tau)$ and $\text{sofar}(\tau, \sigma)$, we have to establish

$$\text{sofar}^=(\tau, Z) . \quad (2.93)$$

We resolve (2.93) by appealing to the transitivity of *sofar* in the presence of (2.92) and (2.90).

Applying the rule for loops to (2.89) produces

$$\begin{array}{c} \vdash_{\text{Hoare}} \\ \{inv\} \\ \mathbf{while } b \mathbf{ do } S \\ \{\lambda(Z, \tau) \cdot inv(Z, \tau) \wedge \text{eval}(\tau)(b) = \mathbf{false}\} \end{array} .$$

Employing the rule of consequence to weaken the precondition and strengthen the postcondition leads directly to the desired (2.88).

Consequence VDM's consequence rule can be seen as an instance of our strengthened consequence rule for Hoare Logic. From the induction hypothesis

$$\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \sigma = Z \wedge p_1(\sigma)\} S \{\lambda(Z, \tau) \cdot q_1(\tau, Z)\}$$

and the side-conditions $p \subseteq p_1$ and $\forall \sigma, \tau. p(\sigma) \Rightarrow q_1(\sigma, \tau) \Rightarrow q(\sigma, \tau)$, we have to derive $\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \sigma = Z \wedge p(\sigma)\} S \{\lambda(Z, \tau) \cdot q(\tau, Z)\}$. From the side-conditions we may conclude

$$\forall Z, \sigma. \sigma = Z \wedge p(\sigma) \Rightarrow \exists Z_1. \sigma = Z_1 \wedge p_1(\sigma) \wedge \forall \tau. q_1(\tau, Z_1) \Rightarrow q(\tau, Z) .$$

Thus, our rule of consequence leads also to the desired correctness formula. \square

There is a one-to-one correspondence between the rules of Hoare-style \vdash_{Hoare} and VDM's decomposition rules \vdash_{VDM} . According to Theorem 2.32, specifications in VDM correspond to a particular class of specification in Hoare Logic, in which the auxiliary variables are devoted to freezing the values of all program variables prior to execution.

The additional flexibility available in Hoare Logic is to blame for the more elaborate consequence rule, whereas the hard-wired perspective between pre- and postconditions in VDM is responsible for a more complicated sequential rule. Ultimately, it is a matter of taste which framework to use.

2.12 Completeness: What does it really mean?

In this section, we take a closer look at the meaning of completeness for verification calculi. We introduce Cook's (1978) notion of *relative completeness* and critically review some of the incompleteness results in the literature. We restrict our discussion to Hoare Logic. The case for VDM is similar.

It is unrealistic to expect than one can design a verification calculus in which one can *derive* all *valid* correctness formulae. As a prerequisite for being complete, the

underlying language in which one formulates assertions must be sufficiently expressive so that one may formulate all intermediate assertions required in the derivation, such as invariants. In particular, for an arbitrary postcondition and program, the assertion language must be able to express the weakest precondition¹⁰

Definition 2.33 (Weakest Precondition) *Let S be an arbitrary program and $q \subseteq \Sigma$ be a set of states.*

$$\text{wp}(S, q) \stackrel{\text{def}}{=} \{ \sigma \mid \exists \tau. (\sigma \xrightarrow{S} \tau) \wedge (\tau \in q) \}$$

As soon as one considers languages with more interesting features such as loops, closure under weakest preconditions leads to logics which, by Gödel's incompleteness theorem, cannot themselves be complete.

To avoid this problem, Cook has proposed that one investigates *relative completeness* in an attempt to separate the reasoning about programs from the reasoning about the underlying logical language. One only considers expressive first-order logics. Furthermore, rules of the verification calculus may be applied in a derivation if the logical side-condition is valid rather than derivable. In particular, completeness no-longer compares a proof-theoretic with a model-theoretic account.

Expressiveness and relative completeness are defined relative to an interpretation I which itself depends on a state σ . Variables are interpreted according to the value of program variables recorded in σ whereas the interpretation of constants e.g., 0 , $+$, \wedge , may vary from interpretation to interpretation. Following the presentation in (Cousot 1990), we characterise expressive interpretations by the following definition:

Definition 2.34 (Expressiveness) *The interpretation I is said to be expressive for the programming language prog and the assertion language L if and only if*

$$\forall S. \forall q. \exists p. \forall \sigma. \llbracket p \rrbracket I(\sigma) \Leftrightarrow \sigma \in \text{wp}(S, \lambda \tau. \llbracket q \rrbracket I(\tau))$$

For the purpose of this section, we redefine validity and derivability of correctness formulae $\{p\} S \{q\} \subseteq L \times \text{prog} \times L$ relative to an arbitrary interpretation I .

Definition 2.35 (Semantics of Hoare Logic)

$$\models_{\text{Hoare}}^I \{p\} S \{q\} \stackrel{\text{def}}{=} \forall \sigma. \llbracket p \rrbracket I(\sigma) \Rightarrow \exists \tau. \sigma \xrightarrow{S} \tau \wedge \llbracket q \rrbracket I(\tau)$$

Definition 2.36 (Hoare Logic) *Let $\vdash_{\text{Hoare}}^I \{.\} . \{.\}$ be the least relation satisfying*

$$\vdash_{\text{Hoare}}^I \{p\} \text{skip} \{p\}$$

¹⁰see e.g., the completeness proof on page 32

$$\frac{\frac{\frac{\vdash_{\text{Hoare}}^I \{p[x \mapsto t]\} x := t \{p\}}{\vdash_{\text{Hoare}}^I \{p\} S_1 \{r\}} \quad \frac{\vdash_{\text{Hoare}}^I \{r\} S_2 \{q\}}{\vdash_{\text{Hoare}}^I \{p\} S_1; S_2 \{q\}}}{\vdash_{\text{Hoare}}^I \{p \wedge b\} S_1 \{q\}} \quad \frac{\vdash_{\text{Hoare}}^I \{p \wedge \neg b\} S_2 \{q\}}{\vdash_{\text{Hoare}}^I \{p\} \text{if } b \text{ then } S_1 \text{ else } S_2 \{q\}}}$$

$$\frac{\forall t : W. \vdash_{\text{Hoare}}^I \{p \wedge b \wedge u = t\} S \{p \wedge u < t\}}{\vdash_{\text{Hoare}}^I \{p\} \text{while } b \text{ do } S \{p \wedge \neg b\}}$$

where $(I(W), I(<))$ is well-founded.

$$\frac{\vdash_{\text{Hoare}}^I \{p_1\} S \{q_1\}}{\vdash_{\text{Hoare}}^I \{p\} S \{q\}}$$

provided for all states σ , both $\llbracket p \Rightarrow p_1 \rrbracket I(\sigma)$ and $\llbracket q_1 \Rightarrow q \rrbracket I(\sigma)$ hold.

Definition 2.37 (Relative Completeness) *Let I be an arbitrary expressive interpretation for the programming language prog and the assertion language L . Then, for any assertion $p, q : L$ and program $S : \text{prog}$, the verification calculus is deemed to be relative complete, if one can show that $\vdash_{\text{Hoare}}^I \{p\} S \{q\}$ implies $\vdash_{\text{Hoare}}^I \{p\} S \{q\}$.*

Our machine-checked proof from page 32 is less general. We have merely shown that Hoare Logic is complete when one considers the standard interpretation for LEGO's internal logic. In particular, we have assumed that the interpretation supports our particular choice of the well-founded domain $(\Sigma, <)$. To establish relative completeness one can make no further assumption about the interpretation besides being expressive in the sense of Def. 2.34.

It is well-known that in many circumstances, this requirement is neither sufficient nor necessary i.e. there may be other interpretations for which one may establish a complete verification calculus or there may be calculi which cannot be shown to be complete for certain interpretations considered expressive according to Def. 2.34:

- Clarke Jr. (1979) has shown that one cannot establish relative completeness for imperative programming languages which support procedures as parameters, recursion, static scoping, global variables and internal procedures. The completeness proof breaks down, because one is forced to consider interpretations with *finite* domains.
- Clarke, German & Halpern (1983) show that expressiveness is not sufficient when one considers recursive procedures. For the completeness proof to go through they restrict interpretations to being both expressible and Herbrand-definable¹¹.

¹¹This refined condition is sufficient but not necessary (Grabowski 1985).

- Bergstra & Tucker (1982) show that, for simple imperative programs and Peano Arithmetic as underlying logical language, *all* interpretations give rise to a complete verification calculus

Incompleteness results in Hoare Logic are sometimes misunderstood. They emphasise that previously investigated notions of expressiveness do not capture the precise requirements of the underlying logical language. Furthermore, such incompleteness results should not be considered as criticism of Hoare Logic as a methodology. Regardless of what language features one is interested in, one ought to always be able to cook up a complete verification calculus in the style of Hoare logic with a *particular* assertion language and a *particular* (standard) interpretation. In particular, merely considering standard interpretations, none of the above (relative) incompleteness results go through. Aczel (1982*b*) writes

“ In the literature the question of the completeness of the proof rules has been entwined with issues concerning the expressiveness of the formal languages to be used in formulating the pre- and post-conditions of the program specifications. In my view the expressiveness of such formal languages should be of no concern when evaluating the completeness of proof rules for program verification. ”

In setting up the notion of validity and derivability of a correctness formula in a machine-checked development, our choice of a shallow embedding of assertions reflects Aczel’s view of completeness. We do not consider syntax of an assertion language. Instead assertions are directly captured by predicates on the state space, which, for a machine-checked development, are typically formulated in the native logic of the logical framework. This is a fundamentally different approach to Hoare Logic. Traditionally, assertions are considered to be simply formulae of first-order logic, which are interpreted in the usual way, except that the value of variables is determined by a state.

Following Aczel’s approach, working out a suitable syntax for assertions can be regarded as an orthogonal problem. In particular, our new approach to auxiliary variables has led to interpreting assertions as relations on the state space *and* a domain of auxiliary variables. This ought to be reflected by also distinguishing program variables from auxiliary variables at the syntactic level.

Furthermore, when new programming features lead to a new notion of the state space e.g., local variables, the syntax of assertions will have to be adapted to access all information in the state space. We refer to Section 3.3.4 on page 90 for further details. As this thesis establishes, using a shallow embedding of assertions to investigate completeness works smoothly for imperative programs in the presence of recursive procedures and blocks. Modern computer-aided proof systems support such shallow

embeddings because of their powerful internal logics. We see no reason why it should not also work when adding further language features.

2.13 Related Work

For a survey of Hoare Logic, we recommend (Cousot 1990). Proving soundness and completeness for Hoare Logic in the context of simple imperative programs is standard. We commence by relating our approach of employing binary relations in assertions with previous work. We then compare our representation with previous machine-checked developments. We discuss related work concerning recursive procedures and local program variables throughout Cha. 3.

2.13.1 A Rigorous Treatment of Auxiliary Variables

The crucial rôle of auxiliary variables is well known in software engineering practice (Clint 1981, Vickers 1991), but previous presentations of Hoare Logic have swept this aspect under the carpet. The idea of representing assertions as binary relations to provide a *semantic* counterpart for auxiliary variables goes back to Apt & Meertens (1980). They show that with the new representation, in the general case of arbitrary context-free schemes a program is (partially) correct if and only if a suitable *finite* system of intermediate assertions can be found.

As far as we are aware, the only other variant of Hoare Logic in which both assertions are considered as binary relations to cater for auxiliary variables is due to Tarlecki (1985). In his system, the consequence rule has been built into every axiom and the rule for loops. Essentially, it only differs from Hoare Logic in that invariants *inv must not* mention auxiliary variables. The assumption of the rule is in VDM form i.e., the auxiliary variables in the precondition freeze the initial value of all program variables. The conclusion caters for arbitrary assertions p and q , and thus the rule of consequence has to be built in through further side-conditions. Another deviation from VDM's rule of loops is that Tarlecki's (1985) variant *sofar* is not required to be well-founded. Termination is guaranteed by a separate relation $<$ relative to a termination measure $t : \Sigma \rightarrow W$.

$$\frac{\begin{array}{c} \{\lambda(Z, \sigma) \cdot Z = \sigma \wedge \text{inv}(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} \\ S \\ \{\lambda(Z, \tau) \cdot \text{sofar}(Z, \tau) \wedge \text{inv}(\tau) \wedge t(\tau) < t(Z)\} \end{array}}{\{p\} \mathbf{while } b \mathbf{ do } S \{q\}}$$

provided

$(W, <)$ is well-founded

$\forall Z, \sigma \cdot p(Z, \sigma) \Rightarrow \text{inv}(\sigma)$ (Consequence)

$\forall \sigma \cdot p(\sigma) \Rightarrow \text{sofar}(\sigma, \sigma)$ (Reflexivity)

$\forall Z, \sigma \cdot \exists \eta \cdot \text{sofar}(Z, \eta) \wedge \text{inv}(\eta) \wedge \text{sofar}(\eta, \sigma) \wedge \text{inv}(\sigma) \Rightarrow \text{sofar}(Z, \sigma)$ (Transitivity)

$\forall Z, \tau \cdot \exists \sigma \cdot$

$(p(Z, \sigma) \wedge \text{sofar}(\sigma, \tau) \wedge \text{inv}(\tau) \wedge \text{eval}(\tau)(b) = \mathbf{false} \wedge t(\tau) \leq t(\sigma)) \Rightarrow q(\tau, Z)$
(Consequence)

The difficulty in program verification is largely due to discovering appropriate invariants (Gries 1981, Gries 1982, Ireland & Stark 1997). Not being able to mention auxiliary variables in the invariant appears to be a troublesome requirement.

2.13.2 Machine-Checked Developments

We are not aware of any previous machine-checked proofs of soundness and completeness for VDM. Unless otherwise indicated, the following formalisations deal with Hoare Logic in the setting of *partial* correctness. We first review work done in the Edinburgh Logical Framework where Hoare Logic is axiomatised and neither soundness nor completeness have been formally pursued. We then discuss formalisations in the system HOL in which soundness is established by deriving the axioms and rules of Hoare Logic from the underlying operational semantics. Finally, we present Nipkow's (1998) machine-checked development in Isabelle which caters for both soundness and completeness by separating between the semantics and a notion of derivability in Hoare Logic.

2.13.2.1 An Axiomatic Approach to Hoare Logic

Employing the Edinburgh Logical Framework, in Mason's (1987) work, terms are either boolean expressions inhabiting the type b , or expressions of type i . All program variables denote values of type i . In particular, one can inspect their value with the help of a global lookup function $! : \mathbf{VAR} \rightarrow i$. This simplifies the treatment of assignments which can thus be represented without dependent types i.e.,

$:= : (\mathbf{VAR} \times i) \rightarrow \text{prog} .$

Assertions are objects of type o which are constructed syntactically from expressions e.g.,

$$\begin{aligned} =_o &: (i \times i) \rightarrow o \\ \Rightarrow_o &: (o \times o) \rightarrow o \end{aligned}$$

To exploit the provisions for λ -binding in the framework, instead of a purely syntactic account of quantification e.g.,

$$\exists_o : (\mathbf{VAR} \times o) \rightarrow o$$

Mason chose

$$\exists_o : (i \rightarrow o) \rightarrow o .$$

Rather than providing an interpretation for terms and assertions, Mason suggests axiomatising a predicate \vdash_o to capture derivability (Harper, Honsell & Plotkin 1993).

Derivability in Hoare Logic is then also axiomatised by a set of rules where correctness formulae are triples of the form $o \times \text{prog} \times o$. The only difficulty is caused by the assignment axiom

$$\{p[x \mapsto t]\} x := t \{p\} , \quad (2.54)$$

because one would have to formalise the notion of updating the value of variables in an assertion. This is the major problem in choosing a deep embedding for assertions. Unlike the shallow embedding scenario, moving to function application to relay the work to the internals of the logical framework does not succeed. In particular, the axiom

$$\vdash_{\text{Hoare}} \{p(t)\} x := t \{p(x!)\} \quad (2.94)$$

for $p : i \rightarrow o$ is unsound. Intuitively, the abstraction in p may not necessarily bind all occurrences of references to the program variable x . More precisely, for

$$p = \lambda u \cdot x! \neq_{\text{int}} u , \quad (2.95)$$

we would be able to erroneously derive

$$\vdash_{\text{Hoare}} \{x! \neq_{\text{int}} 1\} x := 1 \{x! \neq_{\text{int}} x!\} .$$

2.13.2.1.1 Non-Interference Therefore, Mason suggests that one augments the assignment axiom (2.94) with a predicate $\# \subseteq \mathbf{VAR} \times o$ on x and $\forall p$ which guarantees that x does not interfere with p . The author characterises non-interference with six further rule schema e.g.,

$$\begin{array}{c} x \# y! \quad \text{provided } x \neq y \\ \frac{x \# t_1 \quad x \# t_2}{x \# (t_1 =_i t_2)} \end{array}$$

Similar ideas can be found in specification logic.

2.13.2.1.2 Explicit Quantification Another solution to ensure that $x \# \forall p$ has been proposed by Caplan (1995). He extends the notion of a correctness formula CF to include quantification of program variables

$$\begin{array}{c} \{.\} . \{.\} : (o \times \text{prog} \times o) \rightarrow CF \\ \forall_{CF} : (\mathbf{VAR} \rightarrow CF) \rightarrow CF \end{array}$$

His axiom

$$\vdash_{\text{Hoare}} \forall_{CF} (\lambda x . \{p(t(x))\} x := t(x) \{p(x!)\}) \quad (2.96)$$

for $p : i \rightarrow o$ and $t : \mathbf{VAR} \rightarrow i$ ensures that the active program variable of an assignment is bound. His system also includes a rule for permuting the order of quantification and a proof transformation rule to add quantifiers. If one were to apply the rule of assignment to an assertion in which an active program variable occurs freely such as (2.95), α -conversion of the λ -calculus guarantees that the active identifier in (2.96) is suitably renamed. In particular, one may derive

$$\vdash_{\text{Hoare}} \forall_{CF} (\lambda y . \{p(1)\} y := 1 \{p(y!)\}) ,$$

whereas

$$\vdash_{\text{Hoare}} \forall_{CF} (\lambda x . \{p(1)\} x := 1 \{p(x!)\})$$

is *not* an instance of the axiom (2.96). Furthermore, it is not derivable by any other means due to the exclusion of any elimination rules for quantifiers at the level of correctness formulae.

Soundness is not formally investigated. Instead, Mason (1987) and Caplan (1995) verify on paper that their encoding adequately reflects Hoare's (1969) axiomatic presentation.

2.13.2.2 Hoare Logic as a Set of Derived Rules

Machine-checked soundness proofs for verification calculi have been pioneered by Gordon (1989). Instead of axiomatising Hoare Logic, one axiomatises a more basic semantical account¹² for the imperative programming language. Assertions are represented by predicates on the state space. Thus, updating assertions can be expressed in terms of updating states.

Similar to Def. 2.20 on page 30, the *semantics* of Hoare Logic¹³ $\models_{\text{Hoare}} \{.\} \cdot \{.\}$ can then be described in terms of the underlying semantics. Deriving the Hoare Logic rules of Figure 2.1 on page 30 e.g., showing

$$\frac{\begin{array}{l} \models_{\text{Hoare}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \\ \models_{\text{Hoare}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\} \end{array}}{\models_{\text{Hoare}} \{p\} \mathbf{if } b \mathbf{ then } S_1 \mathbf{ else } S_2 \{q\}}$$

then corresponds to a proof of soundness.

2.13.2.2.1 Side Effects In (Homeier 1995) and¹⁴ (Homeier & Martin 1996), expressions are also restricted to two kinds, booleans and natural numbers. Moreover, program variables may only store natural numbers.

As a novelty, expressions in programming language may have side effects. For a program variable x , the expression $++x$, when evaluated, first increments the value of x and then yields its new value. To cater for expressions with side-effects, it is advisable to provide a *deep* embedding of expressions e.g., the meaning of $++x$ is given operationally by

$$\frac{\sigma \xrightarrow{x \Downarrow n} \tau}{\sigma \xrightarrow{++x \Downarrow n+1} \tau[x \mapsto n+1]} .$$

With side-effects, the order of evaluation matters e.g.,

$$\frac{\sigma \xrightarrow{e_1 \Downarrow n_1} \eta \quad \eta \xrightarrow{e_2 \Downarrow n_2} \tau}{\sigma \xrightarrow{e_1 + e_2 \Downarrow n_1 + n_2} \tau} . \quad (2.97)$$

Additionally, the authors give a denotational account for the side-effect free fragment of the class of expressions e.g., one has also $\llbracket e_1 + e_2 \rrbracket I(\sigma) \stackrel{\text{def}}{=} \llbracket e_1 \rrbracket I(\sigma) + \llbracket e_2 \rrbracket I(\sigma)$.

¹²Gordon chooses relational denotational semantics.

¹³Gordon (1989) also shows how to extend this technique to total correctness, VDM, Dijkstra's weakest preconditions and dynamic logic.

¹⁴Beware that the presentation of Hoare Logic in (Homeier & Martin 1996) is (trivially) incomplete because the authors have omitted a consequence rule. Thus, one can e.g. not derive $\{x = 1\} \mathbf{skip} \{\mathbf{true}\}$. Their main contribution is to derive a Verification Condition Generator which is proven sound with respect to an *operational* semantics.

The expression $++x$ must however not occur in assertions and, thus, one has a choice between deep and shallow embedding of assertions. Homeier & Martin chose a deep embedding for assertions. Instead of axiomatising derivability or shallowly embedding assertions as predicates on the state space, assertions are evaluated relative to the standard¹⁵ interpretation e.g.,

$$\begin{aligned} \llbracket t_1 =_{\text{nat}} t_2 \rrbracket I(\sigma) &\stackrel{\text{def}}{=} \llbracket t_1 \rrbracket I(\sigma) = \llbracket t_2 \rrbracket I(\sigma) \\ \llbracket \exists_o x \cdot p \rrbracket I(\sigma) &\stackrel{\text{def}}{=} \exists n \cdot \llbracket p \rrbracket I(\sigma[x \mapsto n]) \end{aligned}$$

To deal with the assignment axiom $\{p[x \mapsto t]\} x := t \{p\}$, one needs to implement a substitution function on assertions which has to translate subexpressions of t of the form $++x$ to $x + n$ for some suitable n e.g., $(x =_{\text{nat}} X)[x \mapsto (++x) + (++x)]$ yields $x + 4 =_{\text{nat}} X$. One ought to also verify the correctness of substitution by showing the substitution lemma

$$\llbracket p[x \mapsto t] \rrbracket I(\sigma) = \llbracket p \rrbracket I(\tau[x \mapsto \llbracket n \rrbracket I(\tau)]) \quad \text{where } \sigma \xrightarrow{t \Downarrow n} \tau,$$

but this does not seem to have been formally established by the authors.

Norrish (1996,1997) is working on formalising the operational semantics of the programming language C. In particular, he introduces non-determinism for evaluating expressions, because, in accordance with the C standard (Schildt et al. 1990), side effects do not have to be applied as they are generated. Furthermore, expressions involving binary operators are not necessarily evaluated by evaluating one argument and then the next. Thus, the rule (2.97) is not sound for C.

Based on the detailed operational semantics, Norrish sketches Hoare Logic rules for a well-behaved class of C programs e.g.,

$$\frac{\models_{\text{Hoare}} \{p\} S_1 \{r\} \quad \models_{\text{Hoare}} \{r\} S_2 \{q\}}{\models_{\text{Hoare}} \{p\} S_1; S_2 \{q\}}$$

provided S_1 contains no interrupt statements.

2.13.2.3 Semantics and Derivability of Correctness Formulae in Hoare Logic

Nipkow (1998) has been the first to conduct a machine-checked *completeness* proof for Hoare Logic dealing with simple imperative programs. To formally deal with completeness, one needs to distinguish between semantics $\models_{\text{Hoare}} \{.\} . \{.\}$ and derivability $\vdash_{\text{Hoare}} \{.\} . \{.\}$ of correctness formulae. For simple imperative programs, instead of appealing to the MGF, completeness is established as a corollary of

$$\vdash_{\text{Hoare}} \{\text{wp}(S, q)\} S \{q\}$$

¹⁵All logical connectives are directly embedded in the native logic of the framework HOL.

for arbitrary programs S and assertions¹⁶ q . Following (Gordon 1989), assertions are encoded as predicates on the state space. Thus, one does not have to worry about how to overcome expressivity conditions such as having to syntactically formulate an assertions which corresponds to $\text{wp}(S, q)$.

The development follows the first 100 pages of Winskel's (1993) textbook on semantics. It includes various operational and denotational accounts together with equivalence proofs. Furthermore, Nipkow produces machine-checked soundness and completeness proofs for Hoare Logic and a Verification Condition Generator. This work uncovered a mistake in Winskel's (1993) completeness proof for Hoare Logic.

¹⁶Induction on S does not go through if one investigates recursive procedures. It then becomes essential to employ the MGF property.

Chapter 3

Recursive Procedures and Local Program Variables

In this chapter, we extend our soundness and completeness results to more interesting program language features. We consider recursive procedures and local program variables with static binding. We produce machine-checked soundness and completeness proofs for parameterless recursive procedures and local program variables. We sketch extensions to mutually recursive procedures and call-by-value parameters.

To adequately represent recursive procedures, we present the verification calculi as a Gentzen-style formal system with contexts. As a new contribution, we improve Sokołowski's (1977) rule for recursive procedures by allowing a well-founded termination argument. In our rules for local program variables, we exploit the fact that, due to our choice of a shallow embedding, assertions may refer to the values of all program variables, and not just those in scope.

In view of the history of unsound and incomplete verification calculi for imperative programs dealing with recursive procedures, the surprising result of this chapter is that, due to our new approach to auxiliary variables, none of the soundness and completeness results are particularly difficult to achieve. Moreover, for Hoare Logic in the setting of total correctness, our results are an improvement over previous work. We require only two thirds of the total number of America & de Boer's (1990) nine rules.

The outline of this chapter is as follows. We first consider recursive procedures. We then focus on a verification calculus for simple imperative programs and local program variables. In Sect. 3.3, we combine recursive procedures with local program variables. Finally, in Sect. 3.4, we sketch extensions to call-by-value parameter passing. We compare our approach to previous work throughout this chapter.

3.1 Parameterless Recursive Procedures

In this section, we extend both Hoare Logic and VDM with parameterless recursive procedures and establish that the new verification calculi are sound and complete. In the previous chapter, we had urged that auxiliary variables should be taken seriously for a more adequate formalisation of Hoare Logic. This section substantiates this claim.

Apt (1981) and America & de Boer (1990) present a verification calculus in the style of Hoare Logic in which, besides a decomposition rule for procedure invocations, they need to add three further structural rules in addition to Hoare's (1969) consequence rule to guarantee completeness. We are able to show that those four structural rules are subsumed by our new consequence rule.

As a further contribution, we show that Hoare's (1971) rule of adaptation, a specially tailored rule structural rule essential in the presence of recursion, is just a trivial instance of our new consequence rule, which we had motivated in the previous chapter for simple imperative programs.

Again, proving these meta-theoretical results for VDM is analogous and we merely highlight technical differences for VDM.

3.1.1 Declaring and Invoking Procedures

Restricting our attention to a single procedure declaration, invoking this procedure can be achieved unambiguously with a constructor **call** : prog.

→ p. 156  **Definition 3.1 (Syntax)** *The class of imperative programs S : prog which may appeal to a recursive procedure is defined by the BNF grammar*

$$S ::= \mathbf{skip} \mid x := t \mid S_1; S_2 \mid \mathbf{if} \ b \ \mathbf{then} \ S_1 \ \mathbf{else} \ S_2 \mid \mathbf{while} \ b \ \mathbf{do} \ S \mid \mathbf{call}$$

where x : **VAR**, t : expression (sort(x)) and b : expression(bo \bar{o} l).

We assume that the procedure declaration is given statically e.g., at compile-time. In the sequel, let S_0 : prog denote the body of the procedure.

→ p. 157  **Example 3.2 (Factorial)** *The body of a recursive procedure computing the factorial of x is given by*

$$S_0 \stackrel{\text{def}}{=} \mathbf{if} \ x = 0 \ \mathbf{then} \ y := 1 \\ \mathbf{else} \ \mathbf{begin} \ x := x - 1; \mathbf{call}; x := x + 1; y := y * x \ \mathbf{end}$$

Notice that the argument x and the result y are not parameters, but global variables. Clearly, x plays the rôle of a call-by-value parameter. The procedure ensures that its value remains invariant. Similarly, the variable y is a designated call-by-name parameter.

3.1.2 Structural Operational Semantics

Whenever a procedure invocation is encountered, computation proceeds by executing the body of the procedure S_0 .

→ p. 157  **Definition 3.3 (Semantics)** *We extend the operational semantics from Def. 2.8 by*

$$\frac{\sigma \xrightarrow{S_0} \tau}{\sigma \xrightarrow{\mathbf{call}} \tau} . \quad (3.1)$$

Again, notice that a denotational characterisation would require more sophisticated mathematical notions such as least fixpoints.

3.1.3 Hoare Logic with Contexts

Without recursion, deriving a correctness formula is easy. Whenever one encounters a procedure invocation, one has to proceed by instead analysing the procedure body (Apt 1981) i.e.,

$$\frac{\vdash_{\text{Hoare}} \{p\} S_0 \{q\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{call} \{q\}} .$$

This rule would however lead to infinite derivations when S_0 calls itself. Induction comes to the rescue. Let us first omit the issue of termination. We may simply assume $\vdash_{\text{Hoare}} \{p\} \mathbf{call} \{q\}$ to conclude $\vdash_{\text{Hoare}} \{p\} S_0 \{q\}$ (Hoare 1971) i.e.,

$$\frac{\{p\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{p\} S_0 \{q\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{call} \{q\}} . \quad (3.2)$$

This rule introduces a fundamental change in deriving correctness formulae. Derivations are now to be considered with respect to a context. Instead of a Hilbert-style calculus, Hoare Logic now amounts to a Gentzen-style sequent calculus. Actually, the rule above is to be understood with respect to an arbitrary context

$$\frac{\{p\} \mathbf{call} \{q\}, \Gamma \vdash_{\text{Hoare}} \{p\} S_0 \{q\}}{\Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{call} \{q\}} . \quad (3.3)$$

The previous presentation needs to be revised to support contexts e.g.,

$$\frac{\Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{skip} \{p\} \quad \Gamma \vdash_{\text{Hoare}} \{p\} S_1 \{r\} \quad \Gamma \vdash_{\text{Hoare}} \{r\} S_2 \{q\}}{\Gamma \vdash_{\text{Hoare}} \{p\} S_1; S_2 \{q\}}$$

Furthermore, such sequent calculi are usually equipped with a collection of structural rules, see e.g. (Takeuti 1975):

$$\begin{array}{c}
\frac{\Gamma \vdash P}{D, \Gamma \vdash P} \quad (\text{Weakening}) \\
\frac{D, D, \Gamma \vdash P}{D, \Gamma \vdash P} \quad (\text{Contraction}) \\
\frac{\Gamma, C, D, \Delta \vdash P}{\Gamma, D, C, \Delta \vdash P} \quad (\text{Exchange})
\end{array}
\qquad
\begin{array}{c}
\frac{\Gamma \vdash P \quad P, \Delta \vdash Q}{\Gamma, \Delta \vdash Q} \quad (\text{Cut}) \\
P \vdash P \quad (\text{Initial Sequent})
\end{array}$$

As usual, we abbreviate $\emptyset \vdash P$ by $\vdash P$.

Olderog (1981) has observed that this presentation is redundant for Hoare Logic in the sense that if $\Gamma \vdash P$ is derivable then there is also a *standard* proof which only involves a *single* application of the procedure rule (3.3). Since we are only interested in deriving correctness formulae in the empty context, it suffices to consider the original version (3.2) after all. Thus, the antecedent contains at most one correctness formula and, apart from the Initial Sequent, none of the structural rules are actually required.

Redundancy in a formal system may be a healthy feature if the additional flexibility gives rise to easier derivations. This is however not the case here when restricting antecedents to at most one correctness formula. Hoare Logic (and VDM) is a syntax-directed methodology (Harel 1980). A rule, read backwards in refinement style, reduces the complexity by focussing the attention on strict subcomponents of the program to be verified. Intuitively, when one has to verify the correctness of $\{p\} \mathbf{call} \{q\}$ one may reduce this task to showing $\{p\} S_0 \{q\}$, where we may discharge *any* further intermediate obligations of the form $\{p'\} \mathbf{call} \{q'\}$ with the assistance of the consequence rule. Just like in the case of a loop, it is crucial to find an appropriately weak precondition p so that all appeals to $\{p\} \mathbf{call} \{q\}$ can be resolved.

Furthermore, unlike traditional sequent calculi, the antecedent may only mention correctness formulae dealing with procedure invocation. In particular, due to our restriction to a single procedure, it suffices to consider contexts with at most one correctness formulae about procedure invocations.

→ p. 158  **Definition 3.4 (Contexts)** A context $\Gamma : \text{Context}$ can be represented by the BNF grammar $\Gamma ::= \emptyset \mid \{p\} \mathbf{call} \{q\}$.

Since we are working in a logical framework which supports contexts at the meta level, the question arises as to whether one can avoid explicitly introducing contexts at the object level. Having already introduced a Hilbert-style notion of derivability, one may be tempted to represent the sequent $P \vdash Q$ by $\vdash P \Rightarrow \vdash Q$. However, in general, $P \vdash Q$ is a *stronger* property.

Consider a formal system which is not complete i.e., there exists a formula P such that one can neither derive P , nor its complement i.e., $\not\vdash P$ and $P \not\vdash \mathbf{false}$. As $\vdash P$ does not hold, we may infer any property from it, in particular, $\vdash P \Rightarrow \vdash \mathbf{false}$; yet, by assumption, $P \vdash \mathbf{false}$ does not hold. Moreover, in the setting of Hoare Logic, de Bakker (1980) shows that $\vdash P \Rightarrow \vdash Q$ does not imply $P \vdash Q$.

An orthogonal complication arises because we define derivability of correctness formulae by considering the smallest fixpoint of a set of predicates on a relation $\vdash_{\text{Hoare}} \{.\} . \{.\}$. A rule of the form

$$(\vdash P \Rightarrow \vdash Q) \Rightarrow \vdash R \quad (3.4)$$

is not an *adequate* representation of

$$(P \vdash Q) \Rightarrow \vdash R . \quad (3.5)$$

Assume that we have to derive $\vdash R$. By (3.4), it suffices to show that from $\vdash P$, we can infer $\vdash Q$. We may now refine $\vdash Q$ and discharge any intermediate proof obligation $\vdash P$. However, due to having closed off the set of rules by the smallest fixpoint, we may additionally assume that $\vdash P$ has been derived by one of the constructors. In particular, we may analyse the *derivation* of $\vdash P$. This is clearly not the intention of (3.5).

Constructors of the form (3.4) are not permitted in inductive definitions due to the negative occurrence of \vdash in the premiss. Such a syntactic check guarantees that there is a smallest fixpoint. Due to the structure of the *other* rules of Hoare Logic, it is however legitimate to add the rule

$$\frac{\vdash_{\text{Hoare}} \{p\} \mathbf{call} \{q\} \Rightarrow \vdash_{\text{Hoare}} \{p\} S_0 \{q\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{call} \{q\}} \quad (3.6)$$

and *derive* that the set of rules has a smallest fixpoint. One can show that it leads to a consistent definition in that only valid correctness formulae may be derived. Moreover, this system is elementary equivalent to the sequent style presentation i.e., it admits precisely the same correctness formulae. However, adding further (sound) rules may jeopardise the soundness of the whole system (Trakhtenbrot et al. 1984).

We have decided against working with a set of rules involving (3.6), because

- our logical framework does not offer any help in closing a set of rules unless it is an inductive definition.
- In our opinion, this presentation is not adequate in that it does not reflect the intuition of the informal rule (3.2).
- The calculus is not sound in the usual sense. In particular, adding further (sound) rules may yield an unsound formal system.

We thus prefer to formalise Hoare Logic with contexts as a Gentzen-style system.

3.1.4 Total Correctness

To guarantee termination, one needs to introduce a termination measure on states. In the case of loops, we compared states before and after an execution of the loop body. For recursive procedures, we can guarantee progress if recursive procedure invocations are only permitted in strictly smaller states with respect to the termination measure. Sokołowski (1977) suggests

$$\frac{\forall n : \text{nat} \cdot \{p(n)\} \text{ call } \{q\} \vdash_{\text{Hoare}} \{p(n+1)\} S_0 \{q\}}{\vdash_{\text{Hoare}} \{\exists n : \text{nat} \cdot p(n)\} \text{ call } \{q\}} \quad \text{provided } \neg p(0). \quad (3.7)$$

This rule is both sound and sufficient to obtain a complete set of rules for recursive procedures (America & de Boer 1990, Schreiber 1997). However, it is too cumbersome to apply in most examples, because of the requirement that the termination measure decreases by exactly one. In particular, in the Quicksort algorithm, which we verify in Chap. 4, the sorting procedure is invoked recursively where the array size is strictly smaller, but not necessarily by one element. We have therefore extended Sokołowski's rule to an arbitrary well-founded measure

$$\frac{\forall t : W \cdot \{\exists u : W \cdot p(u) \wedge u < t\} \text{ call } \{q\} \vdash_{\text{Hoare}} \{p(t)\} S_0 \{q\}}{\vdash_{\text{Hoare}} \{\exists t : W \cdot p(t)\} \text{ call } \{q\}} \quad \text{where } (W, <) \text{ is well-founded.} \quad (3.8)$$

As Apt (1981) points out, merely adding such a rule for procedure invocations in a setting with Hoare's (1969) consequence rule does not lead to a complete system. We will show that a cure is to employ the new rule of consequence (2.70) which is more flexible in dealing with auxiliary variables¹. We have collected the set of rules dealing with recursive programs which we have formalised in Figure 3.1 on the next page. Other solutions have been more elaborate. More precisely, Apt (1981) proposes to add three more rules to be able to modify auxiliary variables in correctness formulae dealing with recursive procedures, see Figure 3.2 on page 64.

However, America & de Boer (1990) have shown that this extension yields an *unsound* system. Their remedy consists of distinguishing different kinds of (auxiliary) variables. In particular, the universally quantified counter variable of the procedure invocation rule must not occur in the list of variables \bar{Y} and \bar{Z} in the Substitution and Elimination rules of Figure 3.2 on page 64.

Having introduced Hoare Logic as a sequent calculus, we extend the semantics to incorporate contexts by

¹We have demonstrated in (Schreiber 1997) that soundness and completeness can also be established when replacing the well-founded measure by the original version from (3.7).

$$\{p\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{p\} \mathbf{call} \{q\} \quad (3.9)$$

$$\begin{array}{c} \Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{skip} \{p\} \\ \Gamma \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma[x \mapsto \text{eval}(\sigma)(t)])\} x := t \{p\} \\ \frac{\Gamma \vdash_{\text{Hoare}} \{p\} S_1 \{r\} \quad \Gamma \vdash_{\text{Hoare}} \{r\} S_2 \{q\}}{\Gamma \vdash_{\text{Hoare}} \{p\} S_1; S_2 \{q\}} \\ \frac{\Gamma \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \quad \Gamma \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\}}{\Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{if} b \mathbf{then} S_1 \mathbf{else} S_2 \{q\}} \end{array}$$

$$\frac{\forall t : W \cdot \Gamma \vdash_{\text{Hoare}} \{\hat{p}\} S \{\lambda(Z, \tau) \cdot p(Z, \tau) \wedge u(\tau) < t\}}{\Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{while} b \mathbf{do} S \{\lambda(Z, \tau) \cdot p(Z, \tau) \wedge \text{eval}(\tau)(b) = \mathbf{false}\}}$$

where $\hat{p}(Z, \sigma) \stackrel{\text{def}}{=} p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true} \wedge u(\sigma) = t$
and $(W, <)$ is well-founded.

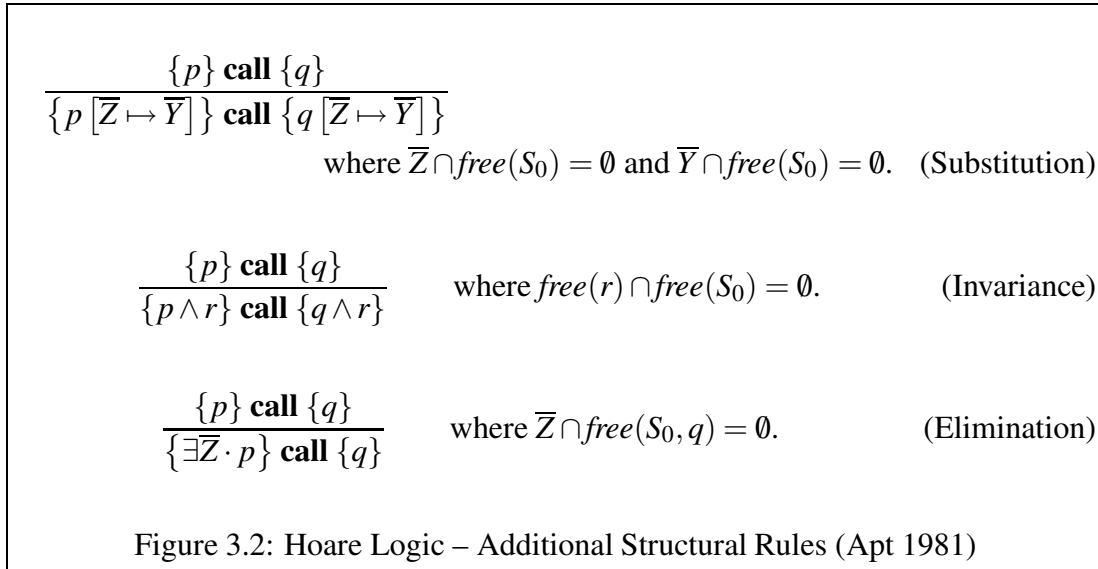

$$\frac{\forall t : W \cdot \{\lambda(Z, \sigma) \cdot \exists u : W \cdot p(u)(Z, \sigma) \wedge u < t\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{p(t)\} S_0 \{q\}}{\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \exists t : W \cdot p(t)(Z, \sigma)\} \mathbf{call} \{q\}}$$

where $(W, <)$ is well-founded. (3.10)

$$\frac{\Gamma \vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{\Gamma \vdash_{\text{Hoare}} \{p\} S \{q\}}$$

where $p_1, q_1 : \text{Assertion}(U)$ and $p, q : \text{Assertion}(T)$ for arbitrary types T and U
and $\forall Z \cdot \forall \sigma \cdot p(Z, \sigma) \Rightarrow \left(\exists Z_1 \cdot p_1(Z_1, \sigma) \wedge (\forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau)) \right)$.

Figure 3.1: Hoare Logic for Recursive Procedures – Total Correctness

→ p. 160 **Definition 3.5 (Semantics of Hoare Logic)**

We define $\Gamma \models_{\text{Hoare}} \{p\} S \{q\}$ by case analysis on the structure of the context Γ :

$$\Gamma \models_{\text{Hoare}} \{p\} S \{q\} \stackrel{\text{def}}{=} \begin{cases} \models_{\text{Hoare}} \{p\} S \{q\} & \text{for } \Gamma = \emptyset, \\ (\models_{\text{Hoare}} \{p'\} \text{ call } \{q'\}) \Rightarrow (\models_{\text{Hoare}} \{p\} S \{q\}) & \text{for } \Gamma = \{p'\} \text{ call } \{q'\}. \end{cases}$$

Notice that, semantically, existential quantification in the precondition corresponds to universal quantification at the level of a correctness formula:

→ p. 160 **Lemma 3.6 (Existential Quantification in Preconditions)**

For all programs S , indexed preconditions $p : U \rightarrow \text{Assertion}(T)$ and postconditions $q : \text{Assertion}(T)$ for arbitrary types T and U , the propositions

$$\models_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \exists t \cdot p(t)(Z, \sigma)\} S \{q\} \quad \text{and} \quad \forall t \cdot \models_{\text{Hoare}} \{p(t)\} S \{q\}$$

are equivalent.

Proof Existential quantification on the left side of an implication is equivalent to universal quantification. □

However, for derivability in Hoare Logic, it is preferable to work with the two existential quantifiers in rule (3.8):

- Replacing the existential quantifier in the premiss would lead to a more complicated notion of contexts.
- Introducing universal quantifiers at the level of correctness formulae in the conclusion alters the notion of derivability.

3.1.5 Soundness

→ p. 162  **Theorem 3.7 (Soundness)**

Let p and q be arbitrary assertions and S be any program. For an arbitrary context Γ , whenever $\Gamma \vdash_{\text{Hoare}} \{p\} S \{q\}$ is derivable, $\Gamma \models_{\text{Hoare}} \{p\} S \{q\}$ holds.

 **Proof** by induction on the derivation of

$$\Gamma \vdash_{\text{Hoare}} \{p\} S \{q\} \quad (3.11)$$

Consider the new case that (3.11) has been derived by applying the rule for procedure invocations (3.10). From the induction hypothesis

$$\forall t : W \cdot \{\lambda(Z, \sigma) \cdot \exists u : W \cdot p(u)(Z, \sigma) \wedge u < t\} \mathbf{call} \{q\} \models_{\text{Hoare}} \{p(t)\} S_0 \{q\} \quad (3.12)$$

for some well-founded structure $(W, <)$, we need to show

$$\models_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \exists t : W \cdot p(t)(Z, \sigma)\} \mathbf{call} \{q\} .$$

Appealing to Lemma 3.6, we may externalise the quantification in the proof obligation, leading to

$$\forall t : W \cdot \models_{\text{Hoare}} \{p(t)\} \mathbf{call} \{q\} .$$

We pursue well-founded induction. We thus have to establish $\models_{\text{Hoare}} \{p(t)\} \mathbf{call} \{q\}$ for a fixed $t : W$ and may additionally appeal to the hypothesis

$$\forall u : W \cdot u < t \Rightarrow \models_{\text{Hoare}} \{p(u)\} \mathbf{call} \{q\}$$

which is equivalent to the required instance of the context in (3.12). □

3.1.6 Completeness

Completeness is again a straight-forward corollary of the MGF property.

→ p. 165  **Theorem 3.8 (MGF)** $\vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{S} Z \right\} S \{ \lambda(Z, \tau) \cdot Z = \tau \}$

In its proof, in the case of a procedure invocation, we have to plant a termination measure in the precondition so that $\exists t : W \cdot \psi(t)(\tau, \sigma)$ is equivalent to $\sigma \xrightarrow{\mathbf{call}} \tau$ for a suitable ψ . We exploit ideas from a completeness proof by America & de Boer (1990) in which $\psi(t)(\tau, \sigma)$ asserts that the execution of $\sigma \xrightarrow{\mathbf{call}} \tau$ can be accomplished with a recursive depth of at most $t : \text{nat}$. In a denotational setting with $\llbracket \cdot \rrbracket : \Sigma \rightarrow \Sigma$, they define

$$\begin{aligned} \psi(t)(\tau, \sigma) &\stackrel{\text{def}}{=} \llbracket S^{[t]} \rrbracket(\sigma) = \tau \wedge \tau \neq \perp \\ \text{where } S^{[t]} &\stackrel{\text{def}}{=} S[S_0^{(t)} / \mathbf{call}] , \\ S_0^{(0)} &\stackrel{\text{def}}{=} \Omega \\ \text{and } S_0^{(t+1)} &\stackrel{\text{def}}{=} S_0[S_0^{(t)} / \mathbf{call}] . \end{aligned}$$

This seems cumbersome. Denotational semantics gives a too abstract view for expressing such fine-grained attributes and one has to simulate a low-level account by selectively substituting the non-terminating program Ω and deduce properties by checking if test runs terminate. In particular, Ω has nothing to do with the notion of recursive depth. We prefer the following definition which is simply an annotated version of the operational semantics where every rule apart from procedure invocation preserves recursive depth.

→ p. 163  **Definition 3.9 (Recursive Depth)**

Let $\sigma \xrightarrow{S} \tau \subseteq \Sigma \times \text{prog} \times \text{nat} \times \Sigma$ be a new judgement which is defined as the least relation satisfying

$$\begin{array}{c}
\sigma \xrightarrow{\text{skip}} \tau \\
\sigma \xrightarrow{x:=t} \tau \quad \tau \equiv \sigma[x \mapsto \text{eval}(\sigma)(t)] \\
\frac{\sigma \xrightarrow{S_1} \eta \quad \eta \xrightarrow{S_2} \tau}{\sigma \xrightarrow{S_1; S_2} \tau} \\
\frac{\sigma \xrightarrow{S_1} \tau}{\sigma \xrightarrow{\text{if } b \text{ then } S_1 \text{ else } S_2} \tau} \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{true} . \\
\frac{\sigma \xrightarrow{S_2} \tau}{\sigma \xrightarrow{\text{if } b \text{ then } S_1 \text{ else } S_2} \tau} \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{false} . \\
\sigma \xrightarrow{\text{while } b \text{ do } S} \tau \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{false} . \\
\frac{\sigma \xrightarrow{S} \eta \quad \eta \xrightarrow{\text{while } b \text{ do } S} \tau}{\sigma \xrightarrow{\text{while } b \text{ do } S} \tau} \quad \text{provided } \text{eval}(\sigma)(b) = \mathbf{true} . \\
\frac{\sigma \xrightarrow{S_0} \tau}{\sigma \xrightarrow{\text{call}} \tau}
\end{array}$$

→ p. 164  **Lemma 3.10 (Non-strict Recursive Depth)** *Bounded Recursive Depth is not a strict bound i.e., if $\sigma \xrightarrow{S} \tau$ then for all $m \geq n$, we may infer $\sigma \xrightarrow{S} \tau$.*

 **Proof** by induction on the derivation of $\sigma \xrightarrow{S} \tau$. □

→ p. 164  **Lemma 3.11 (Bounded Recursive Depth)**

1. If a program terminates, the recursive depth must be finite i.e., if $\sigma \xrightarrow{S} \tau$ then there exists a bound n such that $\sigma \xrightarrow{S}_n \tau$.
2. Bounded recursive depth is a mere annotation of operational semantics i.e., for an arbitrary depth n , $\sigma \xrightarrow{S}_n \tau$ implies $\sigma \xrightarrow{S} \tau$.

 **Proof**

1. by induction on the derivation of $\sigma \xrightarrow{S} \tau$. We need to specify a concrete recursive depth bound. If $\sigma \xrightarrow{S} \tau$ has been derived by one of the axioms (2.4), (2.5) or (2.9), we choose 0. The induction hypotheses for conditional and procedure invocation predetermine the overall recursive depth.

Consider the case of sequential composition. From the induction hypotheses

$$\exists n \cdot \sigma \xrightarrow{S_1}_n \tau \quad \text{and} \quad \exists n \cdot \tau \xrightarrow{S_2}_n \eta$$

we want to conclude $\exists n \cdot \sigma \xrightarrow{S_1; S_2}_n \eta$.

Let n_1 and n_2 be recursive depth bounds such that

$$\sigma \xrightarrow{S_1}_{n_1} \tau \quad \text{and} \quad \tau \xrightarrow{S_2}_{n_2} \eta .$$

Resorting to Lemma 3.10, we weaken these to

$$\sigma \xrightarrow{S_1}_{\max(n_1, n_2)} \tau \quad \text{and} \quad \tau \xrightarrow{S_2}_{\max(n_1, n_2)} \eta .$$

Finally, the rule for sequential composition unites them to

$$\sigma \xrightarrow{S_1; S_2}_{\max(n_1, n_2)} \eta .$$

2. by induction on the derivation of $\sigma \xrightarrow{S}_n \tau$

□

The MGF proof is conducted by induction on the structure of programs. We abbreviate

$$\begin{aligned} \psi(n)(Z, \sigma) &\stackrel{\text{def}}{=} \sigma \xrightarrow{\text{call}}_{n+1} Z \\ \hat{\psi}(n)(Z, \sigma) &\stackrel{\text{def}}{=} \exists u : \text{nat} \cdot \psi(u)(Z, \sigma) \wedge u < n \\ q(Z, \tau) &\stackrel{\text{def}}{=} Z = \tau . \end{aligned}$$

In the case of a procedure invocation, we cannot appeal to an induction hypothesis. Instead we derive the following pseudo-induction hypothesis which allows us to apply the rule for procedure calls (3.10).

→ p. 165  **Lemma 3.12 (Completeness Step)** For an arbitrary recursive depth n , one may derive

$$\{\hat{\psi}(n)\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{\psi(n)\} S_0 \{q\} .$$

 **Proof** Appealing to the consequence rule and the definition of bounded recursive depth, we equivalently transform the proof obligation into

$$\{\hat{\psi}(n)\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{S_0} {}_n Z \right\} S_0 \{q\} .$$

This presentation makes induction more amenable to the structure of the procedure body S_0 .

The cases where S_0 is not a procedure invocation are isomorphic to the corresponding proofs of the MGF property 2.10.3.3 on page 40. One only needs to ensure that recursive depth is preserved. In particular, the correctness formula in the context is ignored.

In the case of $S_0 = \mathbf{call}$, from being able to access the context

$$\{\hat{\psi}(n)\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{\hat{\psi}(n)\} \mathbf{call} \{q\} ,$$

we need to show

$$\{\hat{\psi}(n)\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{\mathbf{call}} {}_n Z \right\} \mathbf{call} \{q\} . \quad (3.13)$$

To arrive at (3.13), we appeal to the rule of consequence. As a side-condition, given arbitrary states τ and σ such that $\sigma \xrightarrow{\mathbf{call}} {}_n \tau$, we have to find a suitable recursive depth $u < n$ such that $\sigma \xrightarrow{\mathbf{call}} {}_{u+1} \tau$. We choose $u = n - 1$. Notice that n cannot have been 0 due to the definition of recursive depth. \square

It is now easy to prove the MGF Theorem:

 **Proof of Theorem 3.8** by induction on the structure of S . In the case of a procedure invocation, we have to establish

$$\vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{\mathbf{call}} Z \right\} \mathbf{call} \{q\} . \quad (3.14)$$

Applying the procedure invocation rule to the pseudo-hypothesis of Lemma 3.12, we may derive

$$\vdash_{\text{Hoare}} \{\lambda(Z, \tau) \cdot \exists n : \text{nat} \cdot \psi(n)(Z, \sigma)\} \mathbf{call} \{q\} .$$

The consequence rule mediates the differences in the preconditions and, given arbitrary states τ and σ such that $\sigma \xrightarrow{\mathbf{call}} \tau$, one has to find a depth u such that $\sigma \xrightarrow{\mathbf{call}} {}_{u+1} \tau$. Applying Lemma 3.11.1 to the assumption, we may extract a depth n satisfying $\sigma \xrightarrow{\mathbf{call}} {}_n \tau$. Again, we choose $u = n - 1$ as n cannot have been 0 due to the definition of recursive depth. \square

For completeness, we are only interested in top-level correctness formulae in the empty context. Specifically, the presentation of Figure 3.1 on page 63 is not complete for arbitrary contexts. The rule for procedure calls has been tailored to only yield atomic correctness formulae.

→ p. 165  **Corollary 3.13 (Completeness)** *Whenever $\vdash_{\text{Hoare}} \{p\} S \{q\}$ is derivable from the axioms and rules of Figure 3.1 on page 63, $\models_{\text{Hoare}} \{p\} S \{q\}$ holds.*

 **Proof** Completeness follows immediately from the MGF Theorem. See the proof of Corollary 2.31 on page 41 for further details. □

3.1.7 An Example Derivation

In this section, we employ the new set of rules to prove that an algorithm to compute $y = x!$ leaves the input x invariant. In particular, we give an example of how to invoke the rule for recursive procedures for a suitable termination measure. The algorithm can be shown correct as easily with Sokołowski's (1977) rule for procedures. For a more complex example, we refer to the case study of Chapter 4.

→ p. 165  **Lemma 3.14 (Invariance Property of the Factorial Algorithm)** *For the declaration of the procedure in Example 3.2 on page 58, we may derive*

$$\vdash_{\text{Hoare}} \{x = X\} \text{ call } \{x = X\} .$$

An interesting aspect of this proof is that our stronger rule of consequence is essential. In particular, Apt (1981) has proven that if one only uses Hoare's (1969) consequence rule, Lemma 3.14 does not hold and thus one would have a seriously incomplete verification calculus. The proof also motivates that in practice it is convenient to be able to use a rule of adaptation to compute preconditions. It will turn out that such a rule is merely a trivial instance of our new rule of consequence.

 **Proof** Termination is guaranteed because the recursive depth is bounded by the initial value of the input parameter x . Employing the consequence rule, we record the convergence measure

$$\vdash_{\text{Hoare}} \{\exists n \cdot p(n)\} \text{ call } \{x = X\} \quad \text{with } p(n) \stackrel{\text{def}}{=} x = X \wedge n = x.$$

Thus the way has been smoothed to invoke the procedure invocation rule² (3.10) leading to the proof obligation

$$\Gamma_n \vdash_{\text{Hoare}} \{p(n)\} S_0 \{x = X\}$$

where $\Gamma_n = \{\exists u \cdot p(u) \wedge u < t\} \mathbf{call} \{x = X\}$ for an arbitrary bound n . (3.15)

We may retrieve the information in the context by axiom (3.9)

$$\Gamma_n \vdash_{\text{Hoare}} \{\exists u \cdot p(u) \wedge u < t\} \mathbf{call} \{x = X\} . \quad (3.16)$$

The strategy is now to successively apply the Hoare Logic rules corresponding to the outermost constructor of the desired proof obligation (3.15). A proof obligation referring to a procedure invocation can be tackled by the assumption (3.16).

We commence with the rule for conditionals. The **then** branch is easily resolved. Otherwise, we have to show

$$\Gamma_n \vdash_{\text{Hoare}} \frac{\{\exists u \cdot p(u) \wedge u < t \wedge x \neq 0\}}{x := x - 1; \mathbf{call}; x := x + 1; y := y * x} \{x = X\} .$$

Since the assignment axiom is left-constructive (Dahl 1992) in that it accepts an arbitrary postcondition, a sound strategy³ is to unroll the program from behind. Thus, when the rule for sequential composition leads to branching in the proof obligation, one ought to concentrate on the second. Eventually, this approach leads to the two goals

$$\begin{aligned} \Gamma_n \vdash_{\text{Hoare}} \{\exists u \cdot p(u) \wedge u < t \wedge x \neq 0\} x := x - 1 \{?i\} \\ \Gamma_n \vdash_{\text{Hoare}} \{?i\} \mathbf{call} \{x + 1 = X\} \end{aligned} \quad (3.17)$$

for some intermediate assertion $?i$. Given a concrete instance, we can employ the rule of consequence to derive (3.17) from (3.16). Since $?i$ is a postcondition in a further proof obligation, it would be best if $?i$ would be as weak as the consequence rule admits. In other words, it would be pragmatically useful to also have a left-constructive version of the rule of consequence. We discuss such rules, also called rules of adaptation, in more detail in the following section. A suitable assertion would be $?i \stackrel{\text{def}}{=} x + 1 = X$. In the next section, we present a rule which automatically computes an equivalent version. \square

²To successfully apply Sokołowski's (1977) version, one has to ensure that $p(0)$ does not hold. A suitable choice would be $p(n) \stackrel{\text{def}}{=} x = X \wedge n = x + 1$, because all variables are declared as natural numbers.

³in particular, for Verification Condition Generators

Notice that regardless of the choice for $?i$ in the above proof, Hoare’s (1969) rule of consequence would fail at this point, because the postconditions of (3.16) and (3.17) are incompatible. We had already discussed this deficiency of the standard presentation of Hoare Logic in Sect. 2.10.3. It is an intrinsic problem for which an inadequate treatment of auxiliary variables is to blame.

Without procedures, completeness is not threatened because a mismatch of auxiliary variables such as (3.28) can always be reconciled by rebuilding the complete derivation. One may compensate by readjusting the auxiliary variables accordingly in the leaves of the proof tree. Whenever axiom (2.71) or (2.72) is encountered one instead chooses an equivalent version where auxiliary variables have been shifted. Such a patch cannot be applied in the presence of rule (3.8). It also introduces an axiom i.e., $\{\exists u \cdot p(u) \wedge u < t\} \text{ call } \{q\}$ for some $t : (W, <)$, but, unlike the axiom for the empty program or an assignment, the pre- and postcondition is bound by the *specific* assertions of a correctness formula in the derivation.

In particular, completeness could be achieved in the standard presentation by integrating our new consequence rule in the procedure invocation rule. We will discuss a similar rule in the following section. However, we feel that pragmatically, it is better to provide an improved consequence rule at all times.

Previously, a common approach has been to retain Hoare’s consequence rule and adopt a flurry of further rules to achieve completeness e.g.,

“ It will turn out that we need five additional [rules], before a completeness theorem becomes possible. ”
(de Bakker 1980)

Perhaps even more worrying is that fact that *four* of these are actually employed in the verification of the invariance property of the factorial function. In such a setting, using Hoare Logic to derive properties of even simple programs appears to be unnecessarily complicated.

3.1.8 Rules of Adaptation

Among the additional rules to add in order to retain completeness for imperative programs dealing with recursive procedures, a rule of adaption has been considered by various authors e.g., (Hoare 1971, Morris n.d., London, Guttag, Horning, Lampson, Mitchell & Popek 1978, Gries & Levin 1980).

In general, rules of adaptation are of the form

$$\frac{\Gamma \vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{\Gamma \vdash_{\text{Hoare}} \{p\} S \{q\}}$$

for arbitrary assertions p_1, q_1, q , and particular proposals for the adapted precondition p . Ideally, the rule should be left-maximal (Dahl 1992) i.e., the precondition p

should be the weakest possible so that

$$\forall S. \models_{\text{Hoare}} \{p_1\} S \{q_1\} \Rightarrow \models_{\text{Hoare}} \{p\} S \{q\} \quad (3.18)$$

holds.

Not distinguishing between program and auxiliary variables, Hoare (1971) has proposed

$$p(\sigma) \stackrel{\text{def}}{=} \exists Z_1. p_1(\sigma) \wedge \forall \tau. q_1(\tau) \Rightarrow q(\tau) \quad (3.19)$$

where Z_1 is a list of all variables⁴ free in p_1, q_1 , but not in q .

However, while adding Hoare's rule of adaptation leads to a complete verification calculus, Morris (n.d.) and Olderog (1983) have shown that, in general, (3.19) is not the weakest possible. Morris (n.d.) points out two⁵ instructive counter examples:

Example 3.15 *Let*

$$\begin{aligned} p_1(\sigma) &\stackrel{\text{def}}{=} q_1(\sigma) \stackrel{\text{def}}{=} \sigma(Z) > 0 \wedge \sigma(x) > 0 \\ q(\sigma) &\stackrel{\text{def}}{=} \sigma(Z) \geq 0 \wedge \sigma(x) > 0 \end{aligned}$$

where Z does not occur in the program under consideration. The weakest precondition is then given by $\lambda\sigma. \sigma(Z) \geq 0 \wedge \sigma(x) > 0$. However, (3.19) requires the stronger $\lambda\sigma. \sigma(Z) > 0 \wedge \sigma(x) > 0$ (modulo equivalence transformations), because the auxiliary variable Z occurs in both premiss and conclusion.

This problem can be solved by formally treating assertions as relations of auxiliary variables and states i.e.,

$$p(Z, \sigma) \stackrel{\text{def}}{=} \exists Z_1. p_1(Z_1, \sigma) \wedge \forall \tau. q_1(Z_1, \tau) \Rightarrow q(Z, \tau) . \quad (3.20)$$

A corresponding rule of adaptation (3.21) is obviously a trivial instance of our rule

$$\frac{\vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{\vdash_{\text{Hoare}} \{\lambda(Z, \sigma). \exists Z_1. p_1(Z_1, \sigma) \wedge \forall \tau. q_1(Z_1, \tau) \Rightarrow q(Z, \tau)\} S \{q\}} \quad (3.21)$$

Figure 3.3: Rule of Adaptation

of consequence (2.70). Conversely, if one replaces the new consequence rule by the

⁴In practice, this would be a list of *auxiliary* program variables.

⁵A third one only applies to partial correctness

rule of adaptation *and* Hoare's (1969) rule of consequence, one retains a sound and complete verification calculus.

Morris' second example shows that the choice for the auxiliary variable Z_1 may have to depend on the value of variables in the final state:

Example 3.16 *Let*

$$\begin{aligned} p_1(Z, \sigma) &\stackrel{\text{def}}{=} Z = 0 \vee Z = 1 \\ q_1(Z, \tau) &\stackrel{\text{def}}{=} \tau(x) \neq Z \\ q(Z, \tau) &\stackrel{\text{def}}{=} \sigma(x) \neq 0 \wedge \sigma(x) \neq 1 \end{aligned}$$

*The weakest precondition is then given by **true**. However, both (3.19) and the weaker (3.20) are equivalent to **false**.*

Relaxing the precondition p so that the witness Z_1 can benefit from inspecting the final value of program variables according to τ leads to

$$p(Z, \sigma) \stackrel{\text{def}}{=} \forall \tau. \exists Z_1. p_1(Z_1)(\sigma) \wedge (q_1(Z_1)(\tau) \Rightarrow q(Z)(\tau)) . \quad (3.22)$$

We do not know if this is the weakest possible precondition for a rule of adaptation in the setting of total correctness. Thus, we can also not answer the question if its corresponding rule of consequence is optimal. We have used the weaker version (3.21) throughout this thesis. The problematic issue raised in the last example did not surface neither in any of the soundness and completeness proofs, nor in any of the examples.

It seems to be easier to design and verify an optimal rule of adaptation for partial correctness. In particular, Morris (n.d.) has been able to show that

$$p(Z, \sigma) \stackrel{\text{def}}{=} \forall \tau. (\forall Z_1. p_1(Z_1, \sigma) \Rightarrow q_1(Z_1, \tau)) \Rightarrow q(Z, \tau)$$

is the weakest possible precondition⁶ which satisfies (3.18). This version is however only sound when one considers *partial* correctness.

3.1.9 Mutually Recursive Procedures

Sokołowski (1977) sketched an extension to mutual recursion of which properties have to be derived simultaneously for *all* procedures with the *same* recursion-depth counter. Let $Proc$ denote a (finite) set of procedure identifiers such that for each $P : Proc$, the program S_P stands for the body of the procedure P . Following Sokołowski (1977), one might then extend our well-founded variant (3.8) to

$$\frac{\forall P : Proc. \forall t : W. \Gamma_t \vdash \{p(t)\} S_P \{q\}}{\forall P : Proc. \{\exists t : W. p(t)\} \mathbf{call} P \{q\}} \quad \text{where } (W, <) \text{ is well-founded}$$

and, for all $P \in Proc$, $(\{\exists u : W. p(u) \wedge u < t\} \mathbf{call} P \{q\}) \in \Gamma_t$.

⁶A more elaborate version has been published by Olderog (1983).

Pandya & Joseph (1986) have pointed out that this rule is difficult to apply, because it forces one to find termination measures across multiple procedure invocations. In their version, one may appeal to some correctness formulae in the context Γ_t without having to worry about decreasing the termination measure. Specifically, one may choose a subset of *header* procedures $H \subseteq \text{Proc}$ such that every cycle in the procedure call graph must contain at least one header procedure. Then, a decrease of the termination measure needs only be established for header procedures i.e.,

$$\Gamma_t = \left\{ \left\{ \exists u : W \cdot p(u) \wedge u < t \right\} \mathbf{call} P \{q\} \mid P \in H \right\} \cup \left\{ \{p(t)\} \mathbf{call} P \{q\} \mid P \in \text{Proc} \setminus H \right\}$$

A further improvement would be to allow different termination measures for different procedures, where assumptions about the correctness of procedure calls can be gradually accumulated. As a *new* rule, we propose

$$\frac{\forall t : W \cdot \Gamma, \left\{ \exists u : W \cdot p(u) \wedge u < t \right\} \mathbf{call} P \{q\} \vdash \{p(t)\} S_P \{q\}}{\Gamma \vdash \left\{ \exists t : W \cdot p(t) \right\} \mathbf{call} P \{q\}} \quad \text{where } (W, <) \text{ is well-founded.} \quad (3.23)$$

Assume that P and Q are two mutually recursive procedures and we want to derive a property of $\mathbf{call} P$ (in the empty context). Applying the above rule (3.23), we consider deriving S_P relative to a context containing a correctness formula about $\mathbf{call} P$. Unrolling the procedure body of S_P , a call to itself can be directly dealt with by appealing to the context. If S_P invokes the procedure Q , we again employ the rule for procedure invocations (3.23). Hence, with a context containing correctness formulae about $\mathbf{call} P$ and $\mathbf{call} Q$, we may resolve the remaining proof obligation concerning the procedure body of Q .

A much more radical approach for dealing with recursive procedures has been advocated by Homeier (1995). Building on ideas of Pandya & Joseph (1986) to analyse the graph structure of recursive calls, he extends the notion of correctness formulae to e.g., also include *Entrance Specifications* $\{p\} S \rightarrow P \{q\}$ and *Path Entrance Specifications* $\{p\} P_1 - ps - P_n \{q\}$. Intuitively

$\{p\} S \rightarrow P \{q\}$ holds if the program S is executed in a state satisfying p , then if at any point within S procedure P is called, then at the entry of P , q is satisfied.

$\{p\} P_1 - ps - P_n \{q\}$ holds if execution begins at the entry of the procedure P_1 in a state satisfying p , and if in the execution of the body S_1 , procedure calls are made successively deeper to the procedures listed in ps , and finally a call is made to the procedure P_n , then at that entry of P_n , q is satisfied.

Such an extension leads to a considerable blow up in the number of verification rules. Further investigations are needed to compare the suitability of a verification calculus with a rule such as (3.23) with Homeier's (1995) system.

3.1.10 The Vienna Development Method

Extending VDM with recursive procedures follows exactly the same paradigm as for Hoare Logic. We introduce contexts along with an axiom for looking up correctness formulae in contexts and supply a rule for recursive procedure invocations. The new rules are identical to those for Hoare Logic, except that preconditions are unary predicates on the state space. Thus, the proofs of soundness and completeness can be carried out with the same techniques discussed for Hoare Logic.

→ p. 170  **Theorem 3.17 (Soundness)** *The rules of Figure 3.4 on the next page are sound.*

 **Proof** by induction on the structure of programs. □

→ p. 171  **Theorem 3.18 (Completeness)** *The rules of Figure 3.4 on the following page are complete.*

 **Proof** This is a straightforward consequence of the MGF property which can be established along the very same lines as in the setting of Hoare Logic. □

3.2 Local Program Variables

To simplify matters, we consider local program variables *without* procedures in this section. Section 3.3 will combine these two features.

To cope with run-time storage allocation in which, due to shadowing, program variables are no longer unique identifiers, one usually extends the notion of states and considers them either as stacks or introduces addresses. Exploiting an implicit stack mechanism (Sieber 1981, Olderog 1981), in our formalisation, we are able to work with essentially the same representation of states as in the case of simple imperative programs.

We start with an informal view of local program variables. We then go on to discuss the new requirements of the state space so that we may formally define syntax and semantics for imperative programs with local program variables. Focussing on Hoare Logic, in Section 3.2.4, we present a new rule for initialised local program variables and establish soundness and completeness. Finally, we sketch a similar extension for VDM.

3.2.1 Initialisation

We introduce local program variables by the constructor **new** $x := t$ **in** S where x is a program variable, t is an expression with *arbitrary* type T and S is a program. Programs of the above form are also called *blocks*. Intuitively, the expression t is evaluated, its value assigned to the variable x and in this updated context, the program S is executed. At the end, the original value of x is restored.

Many real programming languages also allow blocks of the form **new** x **in** S where a suitable amount of memory is allocated, but x may or may not be initialised. The standard approach in program verification is to treat uninitialised variables as a special case of **new** $x := t$ **in** S where t denotes a new canonical value⁷ ω_T (Apt 1981). We only consider (well-formed) initialised local program variables.

“ After all, forgetting to initialize is one of the most common sources of programming error; and if there is no default initialization, debugging is made difficult by the fact that program behaviour is unpredictable in terms of the program text, and that it may even depend on the previous contents of the computer memory. Uninitialized pointer variables are especially troublesome. ”
(Dahl (1992))

Surprisingly, some languages such as C which support initialised variables insist on first allocating the new variable x and only then evaluate the expression t (Schildt et al. 1990). Of course this also leads to undefined values if the variable x is contained in t .

Example 3.19 *Employing the compiler gcc 2.7.2, the program*

```
void main() {
  int c=103; {
    int c=c+1;
    printf ("%i\n", c);
  }
}
```

prints out 5 instead of the expected 104. Java is conservative over C in that initialisations which refer to the value of a program variable to be defined are considered as not being well-formed. Perl is more flexible and the program

```
#!/usr/local/bin/perl
```

```
$c=103; {
```

⁷To avoid having to explicitly deal with such undefined values, de Bakker (1980) suggests to restrict the class of programs with uninitialised values to those where program variables may only be referenced *after* a suitable assignment has taken place.

```
local($c) = $c+1;
print "$c\n"; }
```

yields indeed 104.

3.2.2 States with Dynamic Types

With local program variables, representing the memory as a map from program variables to values of corresponding type is no longer adequate, because one may have multiple copies of program variables with identical names, but different values (and scopes). One usually refines the notion of states,

- either by introducing addresses (de Bakker 1980),
- or by explicitly modelling stacks (Clarke Jr. 1979).

3.2.2.1 Addresses

Addresses serve as unique handles for all program variables. Hence, instead of representing states as functions from program variables to values, states are functions from addresses to values. Scoping is controlled by an environment which is simply a map from program variables to addresses.

Let σ be an instance of the state and E an environment. To lookup the value of the program variable x , one needs to combine the two views of the memory i.e. $\sigma(E(x))$. Thus, evaluation has to additionally take scoping into account. To allocate a new local variable **new** $x := t$ **in** S , one needs to find a fresh address l to update the state space $\sigma[l \mapsto \text{eval}(E, \sigma)(t)]$ and the environment $E[x \mapsto l]$. Afterward executing S , one reinstates the previous environment E .

3.2.2.2 Explicit Stacks

With this approach, the state space is a stack where entries are tuples of program variables and their values. To lookup the value of the program variable x , one needs to access the most recent entry in the stack where the first component is x and output the second component. Thus, scoping and evaluation of terms is determined by the order on the stack. To allocate a new local program variable **new** $x := t$ **in** S , one needs to evaluate the term t and push $(x, \text{eval}(\sigma)(t))$ onto the stack. After having executed the block, one needs to remove the last entry in the stack.

3.2.2.3 Implicit Stacks

Without procedures, one can work with a more naive notion of states which only records the value of all program variables in scope. Stack behaviour is achieved implicitly (Sieber 1981, Olderog 1981).

Let σ be such a state. When considering the execution behaviour of a block **new** $x := t$ **in** S commencing in state σ , it suffices to consider running the program S in the state $\sigma[x \mapsto \text{eval}(\sigma)(t)]$, because the old entry for x cannot be accessed by the program S . The final state of the block is identical to that of the program S , except that the entry for the program variable x needs to be updated by its original value $\sigma(x)$.

When adding other language features, implicit stacks may no longer be adequate. In particular, when one considers procedures with call-by-name parameters, due to aliasing, one is forced to abandon the implicit stack encoding⁸. However, restricting our attention to parameterless⁹ recursive procedures in this thesis, it suffices to work with minor variants of implicit stacks.

Previously, see Def. 2.2 on page 12, states were given relative to a *fixed* variable declaration $\text{sort} : \mathbf{VAR} \rightarrow \text{Type}$. However, in a block **new** $x := t$ **in** S , the sort of x is not determined by a previous variable declaration. Hence, sorts are no longer merely a parameter of states. Instead, states have to be treated as a family of functions over sorts.

→ p. 171  **Definition 3.20 (State Space with Dynamic Types)** $\Sigma(\text{sort}) \stackrel{\text{def}}{=} \prod x : \mathbf{VAR} \cdot \text{sort}(x)$

In particular, updating may change the sort i.e., for $t : T$ and $\sigma : \Sigma(\text{sort})$ for some sort $\mathbf{VAR} \rightarrow \text{Type}$, the updated state $\sigma[x \mapsto t]$ inhabits $\Sigma(\text{sort}[x \mapsto T])$. We also need to revise our previous definitions of expressions and assertions:

→ p. 171  **Definition 3.21 (Expressions)**

$$\text{expression}(\text{sort} : \mathbf{VAR} \rightarrow \text{Type})(T : \text{Type}) \stackrel{\text{def}}{=} (\Sigma(\text{sort})) \rightarrow T .$$

→ p. 172  **Definition 3.22 (Assertions)**

$$\text{Assertion}(\text{sort} : \mathbf{VAR} \rightarrow \text{Type})(T : \text{Type}) \stackrel{\text{def}}{=} (T \times \Sigma(\text{sort})) \rightarrow \text{Prop}$$

⁸Ah-kee (1990) has demonstrated that the address mechanism is suitable to handle aliasing.

⁹Call-by-value parameters would not cause any problems.

3.2.3 Programs with Dynamic Sorts

The BNF grammar

$$S ::= \mathbf{skip} \mid x := t \mid S_1; S_2 \mid \mathbf{if} \ b \ \mathbf{then} \ S_1 \ \mathbf{else} \ S_2 \mid \mathbf{while} \ b \ \mathbf{do} \ S \mid \mathbf{new} \ x := t \ \mathbf{in} \ S$$

does not do justice to the dynamic rôle of program variable declarations. The type-theoretic representation where every constructor is annotated by its type appears to be more informative. One may formulate the empty program and assignment for an arbitrary sort. Apart from the block constructor, all other language constructors simply preserve sorts.

→ p. 172  **Definition 3.23 (Syntax)** Imperative programs prog are defined as an inductive family over $\mathit{sort} : \mathbf{VAR} \rightarrow \mathit{Type}$ by

$$\begin{aligned} & \mathbf{skip} : \mathit{prog}(\mathit{sort}) \\ & x := t : \mathit{prog}(\mathit{sort}) \quad \text{where } t : \mathit{expression}(\mathit{sort})(\mathit{sort}(x)) \\ & \frac{S_1, S_2 : \mathit{prog}(\mathit{sort})}{S_1; S_2 : \mathit{prog}(\mathit{sort})} \\ & \frac{S_1, S_2 : \mathit{prog}(\mathit{sort})}{\mathbf{if} \ b \ \mathbf{then} \ S_1 \ \mathbf{else} \ S_2 : \mathit{prog}(\mathit{sort})} \quad \text{where } b : \mathit{expression}(\mathit{sort})(\mathit{bool}) \\ & \frac{S : \mathit{prog}(\mathit{sort})}{\mathbf{while} \ b \ \mathbf{do} \ S : \mathit{prog}(\mathit{sort})} \quad \text{where } b : \mathit{expression}(\mathit{sort})(\mathit{bool}) \\ & \frac{S : \mathit{prog}(\mathit{sort} [x \mapsto T])}{\mathbf{new} \ x := t \ \mathbf{in} \ S : \mathit{prog}(\mathit{sort})} \\ & \quad \text{where } t : \mathit{expression}(\mathit{sort})(T) \text{ for an arbitrary type } T \end{aligned}$$

→ p. 173  **Definition 3.24 (Structural Operational Semantics)** We extend Def. 2.8 on page 16 with a rule for blocks

$$\frac{\sigma [x \mapsto \mathit{eval}(\sigma)(t)] \xrightarrow{S} \tau}{\sigma \xrightarrow{\mathbf{new} \ x := t \ \mathbf{in} \ S} \tau [x \mapsto \sigma(x)]} \quad (3.24)$$

where for arbitrary type T and declaration $\mathit{sort} : \mathbf{VAR} \rightarrow \mathit{Type}$, we have

$$\begin{aligned} x : \mathbf{VAR} & & \sigma : \Sigma(\mathit{sort}) \\ t : \mathit{expression}(\mathit{sort})(T) & & \tau : \Sigma(\mathit{sort} [x \mapsto T]) \\ S : \mathit{prog}(\mathit{sort} [x \mapsto T]) & & \end{aligned}$$

In all other rules, the sort of states is identical in the premiss and the conclusion.

3.2.4 Hoare Logic

Building on ideas of Lauer (1971), Apt (1981) suggests the following rule

$$\frac{\{p[x \mapsto y] \wedge x = \omega\} S \{q[x \mapsto y]\}}{\{p\} \mathbf{new } x \mathbf{ in } S \{q\}} \quad \text{where } y \notin \text{free}(p, S, q)$$

where ω stands for a special constant denoting an undefined value.

Rather than substituting a fresh *program* variable y for the newly declared local program variable x , we preserve the original value of x in the assertions by updating both pre- and postcondition with a constant v which we introduce by universal quantification¹⁰ in the premiss. Scoping of the implicitly universally quantified p , S and q ensures that $v \notin \text{free}(p, S, q)$. Furthermore, we consider initialised blocks:

$$\frac{\forall v. \{p[x \mapsto v] \wedge x = t[x \mapsto v]\} S \{q[x \mapsto v]\}}{\{p\} \mathbf{new } x := t \mathbf{ in } S \{q\}} \quad (3.25)$$

→ p. 178  **Theorem 3.25 (Soundness)** *The set of rules in Figure 3.5 on the next page is sound.*

 **Proof** by induction on the derivation of $\vdash_{\text{Hoare}} \{p\} S \{q\}$. In the new case of blocks, we fix arbitrary $Z : T$ and $\sigma : \Sigma(\text{sort})$ such that $p(Z, \sigma)$ holds. From the induction hypothesis

$$\forall v. \models_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot p(Z, \sigma[x \mapsto v]) \wedge \sigma(x) = \text{eval}(\sigma[x \mapsto v])(t) \right\} \\ S \\ \left\{ \lambda(Z, \tau) \cdot q(Z, \tau[x \mapsto v]) \right\}$$

we have to produce a final state τ such that $\sigma \xrightarrow{\mathbf{new } x := t \mathbf{ in } S} \tau$ and $q(Z, \tau)$ holds. Instantiating the induction hypothesis with $\sigma(x)$ for v and $\sigma[x \mapsto \text{eval}(\sigma)(t)]$ for the initial state yields a final state η such that

$$\sigma[x \mapsto \text{eval}(\sigma)(t)] \xrightarrow{S} \eta \quad \text{and} \quad q(Z, \eta[x \mapsto \sigma(x)])$$

holds. Hence, appealing to the operational semantics of blocks, we choose

$$\tau \stackrel{\text{def}}{=} \eta[x \mapsto \sigma(x)] .$$

□

¹⁰Alternatively, just like in the case of loops on page 38, one could have extended the domain of auxiliary variables in the premiss to avoid universal quantification.

$$\begin{array}{c}
\vdash_{\text{Hoare}} \{p\} \mathbf{skip} \{p\} \\
\\
\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma [x \mapsto \text{eval}(\sigma)(t)])\} x := t \{p\} \\
\\
\frac{\vdash_{\text{Hoare}} \{p\} S_1 \{r\} \quad \vdash_{\text{Hoare}} \{r\} S_2 \{q\}}{\vdash_{\text{Hoare}} \{p\} S_1; S_2 \{q\}} \\
\\
\frac{\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \quad \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{if } b \mathbf{ then } S_1 \mathbf{ else } S_2 \{q\}} \\
\\
\frac{\forall t : W \cdot \vdash_{\text{Hoare}} \{\hat{p}\} S \{\lambda(Z, \tau) \cdot p(Z, \tau) \wedge u(\tau) < t\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{while } b \mathbf{ do } S \{\lambda(Z, \tau) \cdot p(Z, \tau) \wedge \text{eval}(\tau)(b) = \mathbf{false}\}} \\

\text{and } (W, <) \text{ is well-founded.} \\
\\
\frac{\forall v \cdot \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma [x \mapsto v]) \wedge \sigma(x) = \text{eval}(\sigma [x \mapsto v])(t)\} \\
\quad S \\
\quad \{\lambda(Z, \tau) \cdot q(Z, \tau [x \mapsto v])\}}{\vdash_{\text{Hoare}} \{p\} \mathbf{new } x := t \mathbf{ in } S \{q\}} \quad (3.26) \\
\\
\frac{\vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{\vdash_{\text{Hoare}} \{p\} S \{q\}} \\
\text{where } p_1, q_1 : \text{Assertion}(U) \text{ and } p, q : \text{Assertion}(T) \text{ for arbitrary types } T \text{ and } U \\
\text{and } \forall Z \cdot \forall \sigma \cdot p(Z, \sigma) \Rightarrow \left(\exists Z_1 \cdot p_1(Z_1, \sigma) \wedge (\forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau)) \right). \quad (3.27)
\end{array}$$

Figure 3.5: Hoare Logic for Blocks – Total Correctness

→ p. 178  **Theorem 3.26 (MGF)** $\vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{S} Z \right\} S \{ \lambda(Z, \tau) \cdot Z = \tau \}$

 **Proof** by induction on the structure of S . In the case of a block, from the induction hypothesis

$$\vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{S} Z \right\} S \{ \lambda(Z, \tau) \cdot Z = \tau \}$$

one has to establish

$$\vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma \xrightarrow{\text{new } x := t \text{ in } S} Z \right\} \text{new } x := t \text{ in } S \{ \lambda(Z, \tau) \cdot Z = \tau \} .$$

Given an arbitrary $v : \text{sort}(x)$, we employ the stronger rule of consequence (3.27) to derive

$$\vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \sigma[x \mapsto v] \xrightarrow{\text{new } x := t \text{ in } S} Z \wedge \sigma(x) = \text{eval}(\sigma[x \mapsto v])(t) \right\} \begin{array}{c} S \\ \{ \lambda(Z, \tau) \cdot Z = \tau[x \mapsto v] \} \end{array}$$

from which the rule for blocks (3.26) renders the proof obligation. As a side-condition, given states Z and σ such that

$$\sigma[x \mapsto v] \xrightarrow{\text{new } x := t \text{ in } S} Z \tag{3.28}$$

$$\sigma(x) = \text{eval}(\sigma[x \mapsto v])(t) \tag{3.29}$$

we have to find a state τ such that $\sigma \xrightarrow{S} \tau$ and $Z = \tau[x \mapsto v]$. Inverting the derivation of (3.28), there must be such a state τ which satisfies

$$\sigma[x \mapsto v][x \mapsto \text{eval}(\sigma[x \mapsto v])(t)] \xrightarrow{S} \tau$$

$$Z = \tau[x \mapsto \sigma[x \mapsto v](x)]$$

This completes the proof, because (3.29) ensures that the state σ is (extensionally) equal to $\sigma[x \mapsto v][x \mapsto \text{eval}(\sigma[x \mapsto v])(t)]$. \square

→ p. 178  **Corollary 3.27 (Completeness)** *The set of rules in Figure 3.5 on the facing page is complete.*

 **Proof** Identical to the proof of Cor. 2.31 on page 41 for simple imperative programs. \square

In practice, it is convenient to additionally be able to employ a *left-constructive* rule for blocks. For the correctness proof of Quicksort in Chapter 4, we have also used the following version

$$\frac{\forall v. \{p\} S \{q[x \mapsto v]\}}{\{p[x \mapsto t]\} \mathbf{new} x := t \mathbf{in} S \{q\}} \quad (3.30)$$

which is to be understood as a pretty-printed version of the rule in Figure 3.6. It essentially assumes that the postcondition q does not mention x . Thus, one cannot expect to retain a complete system when replacing the Bottom-Up version (3.25) with this version. We are not aware of previous proposals of left-constructive rules for blocks.

$$\frac{\forall v. \vdash_{\text{Hoare}} \{p\} S \{\lambda(Z, \tau) \cdot q(Z, \tau[x \mapsto v])\}}{\vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma[x \mapsto \text{eval}(\sigma)(t)])\} \mathbf{new} x := t \mathbf{in} S \{q\}}$$

Figure 3.6: Admissible Left-Constructive Rule for Blocks in Hoare Logic

→ p. 178  **Corollary 3.28 (Left-Constructive Rule for Blocks)** *The rule from Figure 3.6 is admissible.*

 **Proof** By soundness and completeness it suffices to establish the semantic counterpart

$$\frac{\forall v. \models_{\text{Hoare}} \{p\} S \{\lambda(Z, \tau) \cdot q(Z, \tau[x \mapsto v])\}}{\models_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma[x \mapsto \text{eval}(\sigma)(t)])\} \mathbf{new} x := t \mathbf{in} S \{q\}}$$

which follows immediately from the operational semantics for blocks. □

3.2.5 The Vienna Development Method

Jones (1990) suggests the right-constructive rule

$$\frac{\{p \wedge x = t\} S \{q\}}{\{p\} \mathbf{new} x := t \mathbf{in} S \{\exists v. q[x \mapsto v]\}} \quad (3.31)$$

to deal with local program variables in VDM. It is, no doubt, useful in practice, but cannot handle shadowed variables. The postcondition of the conclusion cannot record any property of the value of the program variable x which is in scope before and after executing the block. Specifically, one cannot derive $\{\mathbf{true}\} \mathbf{new} x := t \mathbf{in} S \{x = \overleftarrow{x}\}$. Thus, the set of rules given in Jones's (1990) book on VDM is *incomplete*.

This deficiency has been overcome in the formalisation of Ah-kee (1990). He employs an address mechanism to represent states and assertions. Environments E map

program variables to addresses. Assertions are predicates on *addresses*. Thus, one may selectively update addresses corresponding to the *new* local program variable x . For uninitialised local variables¹¹, he proposes

$$\frac{E [x \mapsto l] \mid \{p\} S \{q\}}{E \mid \{p\} \mathbf{new} \ x \ \mathbf{in} \ S \{\lambda(\tau, \sigma) \cdot \exists v', v \cdot q(\tau[l \mapsto v], \sigma[l \mapsto v'])\}}$$

where l is a fresh address.

With the implicit stack mechanism, we discard information about intermediate local program variables. As a drawback, adding a variant of rule (3.31) does not lead to a complete verification calculus. Our solution has been to interpret the rule for Hoare Logic (3.25) in the VDM setting. This yields

$$\frac{\forall v \cdot \{p[x \mapsto v] \wedge x = t[x \mapsto v]\} S \{q[x \mapsto v]\}}{\{p\} \mathbf{new} \ x := t \ \mathbf{in} \ S \{q\}}$$

Formally, this corresponds to (3.32).

→ p. 181  **Theorem 3.29 (Soundness)** *The rules of Figure 3.7 on the following page are sound.*

 **Proof** by induction on the derivation of correctness formulae. □

→ p. 182  **Theorem 3.30 (Completeness)** *The rules of Figure 3.7 on the next page are complete.*

 **Proof** Similar to the corresponding proof in the setting of Hoare Logic. □

3.3 Recursive Procedures and Static Binding

Combining procedures with blocks requires some care. A procedure invocation may occur inside a block so that, at run-time, some local variables have been allocated which conflict with program variables of the procedure in scope at declaration time. Most programming languages, including Algol, C, Cobol, Fortran, Java and Pascal, adhere to static binding¹² where a procedure invocation triggers an environmental change: A procedure may only refer to either global program variables, formal parameters, or its own local program variables. In particular, since we restrict our attention to parameterless procedures, information can only be passed to procedures via global program variables.

We deal with static binding. Some adjustments are necessary because a naïve combination of the rules of the previous two sections would lead to dynamic binding. A known remedy is to only consider programs where all defining occurrences of program

¹¹restricted to the type `int`

¹²also referred to as lexicographical binding

$$\begin{array}{c}
\vdash_{\text{VDM}} \{\lambda\sigma \cdot \mathbf{true}\} \mathbf{skip} \{\lambda(\tau, \sigma) \cdot \tau = \sigma\} \\
\vdash_{\text{VDM}} \{\lambda\sigma \cdot \mathbf{true}\} x := t \{\lambda(\tau, \sigma) \cdot \tau = \sigma [x \mapsto \text{eval}(\sigma)(t)]\} \\
\frac{\vdash_{\text{VDM}} \{p_1\} S_1 \{\lambda(\tau, \sigma) \cdot p_2(\tau) \wedge r_1(\tau, \sigma)\} \quad \vdash_{\text{VDM}} \{p_2\} S_2 \{r_2\}}{\vdash_{\text{VDM}} \{p_1\} S_1; S_2 \{r_2 \circ r_1\}} \\
\frac{\vdash_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \quad \vdash_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\}}{\vdash_{\text{VDM}} \{p\} \mathbf{if } b \mathbf{ then } S_1 \mathbf{ else } S_2 \{q\}} \\
\frac{\vdash_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S \{\lambda(\tau, \sigma) \cdot p(\tau) \wedge \text{sofar}(\tau, \sigma)\}}{\vdash_{\text{VDM}} \{p\} \mathbf{while } b \mathbf{ do } S \{q\}} \\
\text{where } \text{sofar} \text{ is any binary transitive relation on the state space } \Sigma \text{ such that} \\
\lambda(\tau, \sigma) \cdot \text{sofar}(\tau, \sigma) \wedge p(\tau) \text{ is well-founded} \\
\text{and } q(\tau, \sigma) \stackrel{\text{def}}{=} p(\tau) \wedge \text{eval}(\tau)(b) = \mathbf{false} \wedge (\text{sofar}(\tau, \sigma) \vee \tau = \sigma). \\
\frac{\forall v. \vdash_{\text{VDM}} \{\lambda\sigma \cdot p(\sigma[x \mapsto v]) \wedge \sigma(x) = \text{eval}(\sigma[x \mapsto v])(t)\} \\
\quad S \\
\quad \{\lambda(\tau, \sigma) \cdot q(\tau[x \mapsto v], \sigma[x \mapsto v])\}}{\vdash_{\text{VDM}} \{p\} \mathbf{new } x := t \mathbf{ in } S \{q\}} \quad (3.32) \\
\frac{\vdash_{\text{VDM}} \{p_1\} S \{q_1\}}{\vdash_{\text{VDM}} \{p\} S \{q\}} \\
\text{provided } \forall \sigma \cdot p(\sigma) \Rightarrow p_1(\sigma) \text{ and } \forall (\tau, \sigma) \cdot p(\sigma) \Rightarrow q_1(\tau, \sigma) \Rightarrow q(\tau, \sigma).
\end{array}$$

Figure 3.7: VDM and Local Program Variables

variables are denoted differently. In this case, static and dynamic binding coincide (Olderog 1981). We do not make such a simplification. In our treatment, when declaring new variables, one may choose an *arbitrary* program variable name and instantiate it with a value of *arbitrary* type. We cater for static binding by extending implicit stacks with a backup mechanism which records the value of global variables.

We start by annotating the operational semantics with an environment to keep track of the local program variables in scope. We then follow an idea by Ah-kee (1990) to also annotate *correctness formulae* with environments. Without environments, one effectively assumes that all variables in assertions correspond to values of program variables *in scope*. Adding environments leads to more flexibility when formulating verification rules. In particular, since this technique has previously only been applied to VDM, we are able to present an improved set of Hoare Logic rules for recursive procedures and static binding. More precisely, annotating the rules of the previous two sections with environments ensures that a procedure call must take place in the empty environment and the value of all local program variables must be frozen during a call. Without environments, one needs to replace the rule for blocks by a less elegant version to retain a sound verification calculus for static binding (Apt 1981).

We show that our set of rules is sound and complete. We sketch how to achieve similar results for VDM in Sect. 3.3.8.

3.3.1 Static versus Dynamic Binding

The difference between static and dynamic binding is perhaps best explained by means of an example.

→ p. 205  **Example 3.31 (Scoping)** *Let*

$$S_0 \stackrel{\text{def}}{=} x := z$$

$$S \stackrel{\text{def}}{=} z := 1; \mathbf{new} \ z := 0 \ \mathbf{in} \ \mathbf{call}$$

What should be the final value of x ? Invoking the procedure S_0 , should z refer to the global program variable z which is in scope at declaration time, or the most recently allocated local program variable z ? For static binding, the final value of x amounts to 1, whereas dynamic binding yields 0. We restrict our attention to *static* binding which is supported by most programming languages¹³. With the set of rules we are about to introduce, we derive the correctness formula

$$\{\mathbf{true}\} \ z := 1; \mathbf{new} \ z := 0 \ \mathbf{in} \ \mathbf{call} \ \{x = 1\}$$

in Sect. 3.3.7.6 on page 109.

¹³Exceptions are e.g., Emacs Lisp, Perl (Wall, Christiansen & Schwartz 1996) and T_EX(Knuth 1986).

3.3.2 States and Environments

Can we retain the simplicity of implicit stacks if we additionally have to cope with procedure calls? Consider the case where the program **new** $x := t$ **in** S invokes the procedure S_0 . In refining

$$\sigma[x \mapsto \text{eval}(\sigma)(t)] \xrightarrow{S} \tau ,$$

one is confronted with justifying $\sigma' \xrightarrow{\text{call}} \tau'$. However, it would not be correct to investigate $\sigma' \xrightarrow{S_0} \tau'$ at this point, because, due to static scoping, an environmental change is required. The program S_0 must be able to access the *global* value of the program variable x which is no longer present in σ' . In particular, combining blocks and procedures, the operational justification employing the previous implementation of implicit stacks is *not* adequate.

To avoid shadowing, Clarke Jr. (1979) suggests to rename local program variable names¹⁴. Whenever one encounters a block of the form **new** x **in** S , one instead considers the semantics of **new** x' **in** $S[x \mapsto x']$ where x' is fresh. We prefer a semantic account which avoids syntactic modifications. The key idea is to distinguish between global and local program variables, because, for top-level procedure declarations, the procedure body may only inspect *global* program variables, whereas the semantics for blocks only leads to updating of *local* program variables.

Both the address and the explicit stack mechanism would also introduce enough machinery to avoid this problem. But such an approach is redundant in that one does not actually need to worry about all intermediate local program variable allocations. It suffices to access the most recent local program variable as long as we still have access to all global program variables. We duplicate the state space in order to provide a backup of global program variables whenever an environmental change is required.

→ p. 182  **Definition 3.32 (State Space)** *Relative to a parametrised declaration gsort for global program variables, we index the state space by a declaration lsort*

$$\Sigma(\text{lsort}) \stackrel{\text{def}}{=} (\prod x \cdot \text{gsort}(x)) \times (\prod x \cdot \text{lsort}(x))$$

with both global and local declarations mapping program variables to types. Moreover, for $\sigma : \Sigma(\text{lsort})$, let $\sigma.\text{global} : \prod x \cdot \text{gsort}(x)$ and $\sigma.\text{local} : \prod x \cdot \text{lsort}(x)$ denote the global and local components of the state σ .

¹⁴Sieber's (1981) version of this definition is flawed because he erroneously updates x in the declared procedure body S_0 .

Scoping is controlled by an environment $E : \mathbf{VAR} \rightarrow \text{bool}$. Intuitively, $E(x)$ holds if x is a *local* program variable in the current scope. For convenience we employ set notation. In particular,

$$\begin{aligned} x \in E &\stackrel{\text{def}}{=} E(x) \\ \emptyset &\stackrel{\text{def}}{=} \lambda x. \mathbf{false} \\ E \cup \{x\} &\stackrel{\text{def}}{=} \lambda y. (x = y) \vee (y \in E) \end{aligned}$$

Looking up values of program variables in scope depends on both the current environment and state:

$$\text{lookup}(E, \sigma)(x) \stackrel{\text{def}}{=} \mathbf{if } x \in E \mathbf{ then } \sigma.\text{local}(x) \mathbf{ else } \sigma.\text{global}(x) \quad \text{for } \sigma : \Sigma(\text{lsort}).$$

Its type is given by

$$\text{AccSort}(\text{lsort}, E)(x) \stackrel{\text{def}}{=} \mathbf{if } x \in E \mathbf{ then } \text{lsort}(x) \mathbf{ else } \text{gsort}(x)$$

Substitution has to take the environment into account. We define

$$\begin{aligned} \sigma[x \mapsto_E t] &\stackrel{\text{def}}{=} \\ &\mathbf{if } x \in E \mathbf{ then } (\sigma.\text{global}, \sigma.\text{local}[x \mapsto t]) \mathbf{ else } (\sigma.\text{global}[x \mapsto t], \sigma.\text{local}) \end{aligned}$$

and introduce

$$\text{uL}(\sigma, x, v) \stackrel{\text{def}}{=} (\sigma.\text{global}, \sigma.\text{local}[x \mapsto v]) \quad (3.33)$$

for updating the local entry of a program variable.

3.3.3 Expressions

We retain Def. 3.21 on page 79

$$\text{expression}(\text{sort} : \mathbf{VAR} \rightarrow \text{Type})(T : \text{Type}) \stackrel{\text{def}}{=} (\prod x. \text{sort}(x)) \rightarrow T$$

where *sort* corresponds to a particular instance of *AccSort*. A term can only be evaluated in a compatible setting i.e., for a given environment E and a state $\sigma : \Sigma(\text{lsort})$, an expression t must be of type $\text{expression}(\text{AccSort}(\text{lsort}, E))(T)$ for some type T . Evaluation proceeds by plugging in the *accessible* fraction of the state space extracted by the lookup function:

→ p. 183  **Definition 3.33 (Evaluation of Expressions)** Let lsort be an arbitrary sort and E be an arbitrary environment. Given a state $\sigma : \Sigma(\text{lsort})$ and an expression

$$t : \text{expression}(\text{AccSort}(\text{lsort}, E))(T) ,$$

we define evaluation by

$$\text{eval}(E, \sigma)(t) \stackrel{\text{def}}{=} t(\text{lookup}(E, \sigma))$$

3.3.4 Assertions

The state space keeps track of all global variables and, for each program variable name, the value of the most recently allocated local variable. We provide unrestricted access to the state space in assertions.

→ p. 185  **Definition 3.34 (Assertions)** $\text{Assertion}(\text{lsort})(T) \stackrel{\text{def}}{=} (T \times \Sigma(\text{lsort})) \rightarrow \text{Prop}$

In particular, we can explicitly refer to the value of local and global variables. To support such a view of assertions, one needs to also change the syntactic representation. It is no longer adequate to merely consider standard first-order logic where a (free) variable corresponds to a value of a program variable as this approach does not distinguish between global and local program variables.

Example 3.35 (Syntax of Assertions) *One could restrict the domain of auxiliary variables to the state space and retain the convention that auxiliary variables are represented by upper-case letter. To disambiguate global from local program variables, one could decorate local program variables e.g., with a dot. Then*

$$\llbracket A = \dot{c} \wedge a = \dot{A} \rrbracket(Z, \sigma)$$

corresponds to

$$Z.\text{global}(a) = \sigma.\text{local}(c) \wedge \sigma.\text{global}(a) = Z.\text{local}(a) .$$

As a side-effect of such a richer notion of assertion, it is conceivable that some of the perceived short-comings of verification calculi can be avoided e.g., Cousot (1990), in an attempt to explain the intuition behind Clarke Jr.'s (1979) incompleteness results, writes

“ But when considering Algol- or Pascal-like languages, the naming conventions in [assertions] P , Q and [programs] C are totally different. For example, objects deeply buried in the runtime stack cannot be accessed by their name although they can be modified using procedure calls! ”

3.3.5 The Programming Language

→ p. 186  **Definition 3.36 (Syntax)** We extend Def. 3.23 on page 80 by a constructor for procedure invocations

$$\mathbf{call} : \text{prog}(\text{sort})$$

which can be invoked in an arbitrary environment.

Notice that `sort` is expected to be a mapping of all program variables *in scope* to types. In particular, in the definitions of the operational semantics in the following section, `sort` must be a particular instance of `AccSort(lsrt, E)` for some `lsrt : VAR → Type` and environment E . Alternatively, one could directly parametrise the class of programs by a local sort and an environment.

3.3.6 Structural Operational Semantics

Operational semantics has to also take environments into account to ensure that expressions are well-formed. The environment and the sort of local program variables in the final state is always identical to that in the initial state. They may only change for intermediate states, when encountering blocks or procedure invocations.

→ p. 189  **Definition 3.37 (Structural Operational Semantics)** The inductive definition of the operational semantics

$$(\text{lsort}, E) \mid \sigma \xrightarrow{S} \tau$$

depends now explicitly on a sort of local program variables `lsort` and an environment E , where $\sigma, \tau : \Sigma(\text{lsort})$ and $S : \text{prog}(\text{AccSort}(\text{lsort}, E))$. We have collected the set of all rules in Figure 3.8 on the next page.

3.3.6.1 Procedures with Static Binding

Procedure invocations are legitimate in any environment

$$\mathbf{call} : \text{prog}(\text{AccSort}(\text{lsort}, E)) ,$$

but local program variables cease to be accessible i.e., for $S_0 : \text{prog}(\text{gsort})$, we have

$$\frac{(\text{lsort}, \emptyset) \mid \sigma \xrightarrow{S_0} \tau}{(\text{lsort}, E) \mid \sigma \xrightarrow{\mathbf{call}} \tau} . \quad (3.34)$$

Notice that `gsort` is (extensionally) equal to `AccSort(lsrt, \emptyset)`. The proposition

$$(\text{lsort}, \emptyset) \mid \sigma \xrightarrow{S_0} \tau$$

$$\begin{array}{c}
(\text{Isort}, E) \mid \sigma \xrightarrow{\text{skip}} \sigma \\
\\
(\text{Isort}, E) \mid \sigma \xrightarrow{x := t} \sigma[x \mapsto_E \text{eval}(E, \sigma)(t)] \\
\text{where } t : \text{expression}(\text{AccSort}(\text{Isort}, E))(\text{AccSort}(\text{Isort}, E)(x)). \\
\\
\frac{(\text{Isort}, E) \mid \sigma \xrightarrow{S_1} \eta \quad (\text{Isort}, E) \mid \eta \xrightarrow{S_2} \tau}{(\text{Isort}, E) \mid \sigma \xrightarrow{S_1; S_2} \tau} \\
\\
\frac{(\text{Isort}, E) \mid \sigma \xrightarrow{S_1} \tau}{(\text{Isort}, E) \mid \sigma \xrightarrow{\text{if } b \text{ then } S_1 \text{ else } S_2} \tau} \quad \text{provided } \text{eval}(E, \sigma)(b) = \mathbf{true} . \\
\\
\frac{(\text{Isort}, E) \mid \sigma \xrightarrow{S_2} \tau}{(\text{Isort}, E) \mid \sigma \xrightarrow{\text{if } b \text{ then } S_1 \text{ else } S_2} \tau} \quad \text{provided } \text{eval}(E, \sigma)(b) = \mathbf{false} . \\
\\
(\text{Isort}, E) \mid \sigma \xrightarrow{\text{while } b \text{ do } S} \sigma \quad \text{provided } \text{eval}(E, \sigma)(b) = \mathbf{false} . \\
\\
\frac{(\text{Isort}, E) \mid \sigma \xrightarrow{S} \eta \quad (\text{Isort}, E) \mid \eta \xrightarrow{\text{while } b \text{ do } S} \tau}{(\text{Isort}, E) \mid \sigma \xrightarrow{\text{while } b \text{ do } S} \tau} \quad \text{provided } \text{eval}(E, \sigma)(b) = \mathbf{true} . \\
\\
\frac{(\text{Isort}, \emptyset) \mid \sigma \xrightarrow{S_0} \tau}{(\text{Isort}, E) \mid \sigma \xrightarrow{\text{call}} \tau} \\
\\
\frac{(\text{Isort}[x \mapsto T], E \cup \{x\}) \mid \text{uL}(\sigma, x, \text{eval}(E, \sigma)(t)) \xrightarrow{S} \tau}{(\text{Isort}, E) \mid \sigma \xrightarrow{\text{new } x := t \text{ in } S} \text{uL}(\tau, x, \sigma.\text{local}(x))}
\end{array}$$

Figure 3.8: Structural Operational Semantics for Static Binding

is not well-formed in (LEGO's) intensional type theory. Instead, one needs to explicitly introduce type coercions i.e., $\sigma \xrightarrow{\text{coerce}(c)(S_0)} \tau$ for a suitable¹⁵ function *coerce*, where c is a proof of $\forall x \cdot \text{gsort}(x) = \text{AccSort}(\text{lsort}, \emptyset)(x)$. For convenience, we will omit such type coercions in the sequel.

3.3.6.2 Blocks with Backup for Global Program Variables

We extend rule 3.24 on page 80 with a backup mechanism for blocks

$$\frac{(\text{lsort } [x \mapsto T], E \cup \{x\}) \mid \text{uL}(\sigma, x, \text{eval}(E, \sigma)(t)) \xrightarrow{S} \tau}{(\text{lsort}, E) \mid \sigma \xrightarrow{\text{new } x := t \text{ in } S} \text{uL}(\tau, x, \sigma.\text{local}(x))} \quad (3.35)$$

where, for an arbitrary environment E , an arbitrary type T and a declaration lsort , we have

$$\begin{aligned} x &: \text{VAR} & \sigma &: \Sigma(\text{lsort}) \\ t &: \text{expression}(\text{AccSort}(\text{lsort}, E))(T) & \tau &: \Sigma(\text{lsort } [x \mapsto T]) \\ S &: \text{prog}(\text{AccSort}(\text{lsort}, E \cup \{x\}) [x \mapsto T]) \quad . \end{aligned}$$

By distinguishing between global and local program variables, when commencing execution of S , the initial state still contains the *global* entry for x which may be required if S contains a procedure call. Moreover, observe that

$$\text{AccSort}(\text{lsort}, E \cup \{x\}) [x \mapsto T]$$

is (extensionally) equal to

$$\text{AccSort}(\text{lsort } [x \mapsto T], E \cup \{x\}) \quad .$$

3.3.6.3 Recursive Depth

To guarantee termination of recursive calls, similar to Def. 3.9 on page 66, we annotate the operational semantics with a recursive depth n which is an upper bound on the recursive depth required in an execution. We refer to Figure 3.9 on the following page for further details.

→ p. 194  **Lemma 3.38 (Bounded Recursive Depth)**

1. *If a program terminates, the recursive depth must be finite i.e., if*

$$(\text{lsort}, E) \mid \sigma \xrightarrow{S} \tau$$

then there exists a bound n such that $(\text{lsort}, E) \mid \sigma \xrightarrow{S}_n \tau$.

¹⁵This is best defined by induction on the structure of programs and exploits substituting terms in types. See Appendix A.

$$\begin{array}{c}
(\text{lsort}, E) \mid \sigma \xrightarrow{\text{skip}}_n \sigma \\
\\
(\text{lsort}, E) \mid \sigma \xrightarrow{x := t}_n \sigma [x \mapsto_E \text{eval}(E, \sigma)(t)] \\
\text{where } t : \text{expression}(\text{AccSort}(\text{lsort}, E))(\text{AccSort}(\text{lsort}, E)(x)). \quad (3.36) \\
\\
\frac{(\text{lsort}, E) \mid \sigma \xrightarrow{S_1}_n \eta \quad (\text{lsort}, E) \mid \eta \xrightarrow{S_2}_n \tau}{(\text{lsort}, E) \mid \sigma \xrightarrow{S_1; S_2}_n \tau} \\
\\
\frac{(\text{lsort}, E) \mid \sigma \xrightarrow{S_1}_n \tau}{(\text{lsort}, E) \mid \sigma \xrightarrow{\text{if } b \text{ then } S_1 \text{ else } S_2}_n \tau} \quad \text{provided } \text{eval}(E, \sigma)(b) = \mathbf{true} . \\
\\
\frac{(\text{lsort}, E) \mid \sigma \xrightarrow{S_2}_n \tau}{(\text{lsort}, E) \mid \sigma \xrightarrow{\text{if } b \text{ then } S_1 \text{ else } S_2}_n \tau} \quad \text{provided } \text{eval}(E, \sigma)(b) = \mathbf{false} . \\
\\

Figure 3.9: Recursive Depth for Procedures and Blocks

2. Bounded recursive depth is a mere annotation of operational semantics i.e., for an arbitrary depth n , $(\text{lsort}, E) \mid \sigma \xrightarrow{S}_n \tau$ implies

$$(\text{lsort}, E) \mid \sigma \xrightarrow{S} \tau .$$

☞ **Proof** Similar to the proof of Lemma 3.11 on page 67 in the setting without local program variables. \square

3.3.6.4 Adequacy

The rule for blocks (3.35) may be comprehensible, but the interaction with procedures is certainly somewhat subtle. Since we *axiomatise* operational semantics, we cannot argue about its soundness and completeness with respect to a more easily comprehensible semantic notion. Rather than taking its adequacy on good faith, one should investigate a number of properties for clarification. One could for example establish that the operational semantics is conservative over the presentations in the previous two sections where we have dealt with procedures and blocks in isolation. Furthermore, one ought to examine how local program variables interact with procedure calls.

For the soundness and completeness proofs, we have found it useful to establish the following properties.

→ p. 195 ☞ **Lemma 3.39 (Determinism)** *The operational semantics of Figure 3.8 and its annotated version of Figure 3.9 is deterministic.*

☞ **Proof** by induction on the derivation. \square

→ p. 196 ☞ **Lemma 3.40 (Procedure Activation and Environments)** *Let E and E' be arbitrary environments.*

$$\frac{(\text{lsort}, E) \mid \sigma \xrightarrow{\text{call}}_n \tau}{(\text{lsort}, E') \mid \sigma \xrightarrow{\text{call}}_n \tau}$$

☞ **Proof** Inverting the derivation of $(\text{lsort}, E) \mid \sigma \xrightarrow{\text{call}}_n \tau$ yields

$$(\text{lsort}, \emptyset) \mid \sigma \xrightarrow{S_0}_{n-1} \tau .$$

Thus, applying rule (3.34) leads to the desired $(\text{lsort}, E') \mid \sigma \xrightarrow{\text{call}}_n \tau$. \square

The soundness and completeness proofs are more challenging when combining recursive procedure calls with local program variables because one has to relate the behaviour of procedure activations commencing in states which differ in the value of local program variables. However, if these local program variables are not in scope, their value is preserved.

→ p. 196  **Theorem 3.41 (Preserving Local Program Variables)** Let U be any type, y any program variable which is not local i.e., $y \notin E$ and $v : U$. Whenever

$$(\text{lsort}, E) \mid \sigma \xrightarrow{S} {}_n \tau$$

then

$$(\text{lsort}[y \mapsto U], E) \mid \text{uL}(\sigma, y, v) \xrightarrow{S} {}_n \text{uL}(\tau, y, v)$$

holds.

Notice that the type $\text{AccSort}(\text{lsort}, E)$ is (extensionally) equal to

$$\text{AccSort}(\text{lsort}[y \mapsto U], E) \quad \text{for } y \notin E.$$

Due to Lemma 3.38, such results also hold when one omits the recursive depth annotations. But notice that, with such annotations, the above theorem also establishes that the recursive depth is *preserved*.

 **Proof** by induction on the derivation of $(\text{lsort}, E) \mid \sigma \xrightarrow{S} {}_n \tau$. The cases where S amounts to an assignment or a block require some attention, because one needs to show that updating is commutative in these circumstances.

Assignment By the axiom for assignments (3.36), it suffices to establish that

$$\text{uL}(\sigma[x \mapsto_E \text{eval}(E, \sigma)(t)], y, v)$$

is (extensionally) equal to

$$\text{uL}(\sigma, y, v)[x \mapsto_E \text{eval}(E, \text{uL}(\sigma, y, v))(t)] .$$

Since y is not in scope, evaluation of the term t in the environment E cannot depend on the local entry of y in the state σ . Thus, $\text{eval}(E, \text{uL}(\sigma, y, v))(t)$ yields the same result as $\text{eval}(E, \sigma)(t)$. We proceed by case analysis on $x \in E$.

$x \in E$ The program variables x and y must be different. Hence, updating of x and y is interchangeable.

$x \notin E$ The order of updating is irrelevant because one updates the *local* entry for y and the *global* entry for x .

Block We abbreviate

$$\begin{aligned} \text{lsort}_x &\stackrel{\text{def}}{=} \text{lsort}[x \mapsto T] \\ \text{lsort}_{x,y} &\stackrel{\text{def}}{=} \text{lsort}[x \mapsto T][y \mapsto U] \\ \text{lsort}_y &\stackrel{\text{def}}{=} \text{lsort}[y \mapsto U] . \end{aligned}$$

From the assumption

$$(\text{Isort}_x, E \cup \{x\}) \mid \text{uL}(\sigma, x, \text{eval}(E, \sigma)(t)) \xrightarrow{S} {}_n \tau \quad (3.38)$$

and the induction hypothesis

$$y \notin E \cup \{x\} \Rightarrow \\ (\text{Isort}_{x,y}, E \cup \{x\}) \mid \text{uL}\left(\text{uL}(x, \text{eval}(E, \sigma)(t), \sigma), y, v\right) \xrightarrow{S} {}_n \text{uL}(\tau, y, v) ,$$

one needs to show

$$(\text{Isort}_y, E) \mid \text{uL}(\sigma, y, v) \xrightarrow{\text{new } x := t \text{ in } S} {}_n \text{uL}\left(\text{uL}(\tau, x, \sigma.\text{local}(x)), y, v\right) . \quad (3.39)$$

The induction hypothesis is only applicable if x and y are different program variables. If they are identical, we need to appeal to (3.38).

$x = y$ Since $y \notin E$, evaluation of the term t relative to (E, σ) yields the same result as evaluation with respect to $(E, \text{uL}(\sigma, y, v))$. Hence, the initial state of (3.38) is (extensionally) equal to

$$\text{uL}(\text{uL}(\sigma, y, v), x, \text{eval}(E, \text{uL}(\sigma, y, v))(t)) .$$

By the rule for blocks (3.37), we may conclude

$$(\text{Isort}, E) \mid \text{uL}(\sigma, y, v) \xrightarrow{\text{new } x := t \text{ in } S} {}_n \text{uL}(\tau, x, v) . \quad (3.40)$$

This concludes the case $x = y$ because the final states of (3.40) and (3.39) are (extensionally) equal.

$x \neq y$ Since $y \notin E$, we also have $y \notin E \cup \{x\}$ and may exploit the induction hypothesis. For distinct program variables x and y , we may commute the updating operations in the initial state. Thus, the rule for blocks (3.37) leads to

$$(\text{Isort}_y, E) \mid \text{uL}(\sigma, y, v) \xrightarrow{\text{new } x := t \text{ in } S} {}_n \text{uL}(\text{uL}(\tau, y, v), x, \sigma.\text{local}(x))$$

Finally, we commute the updating operations in the final state.

□

→ p. 197  **Corollary 3.42 (Preserving Local Program Variables)**

1. $((\text{lsort}, E) \mid \sigma \xrightarrow{\text{call}} \tau \wedge y \notin E) \Rightarrow \sigma.\text{local}(y) = \tau.\text{local}(y)$
2. Let U be any type and $v : U$ be an arbitrary value. Given any environments E and E' , whenever $(\text{lsort}, E) \mid \sigma \xrightarrow{\text{call}}_n \tau$ holds, one may also derive $(\text{lsort}[y \mapsto U], E') \mid \text{uL}(\sigma, y, v) \xrightarrow{\text{call}}_n \text{uL}(\tau, y, v)$.

 **Proof**

1. We apply Theorem 3.41 and instantiate v with $\sigma.\text{local}(y)$. Thus, by determinism, $\tau = \text{uL}(\tau, y, \sigma.\text{local}(y))$ from which one may deduce that $\tau.\text{local}(y)$ and $\sigma.\text{local}(y)$ are identical.
2. By Lemma 3.40, we may reduce the problem to a setting without any local program variables. Given $(\text{lsort}, \emptyset) \mid \sigma \xrightarrow{\text{call}}_n \tau$, Theorem 3.41 yields

$$(\text{lsort}[y \mapsto U], \emptyset) \mid \text{uL}(\sigma, y, v) \xrightarrow{\text{call}}_n \text{uL}(\tau, y, v) .$$

□

3.3.7 Hoare Logic

We need to revise Hoare Logic to integrate environments. One could either introduce them at the level of atomic correctness formulae

$$((\text{lsort}_1, E_1) \mid \{p_1\} \text{ call } \{q_1\}) \vdash_{\text{Hoare}} ((\text{lsort}_2, E_2) \mid \{p_2\} S \{q_2\})$$

or across a sequent

$$(\text{lsort}, E) \mid (\{p_1\} \text{ call } \{q_1\} \vdash_{\text{Hoare}} \{p_2\} S \{q_2\})$$

It turned out that it is easier to design a *complete* verification calculus for sequents with a single environment. Intuitively, it obviates the requirement for a structural rule to mediate between different environments with *different* sorts of local program variables. However, since the rule for blocks needs to modify the environment in the premiss, both the context and the succedent of the premiss needs to be adjusted. Alternatively, one could consider sequents in which the local sort is shared, whereas the set of local program variable names in scope is attached to atomic correctness formulae.

→ p. 199  **Definition 3.43 (Semantics of Hoare Logic)**

Similar to Def. 3.5 on page 62, we define $(\text{lsort}, E) \mid \Gamma \models_{\text{Hoare}} \{p\} S \{q\}$ by case analysis on the structure of the context Γ .

- In the empty context, we have

$$\begin{aligned} (\text{lsort}, E) \mid \emptyset \models_{\text{Hoare}} \{p\} S \{q\} &\stackrel{\text{def}}{=} \\ \forall Z \cdot \forall \sigma \cdot p(Z, \sigma) &\Rightarrow \exists \tau \cdot ((\text{lsort}, E) \mid \sigma \xrightarrow{S} \tau) \wedge q(Z, \tau) \end{aligned}$$

- For $\Gamma = \{p'\}$ **call** $\{q'\}$, we define validity relative to the empty context i.e.,

$$\begin{aligned} (\text{lsort}, E) \mid \Gamma \models_{\text{Hoare}} \{p\} S \{q\} &\stackrel{\text{def}}{=} \\ ((\text{lsort}, E) \mid \emptyset \models_{\text{Hoare}} \{p'\} \mathbf{call} \{q'\}) &\Rightarrow \\ ((\text{lsort}, E) \mid \emptyset \models_{\text{Hoare}} \{p\} S \{q\}) & \end{aligned}$$

3.3.7.1 Procedure Invocation

Turning to procedure calls, in resolving a correctness formula which invokes a procedure in an environment (lsort, E) , we may assume the correctness of this formulae while proving the correctness of the unfolded procedure body. Since procedure calls cause context switching, we investigate the triggered proof obligation relative to the empty environment. Assertions may inspect all entries of the state space irrespective of scoping restrictions. We may therefore reuse the same assertions as in the rule (3.8) for recursive procedures invocations without local program variables on page 62.

$$\frac{\forall t : W \cdot (\text{lsort}, \emptyset) \mid \{\hat{p}(t)\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{p(t)\} S_0 \{q\}}{(\text{lsort}, E) \mid \emptyset \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \exists t : W \cdot p(t)(Z, \sigma)\} \mathbf{call} \{q\}}$$

where $\hat{p}(t)(Z, \sigma) \stackrel{\text{def}}{=} \exists u : W \cdot p(u)(Z, \sigma) \wedge u < t$ and $(W, <)$ is well-founded. (3.41)

3.3.7.2 Blocks

If one were to insist on assertions being simply first-order logical formulae where some free variables are interpreted as the value of program variables, one would effectively limit scoping in assertions to dynamic binding. Specifically, the rule (3.25) from page 81 would be unsound with respect to static binding (Apt 1981). One can avoid scoping intrusion by substituting program variables in *programs* instead of assertions. For uninitialised variables, Gorelick (1975) proposes

$$\frac{\{p \wedge y = \omega\} S [x \mapsto y] \{q\}}{\{p\} \mathbf{new} x \mathbf{in} S \{q\}} \quad \text{where } y \notin \text{free}(p, S, q). \quad (3.42)$$

However, modifying the program text during the process of verification may not be appreciated, because software engineers may have chosen variable names carefully to reflect their intended usage. Furthermore, Apt (1981) admits that rule (3.25) is easier to use and handle than rule (3.42).

We follow Ah-kee's (1990) technique of annotating correctness formulae with environments and allow assertions to inspect the complete state space and not only the value of variables in scope. This has previously only been applied to VDM. In assertions we may thus explicitly refer to the value of a local and a global program variable¹⁶. We propose the rule

$$\frac{\forall v \cdot (\text{Isort}[x \mapsto T], E \cup \{x\}) \mid \text{Pr}(\Gamma, x, v) \vdash_{\text{Hoare}} \{\text{In}(p, x, v, t, E)\} \quad S \quad \{\text{uL}(q, x, v)\}}{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{new} \ x := t \ \mathbf{in} \ S \ \{q\}}$$

with $\text{Pr}(\Gamma, x, v) \stackrel{\text{def}}{=} \begin{cases} \emptyset & \text{for } \Gamma = \emptyset, \\ \{\text{Pr}(p', x, v)\} \mathbf{call} \ \{\text{Pr}(q', x, v)\} & \text{for } \Gamma = \{p'\} \mathbf{call} \ \{q'\} \end{cases}$ (3.43)

$$\text{Pr}(p, x, v)((Z, V), \sigma) \stackrel{\text{def}}{=} \text{uL}(p, x, v)(Z, \sigma) \wedge \sigma.\text{local}(x) = V$$

$$\text{In}(p, x, v, t, E)(Z, \sigma) \stackrel{\text{def}}{=} \text{uL}(p, x, v)(Z, \sigma) \wedge \sigma.\text{local}(x) = \text{eval}(E, \text{uL}(\sigma, x, v))(t)$$

In the premiss of the rule, we reduce the complexity by considering the derivation of a correctness formula concerning the program S in the updated environment. We have to freeze all references to the local variable x in all assertions of the premiss. Let $v : \text{Isort}(x)$ be a (fresh) constant¹⁷. We overload notation and exploit our previous definition (3.33) for updating the local entry in the state space. Employing

$$\text{uL}(p, x, v)(Z, \sigma) \stackrel{\text{def}}{=} p(Z, \text{uL}(\sigma, x, v))$$

we replace all references to the previous local value of x in all assertions of the premiss by the same v . Since v is fresh, it corresponds to the previous value of the local program variable x when reaching the block. In particular, in the initial state of the succedent in the premiss, for $\sigma : \Sigma(\text{Isort}[x \mapsto T])$, the state $\text{uL}(\sigma, x, v)$ amounts to the initial state of the succedent in the conclusion. Thus, we may add $\sigma.\text{local}(x) = \text{eval}(E, \text{uL}(\sigma, x, v))(t)$ in the precondition for S to ensure that the local value of x is equal to the value of the expression t when evaluated in the original environment E and state σ .

However, due to static scoping, the value of the local program variable x must be preserved across a procedure call in the context $\text{Pr}(\Gamma, x, v)$. The auxiliary variable $V : T$ records the value of the current local program variable x at the time of invoking a procedure. In the context of the rule's premiss, we have extended the domain of

¹⁶A less powerful extension to the notion of assertions to merely add propositions of the form $x \in E$ to check if x is a local program variable (Trakhtenbrot et al. 1984) does not seem to suffice.

¹⁷In the completeness proof, we will see that, due to our choice of permitting (local) program variables with *arbitrary* sorts, it is useful to share the same reference v across the sequent. Thus, v cannot be an auxiliary variable, because they range only over atomic correctness formulae. For a sound and complete calculus where v is represented as an auxiliary variable, one would need to restrict the sort of all (local) program variables to types $SORT \subsetneq \text{Type}$ in which, for every type in $SORT$, one can effectively extract an element of that type.

$$\begin{array}{c}
(\text{Isort}, E) \mid \{p\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{p\} \mathbf{call} \{q\} \\
(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{skip} \{p\} \\
(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma[x \mapsto_E \text{eval}(E, \sigma)(t)])\} x := t \{p\} \\
\frac{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p\} S_1 \{r\} \quad (\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{r\} S_2 \{q\}}{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p\} S_1; S_2 \{q\}} \\
\frac{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \quad (\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\}}{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{if} b \mathbf{then} S_1 \mathbf{else} S_2 \{q\}} \\
\frac{\forall t : W \cdot (\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{\hat{p}\} S \{\lambda(Z, \tau) \cdot p(Z, \tau) \wedge u(\tau) < t\}}{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{while} b \mathbf{do} S \{\lambda(Z, \tau) \cdot p(Z, \tau) \wedge \text{eval}(\tau)(b) = \mathbf{false}\}} \\
\text{where } \hat{p}(Z, \sigma) \stackrel{\text{def}}{=} p(Z, \sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true} \wedge u(\sigma) = t \\
\text{and } (W, <) \text{ is well-founded. } \quad (3.44)
\end{array}$$

$$\frac{\forall t : W \cdot (\text{Isort}, \emptyset) \mid \{\hat{p}(t)\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{p(t)\} S_0 \{q\}}{(\text{Isort}, E) \mid \emptyset \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \exists t : W \cdot p(t)(Z, \sigma)\} \mathbf{call} \{q\}}$$

where $\hat{p}(t)(Z, \sigma) \stackrel{\text{def}}{=} \exists u : W \cdot p(u)(Z, \sigma) \wedge u < t$ and $(W, <)$ is well-founded.

$$\frac{\forall v \cdot (\text{Isort} [x \mapsto T], E \cup \{x\}) \mid \text{Pr}(\Gamma, x, v) \vdash_{\text{Hoare}} \left\{ \begin{array}{c} \text{In}(p, x, v, t, E) \\ S \\ \text{uL}(q, x, v) \end{array} \right\}}{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p\} \mathbf{new} x := t \mathbf{in} S \{q\}}$$

with $\text{Pr}(\Gamma, x, v) \stackrel{\text{def}}{=} \begin{cases} \emptyset & \text{for } \Gamma = \emptyset, \\ \{\text{Pr}(p', x, v)\} \mathbf{call} \{\text{Pr}(q', x, v)\} & \text{for } \Gamma = \{p'\} \mathbf{call} \{q'\} \end{cases}$

$\text{Pr}(p, x, v)((Z, V), \sigma) \stackrel{\text{def}}{=} \text{uL}(p, x, v)(Z, \sigma) \wedge \sigma.\text{local}(x) = V$

$\text{In}(p, x, v, t, E)(Z, \sigma) \stackrel{\text{def}}{=} \text{uL}(p, x, v)(Z, \sigma) \wedge \sigma.\text{local}(x) = \text{eval}(E, \text{uL}(\sigma, x, v))(t)$

$$\frac{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p\} S \{q\}}$$

where $p_1, q_1 : \text{Assertion}(U)$ and $p, q : \text{Assertion}(T)$ for arbitrary types T and U

and $\forall Z \cdot \forall \sigma \cdot p(Z, \sigma) \Rightarrow \left(\exists Z_1 \cdot p_1(Z_1, \sigma) \wedge (\forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau)) \right)$. (3.45)

Figure 3.10: Hoare Logic and Static Binding – Total Correctness

auxiliary variables to generate a fresh constant $V : T$. Therefore, in general, one may no longer a priori fix the domain of auxiliary variables as the state space.

An alternative solution would be to restrict the class of assertions for procedure specifications. As Tarlecki (1985) has pointed out, one usually wants to use a procedure in several different contexts. Therefore, auxiliary variables, which play the rôle of a local reference point, ought to coincide with the value of the variables in the initial state. In other words, one may consider restricting the specification for a procedure activation to the VDM format where the precondition $p'(Z, \sigma)$ is of the form $\sigma = Z \wedge p_{\text{VDM}}(\sigma)$ for some predicate $p_{\text{VDM}} \subseteq \Sigma(\text{Isort})$ and the precondition q' is of the form $\text{Assertion}(\text{Isort})(\Sigma(\text{Isort}))$. Then, for $Z : \Sigma(\text{Isort}[x \mapsto T])$, one may refer to $Z.\text{local}(x)$ instead of V . Hence, the context in the premiss could be simplified to

$$\Pr(\Gamma, x, v) = \begin{cases} \emptyset & \text{for } \Gamma = \emptyset, \\ \{\text{uL}(p', x, v)\} \mathbf{call} \{\Pr(q', x, v)\} & \text{for } \Gamma = \{p'\} \mathbf{call} \{q'\} \end{cases}$$

where $\Pr(q', x, v)(Z, \tau) \stackrel{\text{def}}{=} q(\text{uL}(Z, x, v), \text{uL}(\tau, x, v)) \wedge \tau.\text{local}(x) = Z.\text{local}(x)$

In a setting where the scope of local program variables is provided relative to atomic correctness formulae, one may leave the context (and its environment) invariant in the rule for blocks. When looking up correctness formulae in the context, the difference in environments may then be reconciled in a single step e.g.,

$$\left((\text{Isort}, \emptyset) \mid \{p\} \mathbf{call} \{q\} \right) \vdash_{\text{Hoare}} \left(\left(\text{Isort} \left[\vec{x} \mapsto \vec{T} \right], \vec{x} \right) \mid \{\Pr(p)\} S \{\Pr(q)\} \right)$$

where $\Pr(p)((Z, \vec{v}, \vec{V}), \sigma) \stackrel{\text{def}}{=} \text{uL}(p, \vec{x}, \vec{v})(Z, \sigma) \wedge \bigwedge_{i \in I} \sigma.\text{local}(x_i) = V_i$.

3.3.7.3 Soundness

→ p. 204  **Theorem 3.44 (Soundness)** *The verification calculus defined as the least relation satisfying the rules summarised in Figure 3.10 on the previous page is sound.*

 **Proof** by induction on the derivation of $(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p\} S \{q\}$. Consider the case where we have applied the rule for blocks as the last step of the derivation. We abbreviate $\text{Isort}_x \stackrel{\text{def}}{=} \text{Isort}[x \mapsto T]$. From the induction hypothesis

$$\forall v : \text{Isort}(x) \cdot$$

$$(\text{Isort}_x, E \cup \{x\}) \mid \Pr(\Gamma, x, v) \models_{\text{Hoare}} \{\text{In}(p, x, v, t, E)\} S \{\text{uL}(q, x, v)\} \quad (3.46)$$

we have to establish

$$(\text{Isort}, E) \mid \Gamma \models_{\text{Hoare}} \{p\} \mathbf{new} \ x := t \ \mathbf{in} \ S \{q\} \ .$$

Let Z be an arbitrary auxiliary variable and $\sigma : \Sigma(\text{lsort})$ be an arbitrary initial state such that $p(Z, \sigma)$ holds. In the case where the context Γ contains a correctness formula $\{p'\} \mathbf{call} \{q'\}$, the induction hypothesis is no longer directly applicable¹⁸. As a new aspect in the proof, given

$$(\text{lsort}, E) \mid \emptyset \models_{\text{Hoare}} \{p'\} \mathbf{call} \{q'\} \quad , \quad (3.47)$$

one needs to establish

$$(\text{lsort}_x, E \cup \{x\}) \mid \emptyset \vdash_{\text{Hoare}} \{\text{Pr}(p', x, v)\} \mathbf{call} \{\text{Pr}(q', x'v)\} \quad . \quad (3.48)$$

Let Z', V be arbitrary auxiliary variables and $\sigma' : \Sigma(\text{lsort}_x)$ be an arbitrary initial state such that $p'(Z', \text{uL}(\sigma', x, v))$ and $\sigma'.\text{local}(x) = V$ hold. We need to find a final state $\tau' : \Sigma(\text{lsort}_x)$ such that one has

$$(\text{lsort}_x, E \cup \{x\}) \mid \sigma' \xrightarrow{\mathbf{call}} \tau' \quad (3.49)$$

$$q'(Z', \text{uL}(\tau', x, v)) \quad (3.50)$$

$$\tau'.\text{local}(x) = V \quad (3.51)$$

Appealing to (3.47) we may extract a final state τ which satisfies

$$(\text{lsort}, E) \mid \text{uL}(\sigma', x, v) \xrightarrow{\mathbf{call}} \tau \quad (3.52)$$

and $q'(Z', \tau)$. By Cor. 3.42.2, the derivation (3.52) can be lifted to the updated environment (3.49) with $\tau' \stackrel{\text{def}}{=} \text{uL}(x, \sigma'.\text{local}(x), \tau)$, because σ' is (extensionally) equal to $\text{uL}(x, \sigma'.\text{local}(x), \text{uL}(\sigma', x, v))$. Cor. 3.42.1 guarantees that in the derivation of (3.52), $\tau = \text{uL}(\tau, x, v)$. Thus, $\text{uL}(\tau', x, v) = \tau$ and we may conclude (3.50). Finally, in the light of $\sigma'.\text{local}(x) = V$, applying Cor. 3.42.1 to the derivation (3.49) ensures the desired (3.51). \square

3.3.7.4 Completeness

The proof of completeness follows the structure in the setting with recursive procedures without local program variables in Section 3.1.6 on page 65. We abbreviate

$$\begin{aligned} p_0(S)(\text{lsort}, E)(n)(Z, \sigma) &\stackrel{\text{def}}{=} (\text{lsort}, E) \mid \sigma \xrightarrow{S} {}_n Z \\ \psi(\text{lsort}, E)(n)(Z, \sigma) &\stackrel{\text{def}}{=} p_0(\mathbf{call})(n+1)(\text{lsort}, E)(Z, \sigma) \\ \hat{\psi}(\text{lsort}, E)(n)(Z, \sigma) &\stackrel{\text{def}}{=} \exists u : \text{nat} \cdot \psi(u)(\text{lsort}, E)(Z, \sigma) \wedge u < n \\ q(Z, \tau) &\stackrel{\text{def}}{=} Z = \tau \quad . \end{aligned}$$

¹⁸for $v = \sigma.\text{local}(x)$

The subtle interaction between procedures and local variables is dealt with in the following theorem. It established the pseudo induction hypothesis of the MGF theorem in the case of a recursive procedure call.

→ p. 204  **Theorem 3.45 (Completeness Step)**

$$(\text{lsort}, \emptyset) \mid \{\hat{\psi}(\text{lsort}, \emptyset)(n)\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{\psi(\text{lsort}, \emptyset)(n)\} S_0 \{q\} .$$

 **Proof** Just like the proof of the corresponding Lemma 3.12 on page 67, appealing to the consequence rule and the definition of bounded recursive depth, we equivalently transform the proof obligation into

$$(\text{lsort}, \emptyset) \mid \{\hat{\psi}(\text{lsort}, \emptyset)(n)\} \mathbf{call} \{q\} \vdash_{\text{Hoare}} \{p_0(S_0)(\text{lsort}, \emptyset)(n)\} S_0 \{q\} . \quad (3.53)$$

However, a direct proof by induction on the structure of the procedure body S_0 would not go through, because

- the context would be unaffected and
- programs would not be able to refer to local program variables.

Thus, the new rule for blocks (3.43) would not be applicable. Instead, we have to consider arbitrary environments E . Moreover, we strengthen the proof obligation and replace $\hat{\psi}(\text{lsort}, E)(n)$ and q in the context by arbitrary assertions p_1, q_1 such that, according to the rule of consequence,

$$\frac{(\text{lsort}, E) \mid \emptyset \vdash_{\text{Hoare}} \{p_1\} \mathbf{call} \{q_1\}}{(\text{lsort}, E) \mid \emptyset \vdash_{\text{Hoare}} \{\hat{\psi}(\text{lsort}, E)(n)\} \mathbf{call} \{q\}} .$$

Hence, we pursue

$$\forall p_1, q_1 \cdot \text{KSC}(\hat{\psi}(\text{lsort}, E)(n), q, p_1, q_1) \Rightarrow (\text{lsort}, E) \mid \{p_1\} \mathbf{call} \{q_1\} \vdash_{\text{Hoare}} \{p_0(S)(\text{lsort}, E)(n)\} S \{q\}$$

where

$$\text{KSC}(p, q, p_1, q_1) \stackrel{\text{def}}{=} \forall Z \cdot \forall \sigma \cdot p(Z, \sigma) \Rightarrow \left(\exists Z_1 \cdot p_1(Z_1, \sigma) \wedge (\forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau)) \right)$$

by induction on the structure of S . In comparison to the corresponding proof without blocks, one needs to additionally appeal to the rule of consequence in each case to deal with the arbitrary assertions p_1, q_1 . As an example, we spell out the case of a procedure invocation. The challenging part is the new case when we encounter a block.

Procedure Call Let p_1, q_1 be arbitrary assertions. Given the assumption

$$\text{KSC}(\hat{\psi}(\text{Isort}, E)(n), q, p_1, q_1) ,$$

we need to show

$$(\text{Isort}, E) \mid \{p_1\} \mathbf{call} \{q_1\} \vdash_{\text{Hoare}} \{p_0(\mathbf{call})(\text{Isort}, E)(n)\} \mathbf{call} \{q\} . \quad (3.54)$$

From being able to access the context, we may derive

$$(\text{Isort}, E) \mid \{p_1\} \mathbf{call} \{q_1\} \vdash_{\text{Hoare}} \{p_1\} \mathbf{call} \{q_1\} .$$

An appeal to the rule of consequence yields

$$(\text{Isort}, E) \mid \{p_1\} \mathbf{call} \{q_1\} \vdash_{\text{Hoare}} \{\hat{\psi}(\text{Isort}, E)(n)\} \mathbf{call} \{q\} .$$

Applying the consequence rule once more leads to (3.54). For a justification of the side-condition, see the corresponding proof in the scenario without blocks on page 67.

Blocks We abbreviate $\text{Isort}_x \stackrel{\text{def}}{=} \text{Isort}[x \mapsto T]$. From the induction hypothesis

$$\begin{aligned} \forall p_1, q_1 \cdot \text{KSC}(\hat{\psi}(\text{Isort}, E)(n), q, p_1, q_1) \Rightarrow \\ (\text{Isort}_x, E \cup \{x\}) \mid \{p_1\} \mathbf{call} \{q_1\} \vdash_{\text{Hoare}} \{p_0(S)(\text{Isort}, E)(n)\} S \{q\} \end{aligned}$$

and arbitrary assertions p_1, q_1 satisfying

$$\text{KSC}(\hat{\psi}(\text{Isort}, E)(n), q, p_1, q_1) \quad (3.55)$$

we have to establish

$$(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p_0(\mathbf{new} x := t \mathbf{in} S)(\text{Isort}, E)(n)\} \mathbf{new} x := t \mathbf{in} S \{q\}$$

where $\Gamma = \{p_1\} \mathbf{call} \{q_1\}$. Appealing to the rule for blocks (3.43), it suffices to show

$$\begin{aligned} (\text{Isort}_x, E \cup \{x\}) \mid \text{Pr}(\Gamma, x, v) \vdash_{\text{Hoare}} \{\text{In}(p', x, v, t, E)\} S \{\text{uL}(q, x, v)\} \\ \text{where } p' \stackrel{\text{def}}{=} p_0(\mathbf{new} x := t \mathbf{in} S)(\text{Isort}, E)(n) \end{aligned} \quad (3.56)$$

for an arbitrary constant $v : \text{Isort}(x)$. From now on in the proof, we may refer to v because we had chosen to universally quantify v at the level of a sequent. We now exploit the induction hypothesis and instantiate the precondition with $\text{Pr}(p_1, x, v)$ and the postcondition with $\text{Pr}(q_1, x, v)$. This yields

$$(\text{Isort}_x, E \cup \{x\}) \mid \text{Pr}(\Gamma, x, v) \vdash_{\text{Hoare}} \{p_0(S)(\text{Isort}, E)(n)\} S \{q\} \quad (3.57)$$

provided the side-condition

$$\text{KSC}(\hat{\Psi}(\text{Isort}, E)(n), q, \Pr(p_1, x, v), \Pr(p_2, x, v)) \quad (3.58)$$

is satisfied. The rule of consequence mediates between (3.57) and (3.56). Thus, in addition to (3.58), we are left with having to establish

$$\text{KSC}(\text{In}(p', x, v, t, E), \text{uL}(q, x, v), p_0(S)(\text{Isort}, E)(n), q) . \quad (3.59)$$

(3.59) Expanding the definitions of KSC, p' , In, p_0 and uL, after some straightforward simplifications, this side-condition is similar to the corresponding one in the proof of the MGF theorem on page 83.

(3.58) Given states $Z, \sigma, \tau : \Sigma(\text{Isort}_x)$ such that for some $u < n$, we have

$$(\text{Isort}_x, E \cup \{x\}) \mid \sigma \xrightarrow{\text{call}}_{u+1} Z , \quad (3.60)$$

we have to extract auxiliary variables Z' and v' such that

$$p_1(Z', \text{uL}(\sigma, x, v')) \quad (3.61)$$

and

$$\left(q_1(Z', \text{uL}(\tau, x, v')) \wedge \tau.\text{local}(x) = \sigma.\text{local}(x) \right) \Rightarrow Z = \tau . \quad (3.62)$$

Having universally quantified v in the premiss of the rule for blocks, we still have a suitable candidate for v' in scope. Otherwise, one would need to restrict the class of sorts so that one can effectively generate an element for every data type.

In order to utilise (3.55), we have to lift the assumption (3.60) to

$$(\text{Isort}, E) \mid \text{uL}(\sigma, x, v) \xrightarrow{\text{call}}_n \text{uL}(\tau, x, v)$$

by appealing to Cor. 3.42.2.

From (3.55), we extract the desired auxiliary variable Z' . It satisfies (3.61) and

$$q_1(Z', \text{uL}(\tau, x, v)) \Rightarrow \text{uL}(Z, x, v) = \text{uL}(\tau, x, v) . \quad (3.63)$$

Dealing with the remaining proof obligation (3.62), assume

$$q_1(Z', \text{uL}(\tau, x, v)) \quad \text{and} \quad \tau.\text{local}(x) = \sigma.\text{local}(x) .$$

By (3.63), it suffices to show that the local entry of x in the state spaces Z and σ are identical. This can be established by considering the derivation (3.60). According to Lemma 3.40, the same derivation holds in the empty environment. Thus, one may conclude the proof with the help of Cor. 3.42.1. □

→ p. 204  **Theorem 3.46 (MGF)**

$$(\text{Isort}, E) \mid \emptyset \vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot (\text{Isort}, E) \mid \sigma \xrightarrow{S} Z \right\} S \{q\}$$

 **Proof** by induction on the structure of S .

Procedure Call We need to show

$$(\text{Isort}, E) \mid \emptyset \vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot (\text{Isort}, E) \mid \sigma \xrightarrow{\text{call}} Z \right\} \text{call} \{q\} \quad (3.64)$$

Applying the rule for procedure invocations (3.41) to Theorem 3.45 yields

$$(\text{Isort}, E) \mid \emptyset \vdash_{\text{Hoare}} \left\{ \lambda(Z, \sigma) \cdot \exists n \cdot (\text{Isort}, E) \mid \sigma \xrightarrow{\text{call}}_{n+1} Z \right\} \text{call} \{q\} \quad . \quad (3.65)$$

We employ the rule of consequence to mediate between (3.65) and (3.64). For a justification of the side-condition, see the corresponding proof without blocks on page 68.

Blocks see the corresponding proof in the scenario without procedures on page 83. □

→ p. 204  **Corollary 3.47 (Completeness)**

Whenever $(\text{Isort}, E) \mid \emptyset \vdash_{\text{Hoare}} \{p\} S \{q\}$ is derivable from the axioms and rules of Figure 3.10 on page 101, $(\text{Isort}, E) \mid \emptyset \models_{\text{Hoare}} \{p\} S \{q\}$ holds.

 **Proof** Completeness follows immediately from the MGF Theorem. See the proof of Corollary 2.31 on page 41 for further details. □

3.3.7.5 Admissible Rules

In examples, due to the left-constructive nature of the assignment axiom, it is useful to be able to appeal to admissible *left-constructive* versions of the consequence rule, see Figure 3.1.8 on page 72, and the rule for blocks, see Figure 3.6 on page 84. Moreover, we derive a rule for non-recursive procedure calls. When combining recursive procedures with local program variables, we need to annotate the rules with contexts and environments.

$$\frac{(\text{Isort}, \emptyset) \mid \emptyset \vdash_{\text{Hoare}} \{p\} S_0 \{q\}}{(\text{Isort}, E) \mid \emptyset \vdash_{\text{Hoare}} \{p\} \mathbf{call} \{q\}} \quad (3.66)$$

$$\frac{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{p_1\} S \{q_1\}}{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{\hat{p}\} S \{q\}} \quad \text{with } \hat{p}(Z, \sigma) \stackrel{\text{def}}{=} \exists Z_1 \cdot p_1(Z_1, \sigma) \wedge \forall \tau \cdot q_1(Z_1, \tau) \Rightarrow q(Z, \tau). \quad (3.67)$$

$$\frac{\forall v \cdot (\text{Isort} [x \mapsto T], E \cup \{x\}) \mid \text{Pr}(\Gamma, x, v) \vdash_{\text{Hoare}} \{p\} S \{\text{uL}(q, x, v)\}}{(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \text{uL}(p, x, \text{eval}(E, \sigma)(t))\} \mathbf{new } x := t \mathbf{in } S \{q\}} \quad (3.68)$$

Figure 3.11: Admissible Rules for Static Binding in Hoare Logic

→ p. 205  **Corollary 3.48 (Soundness of Admissible Rules for Static Binding)**

The rules from Figure 3.11 are admissible.

 **Proof**

Procedure Call By soundness and completeness it suffices to show that

$$(\text{Isort}, \emptyset) \mid \sigma \xrightarrow{S_0} \tau$$

implies

$$(\text{Isort}, E) \mid \sigma \xrightarrow{\mathbf{call}} \tau .$$

This follows immediately from the operational semantics.

Adaptation The rule (3.67) is a trivial instance of the consequence rule (3.45).

Blocks Given

$$\forall v \cdot (\text{Isort} [x \mapsto T], E \cup \{x\}) \mid \text{Pr}(\Gamma, x, v) \vdash_{\text{Hoare}} \{p\} S \{\text{uL}(q, x, v)\}$$

we need to establish

$$(\text{Isort}, E) \mid \Gamma \vdash_{\text{Hoare}} \{\lambda(Z, \sigma) \cdot \text{uL}(p, x, \text{eval}(E, \sigma)(t))\} \mathbf{new } x := t \mathbf{in } S \{q\} \quad (3.69)$$

By the rule of consequence, we may replace p by

$$\lambda(Z, \sigma) \cdot \text{In} \left(\text{uL}(p, x, \text{eval}(E, \sigma)(t)), x, v, t, E \right) .$$

Then, the rule for blocks (3.43) is applicable and yields the desired (3.69). □

3.3.7.6 Example

We return to Example 3.31 on page 87 to illustrate how the new set of rules disambiguates global and local program variables.

→ p. 206  **Lemma 3.49 (Static Binding)**

Let E be an arbitrary environment (Isort, E) such that $E \cap \{x, z\} = \emptyset$ i.e., x and z are global program variables. Given the procedure declaration $S_0 \stackrel{\text{def}}{=} x := z$, one may derive $(\text{Isort}, E) \mid \emptyset \vdash_{\text{Hoare}} \{\mathbf{true}\} z := 1; \mathbf{new} z := 0 \mathbf{in call} \{x = 1\}$.

 **Proof** Semantically, the postcondition $\llbracket x = 1 \rrbracket(Z, \tau)$ corresponds to

$$\text{lookup}(E, \tau)(x) = 1$$

which expands to $\tau.\text{global}(x) = 1$. Thus, updating the value of local program variables has no effect. We follow the convention introduced in Example 3.35 on page 90 that $\llbracket x \rrbracket(Z, \sigma) = \sigma.\text{global}(x)$ and $\llbracket \dot{x} \rrbracket(Z, \sigma) = \sigma.\text{local}(x)$.

Appealing to the rule of sequential composition, we split the proof obligation into

$$(\text{Isort}, E) \mid \emptyset \vdash_{\text{Hoare}} \{\mathbf{true}\} z := 1 \{?i_1\} \quad (3.70)$$

$$(\text{Isort}, E) \mid \emptyset \vdash_{\text{Hoare}} \{?i_1\} \mathbf{new} z := 0 \mathbf{in call} \{x = 1\} \quad (3.71)$$

where $?i_1$ is an intermediate proof obligation which can be synthesised courtesy of the *left-constructive* version of the rule for blocks. Refining the second correctness formula (3.71) by the rule (3.68) yields

$$(\text{Isort} [z \mapsto \text{nat}], E \cup \{z\}) \mid \emptyset \vdash_{\text{Hoare}} \{?i_2\} \mathbf{call} \{x = 1\}$$

where

$$?i_1 = \text{uL}(?i_2, z, 0) . \quad (3.72)$$

We then use rule (3.66) to cater for the (non-recursive) procedure invocation. This gives us the new subgoal $(\text{Isort} [z \mapsto \text{nat}], \emptyset) \mid \emptyset \vdash_{\text{Hoare}} \{?i_2\} x := z \{x = 1\}$. By the axiom of assignments, the precondition $?i_2$ gets bound to $z = 1$ where, due to the environmental change caused by the procedure call, z refers to the value of the *global* program variable. Hence, synthesising $?i_1$ according to (3.72) leads to $z = 1$ (and not $0 = 1$). With this instantiation, it is straight-forward to derive the remaining proof obligation (3.70). \square

3.3.8 The Vienna Development Method

We extend the rules of Figure 3.4 on page 76 with environments and a rule for blocks. In the procedure invocation rule, the premiss is restricted to the empty environment to enforce static scoping. The conclusion holds for an arbitrary number of local variables. In the rule for blocks, we need to also adjust the environment of the context. We had already discussed the required modifications for VDM in Sect. 3.3.7.2 on page 99.

→ p. 213  **Theorem 3.50 (Soundness)** *The rules of Figure 3.12 on the next page are sound.*

 **Proof** by induction on the derivation of correctness formulae. □

→ p. 214  **Theorem 3.51 (Completeness)** *The rules of Figure 3.12 on the facing page are complete.*

 **Proof** Similar to the corresponding proof in the setting of Hoare Logic. □

3.4 Parameter Passing

For practical applications, it is clearly important to support procedures with parameters. In this section we discuss call-by-value and call-by-name parameters.

Let $S_0(T \text{ val } a, U \text{ var } x)$ be a procedure declaration in which the program S_0 may refer to the program variables a and x with sorts T and U . One refers to a as a formal value parameter and to x as a formal variable parameter. The procedure is invoked by **call** (t, v) where t is an expression and v a program variable. One refers to t as the actual value parameter and to v as the actual variable parameter (Dahl 1992).

On procedure entry, the expression t is evaluated in the current environment and its value is assigned to the variable a . With call-by-name passing, the variable x is aliased to v i.e., in executing S_0 , all occurrences of x are effectively replaced by v . To adequately deal with call-by-name parameters, it seems advisable to abandon the implicit stack encoding of states. Ah-kee (1990) develops VDM proof rules for parameter passing based on the address mechanism.

Call-by-value parameters are easier to deal with because this mechanism can be simulated in the presence of local program variables (Morgan 1988). One allocates a new variable a , initialises it with the value of t and proceeds with executing S_0 :

$$\frac{(\text{lsort } [a \mapsto T], \{a\}) \mid \text{uL}(\sigma, a, \text{eval}(E, \sigma)(t)) \xrightarrow{S_0} \tau}{(\text{lsort}, E) \mid \sigma \xrightarrow{\text{call } t} \text{uL}(\tau, a, \sigma.\text{local}(a))}$$

However, one needs to take care to evaluate the expression t in the correct environment E . Let us first consider the case where all procedure invocations employ the

$$\begin{array}{c}
(\text{Isort}, E) \mid \{p\} \text{ call } \{q\} \vdash \{p\} \text{ call } \{q\} \\
(\text{Isort}, E) \mid \Gamma \vdash \{\lambda\sigma \cdot \mathbf{true}\} \text{ skip } \{\lambda(\tau, \sigma) \cdot \tau = \sigma\} \\
(\text{Isort}, E) \mid \Gamma \vdash \{\lambda\sigma \cdot \mathbf{true}\} x := t \{\lambda(\tau, \sigma) \cdot \tau = \sigma [x \mapsto \text{eval}(\sigma)(t)]\} \\
\frac{(\text{Isort}, E) \mid \Gamma \vdash \{p_1\} S_1 \{\lambda(\tau, \sigma) \cdot p_2(\tau) \wedge r_1(\tau, \sigma)\} \quad (\text{Isort}, E) \mid \Gamma \vdash \{p_2\} S_2 \{r_2\}}{(\text{Isort}, E) \mid \Gamma \vdash \{p_1\} S_1; S_2 \{r_2 \circ r_1\}} \\
\frac{(\text{Isort}, E) \mid \Gamma \vdash \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S_1 \{q\} \quad (\text{Isort}, E) \mid \Gamma \vdash \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{false}\} S_2 \{q\}}{(\text{Isort}, E) \mid \Gamma \vdash \{p\} \text{ if } b \text{ then } S_1 \text{ else } S_2 \{q\}} \\
\frac{(\text{Isort}, E) \mid \Gamma \vdash \{\lambda\sigma \cdot p(\sigma) \wedge \text{eval}(\sigma)(b) = \mathbf{true}\} S \{\lambda(\tau, \sigma) \cdot p(\tau) \wedge \text{sofar}(\tau, \sigma)\}}{(\text{Isort}, E) \mid \Gamma \vdash \{p\} \text{ while } b \text{ do } S \{q\}} \\
\text{where } \text{sofar} \text{ is any binary transitive relation on the state space } \Sigma \text{ such that} \\
\lambda(\tau, \sigma) \cdot \text{sofar}(\tau, \sigma) \wedge p(\tau) \text{ is well-founded} \\
\text{and } q(\tau, \sigma) \stackrel{\text{def}}{=} p(\tau) \wedge \text{eval}(\tau)(b) = \mathbf{false} \wedge (\text{sofar}(\tau, \sigma) \vee \tau = \sigma). \\
\frac{\forall t : W \cdot (\text{Isort}, \emptyset) \mid \{\lambda\sigma \cdot \exists u \cdot p(u)(\sigma) \wedge u < t\} \text{ call } \{q\} \vdash \{p(t)\} S_0 \{q\}}{(\text{Isort}, E) \mid \emptyset \vdash \{\lambda\sigma \cdot \exists t : W \cdot p(t)(\sigma)\} \text{ call } \{q\}} \\
\text{where } (W, <) \text{ is well-founded.} \\
\frac{\forall v \cdot (\text{Isort } [x \mapsto T], E \cup \{x\}) \mid \text{Pr}(\Gamma, x, v) \vdash_{\text{VDM}} \left\{ \begin{array}{l} \text{In}(p, x, v, t, E) \\ S \\ \text{uL}(q, x, v) \end{array} \right\}}{(\text{Isort}, E) \mid \Gamma \vdash \{p\} \text{ new } x := t \text{ in } S \{q\}} \\
\text{with } \text{Pr}(\Gamma, x, v) \stackrel{\text{def}}{=} \begin{cases} \emptyset & \text{for } \Gamma = \emptyset, \\ \{\text{uL}(p', x, v)\} \text{ call } \{\text{Pr}(q', x, v)\} & \text{for } \Gamma = \{p'\} \text{ call } \{q'\} \end{cases} \\
\text{Pr}(q', x, v)(\tau, \sigma) \stackrel{\text{def}}{=} \text{uL}(q', x, v)(\tau, \sigma) \wedge \tau.\text{local}(x) = \sigma.\text{local}(x) \\
\text{In}(p, x, v, t, E)(\sigma) \stackrel{\text{def}}{=} \text{uL}(p, x, v)(\sigma) \wedge \sigma.\text{local}(x) = \text{eval}(E, \text{uL}(\sigma, x, v))(t) . \\
\frac{(\text{Isort}, E) \mid \Gamma \vdash \{p_1\} S \{q_1\}}{(\text{Isort}, E) \mid \Gamma \vdash \{p\} S \{q\}} \\
\text{provided } \forall \sigma \cdot p(\sigma) \Rightarrow p_1(\sigma) \text{ and } \forall (\tau, \sigma) \cdot p(\sigma) \Rightarrow q_1(\tau, \sigma) \Rightarrow q(\tau, \sigma).
\end{array}$$

Figure 3.12: VDM and Static Binding

same call-by-value parameter t . One may simulate all occurrences of **call** t by the procedure **new** $a := t$ **in** S_0 if the actual value parameter t refers only to *global* program variables. In particular, restricting our attention to non-recursive procedures and partial correctness, in the case where the expression t amounts to a global program variable a' , call-by-value parameter passing can be dealt with by the rule

$$\frac{\forall v \cdot (\text{Isort}[a \mapsto T], \{a\}) \mid \{\text{In}(p, a, v, a', E)\} S_0 \{\text{uL}(q, a, v)\}}{(\text{Isort}, E) \mid \{p\} \text{call } a' \{q\}} \quad \text{for } a' \notin E.$$

Dahl (1992) proposes dealing with the general case of arbitrary expressions t as actual value parameters by considering the translation

$$\begin{aligned} S_0 &\rightsquigarrow \text{new } a := a' \text{ in } S_0 \\ \text{call } t &\rightsquigarrow a' := t; \text{call } a' \end{aligned} \tag{3.73}$$

This leads to the rule

$$\frac{\forall v \cdot (\text{Isort}[a \mapsto T], \{a\}) \mid \{\text{In}(p, a, v, a', E)\} S_0 \{\text{uL}(q, a, v)\}}{(\text{Isort}, E) \mid \{\lambda(Z, \sigma) \cdot p(Z, (\sigma.\text{global}[a' \mapsto t], \sigma.\text{local}))\} \text{call } t \{q\}} \quad \text{for } a' \notin E.$$

It would be an interesting further research contribution to mechanically establish soundness and completeness for verification calculi dealing with parameter passing. In the following chapter, in verifying Quicksort, we avoid call-by-value parameter passing by directly translating all procedure calls and procedure bodies according to (3.73). Moreover, we replace call-by-name parameters by global program variables.

Chapter 4

Case Study: Quicksort

In the previous chapters, we have demonstrated that it is feasible to conduct soundness and completeness proofs for verification calculi on a machine. As a by-product, we have gained a new set of verification rules for imperative programs dealing with recursive (parameterless) procedures and local variables. Soundness and completeness are important meta-theoretical properties. However, it remains to be shown that the new verification calculi are suitable in practice. Clearly, we cannot really expect to verify industrial-size programs at this stage. Our results would need to be extended to better support modular program development. In particular, we cannot directly deal with multiple procedures or parameter passing.

In this chapter, using Hoare's (1961) Quicksort algorithm as an example, we show that our Hoare Logic rules lend themselves to proving the correctness of a concrete recursive procedure with local and global variables.

Verification systems such as Hoare Logic themselves do not actually impose a strict methodology on how to verify programs. At one end of the spectrum, one can derive a Verification Condition Generator (VCG) from the set of rules. Given a program annotated with loop invariants and specifications for recursive procedures, a VCG automatically produces a set of propositions, which, if proven correct, guarantee the correctness of the desired program. Using the B method (Abrial 1996) as the underlying verification system, this approach has for example been employed by *GEC Alstom* to verify the speed- and switching-control software used in all of France's 6000 electric trains. On the other end of the spectrum, Dijkstra (1990), Gries (1981) and others advocate developing the program hand-in-hand¹ with its proof of correctness.

Our specification follows Reynolds's (1981) presentation. The arguments in the correctness proof are well-known. Foley & Hoare had already published a proof of partial correctness for Quicksort in 1971. In our presentation, besides also considering

¹Formally, such an approach may be described by first-order deliverables (Burstall & McKinnon 1993).

termination, we highlight the rôle of the strengthened consequence rule and the new rules required in the presence of recursive procedures and local variables.

The formal rigour of the correctness proof is an orthogonal issue. Current industrial applications seem to be aided by some tool support, but purely logical propositions (arising from a consequence rule) are mostly dealt with on paper only. We have conducted the complete verification using the LEGO system.

The outline of this chapter is as follows. We first sketch the required background theory of sorted arrays. We then present Reynolds's (1981) specification and discuss the modifications required so that the program can be expressed in our toy language framework. At the heart of the chapter lies the verification proof.

4.1 A Theory of Sorted Arrays

In his thesis, McKinna (1992) investigates correctness proofs of *functional* programs in LEGO. We chose to reuse a substantial amount of his theory of sorted lists, which McKinna formalised to justify the correctness of *Insert Sort*.

In an imperative scenario, we have to deal with arrays. These are quite different from lists. There is no recursive structure and any element can be accessed in constant time. For efficiency, the algorithms rely on call-by-name passing (or global variables) of arrays. An imperative sorting algorithm requires three arguments: the array, the lower and the upper bound. The verification requires a little more care, because one has to ensure that a recursive call only manipulates the array within the specified bounds. We decided to represent arrays as (total) function spaces. We chose $\text{nat} \rightarrow \text{nat}$ as the sort for the program variable x storing the array. Any entry in an array $x[c]$ corresponds to $x(c)$. An assignment to a particular field in an array can then be represented by updating, see Section 2.6.1 on page 15 for details.

As a disadvantage of reusing McKinna's (1992) scripts, we have to convert functions to lists relative to some array bounds. Thus, we can no longer directly exploit the structure of arrays. It might have been more elegant to develop a theory of sorting based directly on arrays. However, we believe this would have taken more time and decided it would not be worth the effort. We will keep the presentation short and informal.

4.1.1 Ordered Lists

Given an ordering relation such as $<$ on natural numbers, one can lift this relation pointwise to lists. We overload notation e.g., if k and l are lists of natural numbers, $k < l$ denotes that every element in the list k is less than every element in the list l .

Lifting is also useful to define the notion of an ordered list. For every element x in the list, every element appearing later than x in the list must be greater than or equal to x .

Definition 4.1 (Ordered Lists) *Let $R \subseteq T \times T$ be an arbitrary relation.*

$$\begin{aligned} \text{ord}(R)([]) &= \mathbf{true} \\ \text{ord}(R)(a :: l) &= [a] R l \wedge \text{ord}(R)(l) \end{aligned}$$

4.1.2 Subarrays

In sorting algorithms such as Quicksort, one needs to assert that a subarray, characterised by array boundaries, is sorted. Representing arrays as functions, we have implemented a function $\text{natl}(x)(a, b)$, which, given a function x with domain nat and boundaries $a, b : \text{nat}$, returns the list of all elements between a and b , intuitively, $[x(a), \dots, x(b)]$.

The main idea behind Quicksort is to recursively partition the array into two subarrays such that all elements in the first are less than or equal to those in the second. This involves swapping of elements. Due to the assignment axiom, on the level of assertions, one needs to update array elements. One therefore has to investigate how updating interacts with the translation from functions to lists. Either updating has no effect, because it affects elements outside the array bounds, or it changes an intermediate value and one may factorise the array accordingly.

→ p. 217  **Lemma 4.2 (External Update)** *Let a, b and c be natural number such that either $c < a$ or $b < c$, then $\text{natl}(x[c \mapsto t])(a, b) = \text{natl}(x)(a, b)$.*

 **Proof** by induction on the array bounds a and b for a fixed element t . □

→ p. 217  **Lemma 4.3 (Factorisation)** *Let a, b and c be natural numbers such that $a \leq b \leq c$, then*

$$\begin{aligned} \text{natl}(x[b \mapsto t])(a, c) = \\ (\mathbf{if } b = 0 \mathbf{ then } [] \mathbf{ else } \text{natl}(x)(a, b - 1)) @ (t :: (\text{natl}(x)(b + 1, c))) \end{aligned} .$$

Notice that the conditional is necessary, because, for $a = b = 0$, we have by definition that $b - 1 = 0 : \text{nat}$. Thus, $\text{natl}(x)(a, b - 1)$ reduces to $x(0)$ and not the required empty list.

 **Proof** by induction on the array bounds a and c . The proof has an interesting twist in that one needs to generalise over an arbitrary term t . □

Having explored the effect of updating, we can show that swapping two elements via updating preserves the permutation property.

Definition 4.4 (Permutation) *McKinna defines \sim as the smallest equivalence relation which identifies lists up to the commutativity of the append function, and is closed under adding a new element at the front:*

$$l \sim l \quad \frac{k \sim l}{l \sim k} \quad \frac{k \sim l \quad l \sim m}{k \sim m} \quad k @ l \sim l @ k \quad \frac{k \sim l}{(a :: k) \sim (a :: l)}$$

→ p. 217  **Lemma 4.5 (Swapping Elements)** *Let a, b, c and d be natural numbers with $a \leq c \leq b$ and $a \leq d \leq b$. Then $\text{natl}(x[d \mapsto x(c)][c \mapsto x(d)])(a, b) \sim \text{natl}(x)(a, b)$.*

 **Proof** by case analysis on whether $c < d$, $c = d$ or $c > d$. □

New in the imperative scenario is the desired property that elements outside the boundaries of the array are not affected by the sorting algorithm. Hence, we need to express that two arrays X and x are permutations within a specified region and identical otherwise.

→ p. 219  **Definition 4.6 (Permutation on Subarrays)**

$$X \text{ }_a\sim^b x \stackrel{\text{def}}{=} (\text{natl}(X)(a, b) \sim \text{natl}(x)(a, b)) \wedge (\forall c. (c < a \vee b < c) \Rightarrow X(c) = x(c))$$

4.1.3 High-Level Correctness Argument

The array to be sorted undergoes a series of transformations during the process of Quicksort. First, it is reordered to form a partition such that elements in the first are smaller than or equal to all elements in the second. Then, the algorithm is applied recursively to the two partitions.

Starting with the original array X_0 , let X_1 and X_2 denote the two intermediate arrays, and X_3 the final array. From the progress achieved in the individual steps, one needs to establish that X_3 is ordered, a permutation of X_0 and that none of the elements outside of the array boundaries have been modified.

→ p. 219  **Definition 4.7 (Sorted Arrays)** $X \text{ }_a\text{Sorted}^b x \stackrel{\text{def}}{=} \text{ord}(\leq)(\text{natl}(x)(a, b)) \wedge X \text{ }_a\sim^b x$

→ p. 219  **Theorem 4.8 (Quicksort)** Let a and b be the array boundaries, and c the intermediate position computed by the partitioning process such that $a < c \leq b$. Given

$$X_0 \text{ }_a\sim^b X_1 \tag{4.1}$$

$$\text{natl}(X_1)(a, c - 1) \leq \text{natl}(X_1)(c, b) \tag{4.2}$$

$$X_1 \text{ }_a\text{Sorted}^{c-1} X_2 \tag{4.3}$$

$$X_2 \text{ }_c\text{Sorted}^b X_3 \tag{4.4}$$

one can justify $X_0 \text{ }_a\text{Sorted}^b X_3$.

 **Proof** Combining the stability conditions outside the array boundaries of (4.3) and (4.4), we may exploit

$$\text{natl}(X_1)(c, b) = \text{natl}(X_2)(c, b) \tag{4.5}$$

$$\text{natl}(X_2)(a, c - 1) = \text{natl}(X_3)(a, c - 1) \tag{4.6}$$

We show how to establish $\text{ord}(\leq)(\text{natl}(X_3)(a, b))$ in more detail. Appealing to the permutation properties of (4.3) and (4.4), as well as the equalities (4.5) and (4.6), from the partitioning (4.2), we may conclude

$$\text{natl}(X_3)(a, c - 1) \leq \text{natl}(X_3)(c, b) . \tag{4.7}$$

Moreover, rewriting (4.3) with the help of (4.6) yields

$$\text{ord}(\leq)(\text{natl}(X_3)(a, c - 1)) \tag{4.8}$$

Hence, combining (4.7), (4.8) and the order property of (4.4) established that the list $\text{natl}(X_3)(a, b)$ is sorted. □

4.2 Specification of Quicksort

We follow Reynolds's (1981) top-down presentation. Relative to a program *Prepare* which partitions the array into two fragments k and l with $k \leq l$, we recursively sort k and l . A Hoare triple which characterises the behaviour of *Prepare* is

$$\{a < b \wedge a = A \wedge b = B \wedge x = X\}$$

Prepare

$$\{A < c \leq B \wedge \text{natl}(X)(A, c - 1) \leq \text{natl}(X)(c, B) \wedge x \text{ }_A\sim^B X \wedge a = A \wedge b = B\}$$

Lemma 4.9 (Rigorous Correctness of Quicksort) We pass the boundaries a, b as call-by-values and the array x as call-by-name.

```

procedure quicksort(nat val  $a, b$ ; nat array var  $x$ );
  { $a = A \wedge b = B \wedge x = X$ }
  if  $a < b$  then begin nat  $c$ ;
    Prepare;
    quicksort( $a, c - 1, x$ ); quicksort( $c, b, x$ )
  end
  { $X \text{ }_A\text{Sorted}^B x$ }

```

The Prepare fragment builds on a general partition procedure

```

procedure partition(nat val  $a, b, r$ ; nat var  $c$ ; nat array var  $x$ );
  { $a = A \wedge b = B \wedge x = X$ }
  begin nat  $d$ ;
     $c := a$ ;  $d := b$ 
    while  $c \leq d$  do
      if  $x[c] \leq r$  then  $c := c + 1$  else
        if  $x[d] > r$  then  $d := d - 1$  else
          begin
            begin nat  $t$ ;  $t := x[c]$ ;  $x[c] := x[d]$ ;  $x[d] := t$  end;
             $c := c + 1$ ;  $d := d - 1$ 
          end
        end
      end
    end
  { $A \leq c \leq d + 1 \wedge \text{natl}(x)(A, c - 1) \leq r \wedge r < \text{natl}(x)(c, B) \wedge x \text{ }_A\sim^B X \wedge$   

 $a = A \wedge b = B$ }

```

If Prepare were to simply call $\text{partition}(a, b, r, c, x)$, there would be no guarantee that both partitions are strictly smaller. Without this additional property, the above Quicksort procedure may not terminate. Reynolds (1981) overcomes this problem by analysing the outermost elements $x[a]$ and $x[b]$ and swaps them in case $x[a] > x[b]$. By narrowing the partitioning algorithm to the subarray $\text{natl}(x)(a + 1, b - 1)$ for some intermediate pivot element r which lies between $x[a]$ and $x[b]$, one can guarantee that Prepare finds a value c such that $a < c \leq b$:

Definition 4.10 (Prepare)

```

{ $a < b \wedge a = A \wedge b = B \wedge x = X$ }
begin nat  $r$ ;
  if  $x[a] > x[b]$  then begin nat  $t$ ;  $t := x[a]$ ;  $x[a] := x[b]$ ;  $x[b] := t$  end;
   $r := (x[a] + x[b]) \div 2$ ;
  partition( $a + 1, b - 1, r, c, x$ )

```

end

$$\{A < c \leq B \wedge \text{natl}(X)(A, c - 1) \leq \text{natl}(X)(c, B) \wedge x_{A \sim^B X} \wedge a = A \wedge b = B\}$$

4.2.1 Mechanisation

Being primarily interested in the meta-theory of verification calculi, we have chosen a shallow embedding for assertions. Unfortunately, this renders examples illegible. For the purpose of this chapter, we present assertions at the syntactic level. These have been translated by hand from the actual LEGO scripts.

All local program variables have sort `nat`. We therefore annotate correctness formulae only with a set of local program variables in scope E instead of an environment $(\text{l-sort}, E)$.

We only consider assertions where the domain of auxiliary variables coincides with the state space. In assertions, lowercase (free) variable names correspond to the value of program variables in the current state, whereas uppercase variable names correspond to auxiliary variables. Intuitively, auxiliary variables capture the initial value of program variables.

Example 4.11 *In an environment E recording all local variables, the assertion*

$$a = A \wedge b = B \wedge a < b$$

is to be parsed as

$$\begin{aligned} \lambda(Z, \sigma) \cdot \text{lookup}(E, \sigma)(a) &= \text{lookup}(E, Z)(a) \wedge \\ \text{lookup}(E, \sigma)(b) &= \text{lookup}(E, Z)(b) \wedge \text{lookup}(E, \sigma)(a) < \text{lookup}(E, \sigma)(b) \end{aligned} .$$

Our toy language does not support multiple procedures, nor parameter passing. Therefore, we need to reformulate the algorithm in more primitive terms. To circumvent parameter passing in Def. 4.9, we replace the call-by-name parameter x by a global program variable.

We eliminate call-by-value parameters by following the recipe of Sect. 3.4 on page 110. We declare the parameters a' and b' as global program variables. At the beginning of the procedure, we allocate two *local* variables a and b and initialise them with the values of a' and b' at procedure invocation time. Moreover, we have to take care of uninitialised local program variables, either by rearranging code, or, by choosing some arbitrary initial value.

→ p. 221  **Definition 4.12 (Quicksort)**

```
 $S_0 \stackrel{\text{def}}{=} \text{new } a := a' \text{ in new } b := b' \text{ in}$   
  if  $a < b$  then new  $c := 0$  in  
    begin  
      Prepare;  
       $a' := a; b' := c - 1$   
      call;  
       $a' := c; b' := b;$   
      call  
    end
```

As the partitioning algorithm is non-recursive, we macro-expand its invocation in Def. 4.10. As a further simplification, we set the pivot element to $x[a]$ instead of $(x[a] + x[b]) \div 2$, because, given $x[a] \leq x[b]$, it is easier to show $x[a] \leq x[a] \leq x[b]$ than $x[a] \leq (x[a] + x[b]) \div 2 \leq x[b]$.

→ p. 220  **Definition 4.13 (Prepare)**

```
Prepare  $\stackrel{\text{def}}{=} \text{if } x[a] > x[b]$  then new  $t := x[a]$   
  in begin  $x[a] := x[b]; x[b] := t$  end;  
  new  $r := x[a]$  in  
    begin  
       $c := a + 1;$   
      new  $d := b - 1$  in  
        while  $c \leq d$  do  
          if  $x[c] \leq r$  then  $c := c + 1$  else  
            if  $x[d] > r$  then  $d := d - 1$  else  
              begin  
                new  $t := x[c]$   
                in begin  
                   $x[c] := x[d]; x[d] := t$   
                end;  
                 $c := c + 1; d := d - 1$   
              end  
            end  
          end  
        end  
      end
```

The specification for the Quicksort algorithm remains the same. However, due to our encoding of parameter passing, we have to ensure that the program variables a' , b' and x are global.

→ p. 235  **Lemma 4.14 (Correctness of Quicksort)** *Let E be an arbitrary environment such that $E \cap \{a', b', x\} = \emptyset$. We can then derive*

$$E \mid \emptyset \vdash_{\text{Hoare}} \{a' = A' \wedge b' = B' \wedge x = X\}$$

call

$$\{X \text{ }_{A'}\text{Sorted}^{B'} x\}$$

In order to prove this, we establish the intermediate result:

→ p. 234  **Lemma 4.15 (Correctness of Prepare)** *Let E be an arbitrary environment² and Γ be an arbitrary context.*

$$E \mid \Gamma \vdash_{\text{Hoare}} \{a < b \wedge a = A \wedge b = B \wedge x = X\}$$

Prepare

$$\{\text{variant}_{\text{Prepare}}(x)(c) \wedge a = A \wedge b = B\}$$

where

→ p. 222  **Definition 4.16 (Variant for Prepare Fragment)**

$$\text{variant}_{\text{Prepare}}(x)(c) \stackrel{\text{def}}{=} A < c \leq B \wedge \text{natl}(X)(A, c - 1) \leq \text{natl}(X)(c, B) \wedge x \text{ }_A\sim^B X$$

An important and challenging aspect of the specification is to provide a suitable loop invariant. Based on Reynolds's (1981) version for the partition algorithm, we have employed the following assertion:

→ p. 222  **Definition 4.17 (Invariant for Prepare Fragment)**

$$\text{inv}_{\text{Prepare}}(c, d) \stackrel{\text{def}}{=} A < c \leq d + 1 \wedge d < B \wedge$$

$$\text{natl}(x)(A, c - 1) \leq r \wedge r < \text{natl}(x)(d + 1, B - 1) \wedge r \leq x[B] \wedge$$

$$x \text{ }_A\sim^B X \wedge a = A \wedge b = B$$

4.3 A Guided Tour of the Verification Proof

Our formalised verification calculus does not directly permit multiple procedures. The declaration of the procedure in Def. 4.12 contains only procedure activations of itself. We have used LEGO's support for definitions to emphasise that the Prepare fragment corresponds to a procedure invocation. In the correctness proof, we exploit LEGO's

²For simplicity, in the mechanised proof, we only consider the particular environment $E = \{a, b, c\}$ arising in the proof of Quicksort.

support for structuring proofs to *independently* verify the correctness of Prepare and Quicksort.

We commence by assuming Lemma 4.15 and show Lemma 4.14 i.e., that the skeleton of the Quicksort algorithm is correct. Afterwards, we complete the proof by verifying the Prepare implementation.

The main purpose of this section is to clarify how to use our set of Hoare Logic rules in practice. It is well-known that the whole process can be automated with a Verification Condition Generator.

4.3.1 Verification of Quicksort Skeleton

Our proof strategy is to employ the rule for well-founded recursion (3.41) on page 99. To use this we need to plant a termination measure in the precondition. For Quicksort, every call works on a smaller subarray. Its length is determined by the expression $(b' - a') + 1$. We therefore employ the consequence rule (3.45) to equivalently transform the precondition to $\exists n \cdot n = (b' - a') + 1 \wedge a' = A' \wedge b' = B' \wedge x = X$. Specialising rule (3.41) to the usual well-founded order $<$ on nat results in the subgoal

$$\emptyset \mid \Gamma \vdash_{\text{Hoare}} \{n = (b' - a') + 1 \wedge a' = A' \wedge b' = B' \wedge x = X\} \\ S_0 \\ \{X \text{ }_{A'}\text{Sorted}^{B'} x\}$$

where $n : \text{nat}$ is an arbitrary reference and

$$\Gamma \stackrel{\text{def}}{=} \{\exists m \cdot m = (b' - a') + 1 \wedge a' = A' \wedge b' = B' \wedge x = X \wedge m < n\} \\ \mathbf{call} \\ \{X \text{ }_{A'}\text{Sorted}^{B'} x\}$$

The outermost constructors of the program S_0 successively determine which verification rules to apply. We commence by compensating for the local variable a . Since the pre- and postcondition do not mention another (local) program variable a , the rule for blocks (3.43) on page 100 only adds $a = a'$ in the precondition and $a = A$ in both assertions of the context. In particular, we have to derive

$$\{a\} \mid \text{Pr}(\Gamma, a, v_a) \vdash_{\text{Hoare}} \{n = (b' - a') + 1 \wedge a' = A' \wedge b' = B' \wedge x = X \wedge a = a'\} \\ \mathbf{new } b := b' \mathbf{ in} \\ \mathbf{if } a < b \mathbf{ then new } c := 0 \mathbf{ in} \\ \mathbf{begin} \\ \text{Prepare}; \\ a' := a; b' := c - 1 \\ \mathbf{call};$$

$$\begin{array}{c}
a' := c; b' := b; \\
\mathbf{call} \\
\mathbf{end} \\
\{X_{A'} \text{Sorted}^{B'} x\}
\end{array}$$

Similarly, we remove the other local variable declarations and split the conditional. The case where the array to be sorted contains at most one element can be resolved easily. Otherwise, we have to show

$$\{a, b, c\} \mid \Gamma_{a,b,c} \vdash_{\text{Hoare}} \{n = (b' - a') + 1 \wedge a' = A' \wedge b' = B' \wedge x = X \wedge a = a' \wedge b = b' \wedge a < b \wedge c = 0\}$$

$$\begin{array}{c}
\text{Prepare;} \\
a' := a; b' := c - 1 \\
\mathbf{call}; \\
a' := c; b' := b; \\
\mathbf{call} \\
\{X_{A'} \text{Sorted}^{B'} x\}
\end{array}$$

where for

$$\begin{aligned}
p_1(A, A', B, B', C, X)(a, a', b, b', c, x) &\stackrel{\text{def}}{=} \\
&\exists m \cdot m = (b' - a') + 1 \wedge a' = A' \wedge b' = B' \wedge x = X \wedge m < n \wedge \\
&a = A \wedge b = B \wedge c = C
\end{aligned}$$

and

$$\begin{aligned}
q_1(A, A', B, B', C, X)(a, a', b, b', c, x) &\stackrel{\text{def}}{=} \\
&X_{A'} \text{Sorted}^{B'} x \wedge a = A \wedge b = B \wedge c = C
\end{aligned}$$

we define

$$\begin{aligned}
\Gamma_{a,b,c} &\stackrel{\text{def}}{=} \Pr \left(\Pr \left(\Pr(\Gamma, a, v_a), b, v_b \right), c, v_c \right) \\
&= \{p_1(A, A', B, B', C, X)(a, a', b, b', c, x)\} \cdot \\
&\quad \mathbf{call} \\
&\quad \{q_1(A, A', B, B', C, X)(a, a', b, b', c, x)\}
\end{aligned}$$

The assignment axiom can cope with an arbitrary postcondition. Hence, it is advisable, to break down the sequence of statements in reverse order. Splitting off the last procedure invocation yields

$$\{a, b, c\} \mid \Gamma_{a,b,c} \vdash_{\text{Hoare}} \{n = (b - a) + 1 \wedge a' = A' \wedge b' = B' \wedge x = X \wedge$$

$$a' = a \wedge b' = b \wedge a' < b' \wedge c = 0\}$$

Prepare;

$$a' := a; b' := c - 1$$

call

$$\{?i[b \mapsto b'] [a \mapsto c]\}$$

and

$$\{a, b, c\} \mid \Gamma_{a,b,c} \vdash_{\text{Hoare}} \{?i\} \mathbf{call} \{X_{A'} \text{Sorted}^{B'} x\} \quad (4.9)$$

where $?i$ is an intermediate assertion to be synthesised.

Ideally, $?i$ should be as weak as possible. It can be computed with the help of the rule of adaptation (3.67) applied to (4.9) and the correctness formula in the context $\Gamma_{a,b,c}$. This yields the precondition

$$\begin{aligned} & \exists A_1, A'_1, B_1, B'_1, C_1, X_1 \cdot p_1(A_1, A'_1, B_1, B'_1, C_1, X_1)(a, a', b, b', c, x) \wedge \\ & \forall a_1, a'_1, b_1, b'_1, c_1, x_1 \cdot (q_1(A_1, A'_1, B_1, B'_1, C_1, X_1)(a_1, a'_1, b_1, b'_1, c_1, x_1) \Rightarrow \\ & \qquad \qquad \qquad X_{A'} \text{Sorted}^{B'} x_1) \end{aligned}$$

The existential quantifiers are uniquely determined by the assertion p_1 . Furthermore, we can simplify q_1 because the variables a_1, a'_1, b_1, b'_1 and c_1 do not occur in the assertion $X_{A'} \text{Sorted}^{B'} x_1$. Thus, we may instantiate

$$?i = (b' - a') + 1 < n \wedge (\forall X_3 \cdot x_{A'} \text{Sorted}^{B'} X_3 \Rightarrow X_{A'} \text{Sorted}^{B'} X_3)$$

Adopting the same strategy, we remove the first recursive procedure invocation and are left with having to show

$$\{a, b, c\} \mid \Gamma_{a,b,c} \vdash_{\text{Hoare}} \{n = (b' - a') + 1 \wedge a' = A' \wedge b' = B' \wedge x = X \wedge a = a' \wedge b = b' \wedge a < b \wedge c = 0\}$$

Prepare

$$\begin{aligned} & \{((c - 1) - a') + 1 < n \wedge (b' - c) + 1 < n \wedge \\ & (\forall X_2 \cdot x_{A'} \text{Sorted}^{c-1} X_2 \Rightarrow \\ & \quad \forall X_3 \cdot X_2 \text{Sorted}^{b'} X_3 \Rightarrow X_{A'} \text{Sorted}^{B'} X_3)\} \end{aligned}$$

One could continue this strategy and push the cumulative postcondition through the Prepare fragment. Instead, we follow Reynolds's specification in which Prepare is a procedure and proceed by stepwise-refinement i.e., we employ the consequence rule (3.45) to resolve the open goal with the help of the postulated correctness of the Prepare fragment according to Lemma 4.15. We then independently establish the correctness of the partitioning for a concrete implementation.

Notice that we require the strengthened consequence rule (3.45) to exploit $n = (b' - a') + 1$, a property exclusively recorded in the *precondition* when resolving the termination guarantees $((c - 1) - a') + 1 < n$ and $(b' - c) + 1 < n$ of the *postcondition*. More precisely, modulo some trivial simplifications, our strengthened consequence rule generates the following side-condition:

$$\begin{aligned}
n = (b' - a') + 1 \wedge a' = A' \wedge b' = B' \wedge x = X \wedge a = A' \wedge b = b' \wedge a < b \Rightarrow \\
\forall c, X_1 \cdot \text{variant}_{\text{Prepare}}(X_1)(c) \Rightarrow \\
((c - 1) - a') + 1 < n \wedge (b' - c) + 1 < n \wedge \\
(\forall X_2 \cdot x \text{ }_{a'}\text{Sorted}^{c-1} X_2 \Rightarrow \forall X_3 \cdot X_2 \text{ }_c\text{Sorted}^{b'} X_3 \Rightarrow X \text{ }_{A'}\text{Sorted}^{B'} X_3)
\end{aligned}$$

The inequalities are easily resolved. The last part of the conjunction corresponds to Theorem 4.8 on page 116 in the presence of $\text{variant}_{\text{Prepare}}(X_1)(c)$.

4.3.2 Verification of the Prepare fragment

The only interesting aspect in this proof revolves around the loop. Using the sequential rule, we first split the proof obligation into

$$\begin{aligned}
E \mid \Gamma \vdash_{\text{Hoare}} \{a < b \wedge a = A \wedge b = B \wedge x = X\} \\
\quad \mathbf{if} \ x[a] > x[b] \ \mathbf{then} \ \mathbf{new} \ t := x[a] \\
\quad \quad \quad \mathbf{in} \ \mathbf{begin} \ x[a] := x[b]; \ x[b] := t \ \mathbf{end} \\
\quad \{?i_1\}
\end{aligned}$$

and

$$\begin{aligned}
E \mid \Gamma \vdash_{\text{Hoare}} \{?i_1\} \\
\quad \mathbf{new} \ r := x[a] \ \mathbf{in} \\
\quad \quad \mathbf{begin} \\
\quad \quad \quad c := a + 1; \\
\quad \quad \quad \mathbf{new} \ d := b - 1 \ \mathbf{in} \\
\quad \quad \quad \quad \mathbf{while} \ c \leq d \ \mathbf{do} \\
\quad \quad \quad \quad \quad \mathbf{if} \ x[c] \leq r \ \mathbf{then} \ c := c + 1 \ \mathbf{else} \\
\quad \quad \quad \quad \quad \quad \mathbf{if} \ x[d] > r \ \mathbf{then} \ d := d - 1 \ \mathbf{else} \\
\quad \quad \quad \quad \quad \quad \quad \mathbf{begin} \\
\quad \quad \quad \quad \quad \quad \quad \quad \mathbf{new} \ t := x[c] \\
\quad \quad \quad \quad \quad \quad \quad \quad \quad \mathbf{in} \ \mathbf{begin} \\
\quad \quad \quad \quad \quad \quad \quad \quad \quad \quad x[c] := x[d]; \ x[d] := t \\
\quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \mathbf{end}; \\
\quad \quad \quad \quad \quad \quad \quad \quad c := c + 1; \ d := d - 1 \\
\quad \quad \quad \quad \quad \quad \quad \mathbf{end} \\
\quad \quad \quad \quad \mathbf{end} \\
\quad \quad \mathbf{end}
\end{aligned}$$

end

$$\{\text{variant}_{\text{Prepare}}(x)(c) \wedge a = A \wedge b = B\}$$

where the intermediate assertion $?i_1$ is eventually uniquely determined by the loop invariant and can be synthesised, provided we employ the *left-constructive* version of the rule for dismantling blocks (3.68) which unifies

$$?i_1 = \text{uL}(?i_2, r, x[a])$$

and yields the proof obligation

$$\begin{aligned}
& E \cup \{r\} \mid \text{Pr}(\Gamma, r, v_r) \vdash_{\text{Hoare}} \{?i_2\} \\
& \quad c := a + 1; \\
& \quad \mathbf{new } d := b - 1 \mathbf{ in} \\
& \quad \quad \mathbf{while } c \leq d \mathbf{ do} \\
& \quad \quad \quad \mathbf{if } x[c] \leq r \mathbf{ then } c := c + 1 \mathbf{ else} \\
& \quad \quad \quad \quad \mathbf{if } x[d] > r \mathbf{ then } d := d - 1 \mathbf{ else} \\
& \quad \quad \quad \quad \mathbf{begin} \\
& \quad \quad \quad \quad \quad \mathbf{new } t := x[c] \\
& \quad \quad \quad \quad \quad \quad \mathbf{in begin} \\
& \quad \quad \quad \quad \quad \quad \quad x[c] := x[d]; x[d] := t \\
& \quad \quad \quad \quad \quad \quad \quad \mathbf{end;} \\
& \quad \quad \quad \quad \quad c := c + 1; d := d - 1 \\
& \quad \quad \quad \quad \mathbf{end} \\
& \quad \{ \text{variant}_{\text{Prepare}}(x)(c) \wedge a = A \wedge b = B \}
\end{aligned}$$

We employ the sequential, assignment and left-constructive rule for blocks to successively decompose the program fragment until we reach the loop. This process yields another intermediate assertion $?i_3$ such that

$$\begin{aligned}
?i_2 &= ?i_3 [c \mapsto a + 1] \\
?i_3 &= \text{uL}(\text{inv}_{\text{Prepare}}(c, d), d, b - 1)
\end{aligned}$$

and

$$\begin{aligned}
& E \cup \{r, d\} \mid \Gamma_{r,d} \vdash_{\text{Hoare}} \mathbf{while } c \leq d \mathbf{ do} \\
& \quad \quad \mathbf{if } x[c] \leq r \mathbf{ then } c := c + 1 \mathbf{ else} \\
& \quad \quad \quad \mathbf{if } x[d] > r \mathbf{ then } d := d - 1 \mathbf{ else} \\
& \quad \quad \quad \mathbf{begin} \\
& \quad \quad \quad \quad \mathbf{new } t := x[c] \\
& \quad \quad \quad \quad \quad \mathbf{in begin}
\end{aligned}$$

$$\begin{array}{c}
x[c] := x[d]; x[d] := t \\
\mathbf{end}; \\
c := c + 1; d := d - 1 \\
\mathbf{end} \\
\{\text{variant}_{\text{Prepare}}(x)(c) \wedge a = A \wedge b = B\}
\end{array}$$

with

$$\Gamma_{r,d} \stackrel{\text{def}}{=} \text{Pr}(\text{Pr}(\Gamma, r, v_r), d, v_d) .$$

Dealing with the loop, we apply the consequence rule to strengthen the postcondition to $\text{inv}_{\text{Prepare}}(c, d) \wedge \neg(c \leq d)$. Progress is achieved by extending the first segment, the second segment, or both. A suitable termination measure keeps track of the length of the intermediate segment $(d + 1) - c$. Thus, applying the rule for well-founded loops (3.44), for a constant $w : (\text{nat}, <)$, we are left with having to establish

$$\begin{array}{c}
E \cup \{r, d\} \mid \Gamma_{r,d} \vdash_{\text{Hoare}} \{\text{inv}_{\text{Prepare}}(c, d) \wedge c \leq d \wedge (d + 1) - c = w\} \\
\mathbf{if} \ x[c] \leq r \ \mathbf{then} \ c := c + 1 \ \mathbf{else} \\
\quad \mathbf{if} \ x[d] > r \ \mathbf{then} \ d := d - 1 \ \mathbf{else} \\
\quad \quad \mathbf{begin} \\
\quad \quad \quad \mathbf{new} \ t := x[c] \\
\quad \quad \quad \mathbf{in} \ \mathbf{begin} \\
\quad \quad \quad \quad x[c] := x[d]; x[d] := t \\
\quad \quad \quad \quad \mathbf{end}; \\
\quad \quad \quad \quad c := c + 1; d := d - 1 \\
\quad \quad \quad \mathbf{end} \\
\quad \quad \quad \{\text{inv}_{\text{Prepare}}(c, d) \wedge (d + 1) - c < w\}
\end{array}$$

The cases where either $x[c] \leq r$ or $x[d] > r$ are straightforward. Otherwise, we have to show

$$\begin{array}{c}
E \cup \{r, d\} \mid \Gamma_{r,d} \vdash_{\text{Hoare}} \{\text{inv}_{\text{Prepare}}(c, d) \wedge c \leq d \wedge (d + 1) - c = w \wedge \\
\quad \neg(x[c] \leq r) \wedge \neg(x[d] > r)\} \\
\mathbf{new} \ t := x[c] \\
\mathbf{in} \ \mathbf{begin} \\
\quad x[c] := x[d]; x[d] := t \\
\mathbf{end} \\
\{\text{inv}_{\text{Prepare}}(c + 1)(d - 1) \wedge ((d - 1) + 1) - (c + 1) < w\}
\end{array}$$

To complete the proof, we need to appeal once more to the rule of consequence. We could either

1. commence by applying the top-down version of the rule for blocks (3.43) and appeal to the consequence rule when dealing with the assignment $x[c] := x[d]$.
2. first apply the rule of consequence so that the left-constructive version of the rule for blocks (3.11) becomes applicable. One can then immediately resolve $x[c] := x[d]$ by the axiom for assignments.

We have pursued the first option. Given

$$\begin{aligned}
& \text{inv}_{\text{Prepare}}(c, d) \\
& c \leq d \wedge \neg(x[c] \leq r) \wedge \neg(x[d] > r) \tag{4.10} \\
& (d + 1) - c = w \\
& t = x[c]
\end{aligned}$$

we have to show

$$\begin{aligned}
& \text{inv}_{\text{Prepare}}(c + 1)(d - 1)[x \mapsto x[d \mapsto t]][x \mapsto x[c \mapsto x[d]]] \tag{Invariant} \\
& ((d - 1) + 1) - (c + 1) < w \tag{Termination}
\end{aligned}$$

Invariant Having represented arrays as functions, we need to remove redundant updates by appealing to the Lemmata 4.2 and 4.5.

Termination The premiss (4.10) is equivalent to $c < d$.

4.4 Conclusions

Much of the discussion in the above proofs has been focussed on choosing appropriate verification rules at strategic points and explaining the resulting proof obligations. Our main motivation has been to clarify the effect of the new set of rules by way of an example.

The only challenging aspect is to devise suitable invariants for loops. Furthermore, one needs to have a succinct specification of the recursive procedure. In an early proof attempt, we had forgotten to specify that array elements outside the array bounds remain invariant.

Given such invariants and specifications of recursive procedures, it is well-known that the complete verification can be automated by a VCG. This produces the same set of purely logical obligations arising from side-conditions of the consequence rule which we had to deal with after manually applying the axioms and rules of Hoare Logic.

Our proof has been unnecessarily complicated, because we have no support for parameter passing at the level of Hoare Logic. We had to introduce further global and local program variables. In particular, it caused more proof obligations involving values of the additional program variables.

LEGO's implementation of existential variables (such as $?i$) has been very helpful when applying verification rules. It allowed us to apply them without having to specify the assertions. Later in the correctness proof, LEGO synthesised these automatically.

Unfortunately, it turned out to be time consuming to prove the arising (purely logical) verification conditions in LEGO. Due to our choice of a shallow embedding of assertions, the proof tool has no syntactic guidance to reduce the resulting excessively large proof obligations³.

To check the correctness of the Quicksort algorithm, LEGO had to run for more than 37 hours requiring more than 80MB on a SUN SPARC station 20 with sufficient physical memory to avoid swapping⁴. To speed up the process, one could either employ a deep embedding of assertions, or directly guide the system to simplify proof obligations.

³See pages 222–234.

⁴In comparison, on the same architecture, the completeness proof for Hoare Logic dealing with recursive procedures and local variables could be dealt with in less than 15 minutes requiring less than 25MB. In both cases, we started LEGO in the empty environment.

Chapter 5

Conclusions and Future Work

If a verification calculus is unsound, one may derive properties of a program which do not hold. If it is incomplete, one may not be able to derive a desired property of a program despite it being satisfied. It is well known that establishing soundness and completeness for verification calculi is a challenging task. Many incorrect results based on doing proofs by hand have been published in the past.

We have taken advantage of the LEGO system to interactively derive machine-checked soundness and completeness proofs for Hoare Logic and the operation decomposition rules of the Vienna Development Method (VDM). We have dealt with parameterless recursive procedures and local variables in the context of total correctness. Previously, machine-checked completeness results had only been established for simple imperative programs without recursive procedures in a scenario of partial correctness.

With computer-aided proof systems, one attains a high-level of confidence concerning the correctness of machine-checked proofs e.g., in LEGO, less than 200 lines of SML code are responsible for checking that a given derivation is correct. Today's proof tools are sufficiently advanced to be of significant help in investigating meta-theory of verification calculi. In our opinion, soundness and completeness are difficult concepts which have to be tackled by appealing to intricate induction principles. A computer-aided proof system is very good at managing such tasks.

5.1 Syntax of Assertions

To prove completeness, one needs to be able to construct assertions which express semantic properties of the programming language. One usually simply assumes that the assertion language is sufficiently expressive. Both soundness and completeness proofs can be simplified if one does not worry about the actual syntactic representation of assertions.

A disadvantage of this approach is that examples are more difficult to read. Moreover, verifying the Quicksort algorithm, we found that the resulting proof obligations arising from the side-condition of the rule of consequence become too large for the LEGO system to efficiently process. Without syntactic structure, the proof tool has little guidance on how to reduce such proof obligations.

5.2 The Rôle of Auxiliary Variables in Hoare Logic

The required formal detail in a completely machine-checked proof encourages one to more critically analyse the theory under investigation. Often, simplifications are vital for a machine-checked development to be feasible. As our main contribution, we have illuminated the rôle of auxiliary variables in Hoare Logic. They are required to relate the value of program variables in *different* states. We felt that, in previous Hoare Logic calculi, some of the encountered difficulties arose because the rôle of auxiliary variables had not been adequately reflected in the rules.

We have followed a proposal by Apt & Meertens (1980) to interpret assertions as relations on the state space *and* a domain of auxiliary variables. Moreover, we have proposed a new consequence rule to adjust auxiliary variables while strengthening preconditions and weakening postconditions. This rule is stronger than all previously suggested structural rules, including Hoare's (1969) rule of consequence and rules of adaptation. As a direct consequence

- we were able to show that, contrary to common belief, VDM is more restrictive than Hoare Logic in that every derivation in VDM can be naturally embedded in Hoare Logic.
- We have clarified how to uniformly establish completeness as a corollary of Gorelick's (1975) Most General Formula (MGF) theorem which focusses on deriving a specific correctness formula. One may appeal to our new consequence rule to derive completeness in a single step from the MGF.
- No further structural rules are required to cater for recursive procedures.

The new approach has already been taught by Hofmann (1997) to undergraduate students as part of a course on semantics and verification.

5.3 Future Work

Following Apt (1981) and America & de Boer (1990), we have restricted our attention to a single procedure declaration without parameters. We have however proposed a new

rule to handle mutually recursive procedures which may conceivably be easier to apply than previous suggestions. Furthermore, we have sketched extensions to procedures with call-by-value parameters.

We were able to work with a simple notion of states which maps program variables to values. To extend this work to call-by-name parameters, and thus deal with aliasing, it seems advisable to consider a more elaborate mechanism for representing the state space such as an address mechanism. It would be interesting and rewarding to employ a computer-aided proof tool to investigate soundness and completeness for such verification calculi.

Appendix A

Some Remarks on Working with the LEGO System

The LEGO system was developed at the University of Edinburgh by Pollack (1994) with contributions by Claire Jones and McBride (1998). We recommend Underwood's (1997) lecture notes as an introduction to the system. LEGO implements Luo's (1994) Unifying Theory of dependent Types (UTT) which has been established as being consistent by Goguen (1994). UTT combines an extension of the Calculus of Constructions (Luo 1990) with (intensional) Martin-Löf type theory (Coquand, Nordström, Smith & von Sydow 1994). UTT has a well-established theory which consists of less than 100 rules. The algorithm which checks proof terms is relatively small. It has been programmed in SML in less than 200 lines. Thus confidence in the system is high (Pollack 1998).

In this chapter, we describe in more detail some of the peculiarities of working in type theory, with particular emphasis on the LEGO implementation. We commence with introducing the notation for term structure to clarify the outline of the scripts in the following chapter. In Sect. A.2, we introduce the system's facility for defining recursive functions. In Sect A.3, we present the encoded well-founded induction principle. Next, we explain in detail how we have encoded an equality such that one may replace terms in any type. Thus we may implement substitution on dependent functions.

A.1 Notation

Functional abstraction $\lambda x : T \cdot U$ is represented by $[x : T] U$. Its type $\prod x : T \cdot U$ is rendered as $\{x : T\} U$. If one replaces the colon with a vertical bar, LEGO attempts to synthesise the value of such implicit variables in an application (Pollack 1992).

Example A.1 (Implicit Arguments) *The `seq` constructor for sequential composition of imperative programs inhabits the type*

$\{\text{sort} \mid \text{SORT}(\text{VAR})\} \{\text{S1}, \text{S2} : \text{prog}(\text{sort})\} \text{prog}(\text{sort})$

It expects three elements, a sort and two imperative programs where program variables adhere to this sort. It returns a program with the same sort. However, the implicit argument `sort` of the compound program can be synthesised from the other arguments. In particular, the term `seq(S1) (S2)`, where `S1` and `S2` are programs of type `prog(sort)`, is well-formed.

A.2 Recursion

Recursion is restricted to higher-order *primitive* recursion. Every inductively defined type is equipped with an elimination principle which enforces that the new type is closed by its constructors.

Example A.2 *Polymorphic Lists are defined by*

```

Inductive      [list : Type -> Type]
Constructors  [nil  : {T : Type} list (T) ]
              [cons : {T | Type} T -> list (T) -> list (T) ]

```

From such a definition, LEGO generates the elimination principle

$$\frac{\prod T \cdot C(\mathbf{nil}(T)) \quad \prod T \cdot \prod x \cdot \prod xs \cdot C(xs) \rightarrow C(\mathbf{cons}(x)(xs))}{\prod T \cdot \prod z \cdot C(z)} \quad (\text{list}_{\text{elim}})$$

and the two computation rules

$$\begin{aligned} \text{list}_{\text{elim}}(C)(f)(g)(\mathbf{nil}(T)) &\triangleright_{\delta} f(T) \\ \text{list}_{\text{elim}}(C)(f)(g)(\mathbf{cons}(x)(xs)) &\triangleright_{\delta} g(x)(xs)(\text{list}_{\text{elim}}(C)(f)(g)(xs)) \end{aligned}$$

where C is a dependent function inhabiting $\prod T \mid \text{Type} \cdot \text{list}(T) \rightarrow \text{Type}$. In particular, the constant `listelim` expects as arguments a function C and descriptions of the behaviour in the base and step cases. It returns a function mapping an arbitrary list z to $C(z)$.

Consider the definition of the **append** function in the programming language SML (Paulson 1990)

```

fun append(nil)(y) = y
      |append(x::xs)(y) = x::(append(xs)(y))

```

where `::` denotes the uncurried version of **cons**. It follows a primitive-recursive pattern and one may immediately reflect its definition in LEGO by applying `listelim` to the three arguments

1. $\lambda T \cdot \lambda _ : \text{list}(T) \cdot \text{list}(T) \rightarrow \text{list}(T)$
2. $\lambda T \cdot \lambda y \cdot y$
3. $\lambda T \cdot \lambda x \cdot \lambda _ : \text{list}(T) \cdot \lambda \text{append_xs} : \text{list}(T) \rightarrow \text{list}(T) \cdot \lambda y \cdot \mathbf{cons}(x)(\text{append_xs}(y))$

A.3 Well-Founded Relations

A relation $R \subseteq T \times T$ is well-founded if, and only if, there are no infinite decreasing sequences $x_0 R^{-1} x_1 R^{-1} \dots$ e.g., $< \subseteq \text{nat} \times \text{nat}$ is well-founded, whereas $< \subseteq \text{int} \times \text{int}$ is not. Well-founded relations play an important rôle in specifying a termination measure required in proofs of termination (Dershowitz & Manna 1979). If a verification rule refers to a well-founded relation R to cater for termination, its soundness proof has to appeal to well-founded induction:

$$\frac{\forall n \cdot (\forall x \cdot x R n \Rightarrow P(x)) \Rightarrow P(n)}{\forall z \cdot P(z)} \quad (\text{WF})$$

One may consider the induction scheme as a constructive version of the definition of well-foundedness.

A.4 Equality

Representing equality in type theory is a delicate subject. In this section, we show in detail how one can set up a powerful notion of extensional equality which supports dependent substitutions. Thus, we may implement updating of dependent functions which is required to represent a model of the state space.

LEGO's tactics can be configured to work for an arbitrary equality, provided it is reflexive and substitutive. It uses these ingredients to derive, amongst other properties, a proof that the equality is also symmetric. We chose Hofmann's (1995) encoding of an extensional equality. It is based on Leibniz equality which equates two terms if they fulfil the same property:

→ p. 235  **Definition A.3 (Leibniz Equality)** $x = y \stackrel{\text{def}}{=} \forall P : T \rightarrow \text{Prop} \cdot P(x) \Rightarrow P(y)$

Leibniz equality is obviously reflexive and substitutive. Let $\text{Eq_refl}(x)$ be an abbreviation for the proof of reflexivity $\lambda P \cdot \lambda p : P(x) \cdot p$.

Substitutivity is somewhat limited. One may only replace two equal terms within a *proposition*. We therefore axiomatise¹

¹Notice that we cannot employ Eq_subst to *define* equality, because $\text{Eq_subst}(x, y)$ is a type and not a proposition.

→ p. 235  **Axiom 1 (Substitutivity)**

$$\begin{aligned} & \prod x, y : T \cdot x = y \rightarrow \prod C : T \rightarrow \text{Type} \cdot C(x) \rightarrow C(y) && (\text{Eq_subst}) \\ & \forall C : T \rightarrow \text{Type} \cdot \forall a : T \cdot \forall b : C(a) \cdot \text{Eq_subst}(a, a)(\text{Eq_refl}(a))(C)(b) = b && (\text{Eq_subst_comp}) \end{aligned}$$

The axiom `Eq_subst` allows one to substitute within a *type*. The second axiom permits removing redundant substitutions such as substituting a for a , provided that the equality $a = a$ has been established by the canonical proof of reflexivity. In practice, we also want to remove redundant substitutions if the equality has been established by other means, in particular, by appeal to an assumption. In such a scenario, it would help to assume that there is only one canonical proof of two terms being equal. We go further and adopt the stronger proof irrelevance principle stating that regarding any proposition, proofs are unique.

→ p. 236  **Axiom 2 (Proof Irrelevance)** $\forall P : \text{Prop} \cdot \forall x, y : P \cdot x = y$

With proof irrelevance, we can strengthen substitutivity to replace terms in a dependent context:

→ p. 237  **Lemma A.4 (Dependent Substitution)** *Let A be any type, B a type depending on elements of the type A , and C inhabiting $\prod a : A \cdot B(a) \rightarrow \text{Type}$. Then, for any two elements a and \hat{a} in A , given a proof p that they are propositionally equal, for any dependent term $b : B(a)$, we may replace $C(a)(b)$ by $C(\hat{a})(\text{Eq_subst}(a, \hat{a})(p)(B)(b))$.*

 **Proof** Let p be a proof of $a = \hat{a}$. We show

$$\prod b : B(a) \cdot C(\hat{a})(\text{Eq_subst}(a, \hat{a})(p)(B)(b)) \rightarrow C(a)(b)$$

by applying `Eq_subst` to the proof p and

$$\lambda a \cdot \prod p : a = \hat{a} \cdot \prod b : B(a) \cdot C(\hat{a})(\text{Eq_subst}(a, \hat{a})(p)(B)(b)) \rightarrow C(a)(b) .$$

This leaves us with having to establish

$$\prod b : B(\hat{a}) \cdot C(\hat{a})(\text{Eq_subst}(\hat{a}, \hat{a})(p')(B)(b)) \rightarrow C(\hat{a})(b)$$

where p' is a witness for $\hat{a} = \hat{a}$. Due to proof irrelevance, we may replace p' with the canonical proof `Eq_refl`(\hat{a}). Appealing to Axiom 1, the substitution collapses. \square

Finally, we assume that two (dependent) functions are equal if their input/output behaviour is identical. This is required in the soundness proof for the verification rule for blocks on page 102 to replace a function f by $f[x \mapsto t][x \mapsto f(x)]$.

→ p. 236  **Axiom 3 (Extensionality)** *Let T be a type and $C : T \rightarrow \text{Type}$ be an indexed type. Consider any dependent functions $f, g : \prod x : T \cdot C(x)$. If, for all inputs $x : T$, $f(x) = g(x)$ holds, one may conclude $f = g$.*

In his thesis, Hofmann (1995) has shown that it is consistent to assume all of these axioms.

A.5 Updating Dependent Functions

We use dependent functions to model the state space. An assignment to a variable then corresponds to updating the function. Unlike non-dependent functions, updating requires some care and we have to resort to the first two axioms to achieve the goal.

In a constructive framework, we can only effectively update a (dependent) function if equality on its domain is decidable. For the purpose of this section, let T be such a domain. We characterise that equality is decidability by relying on a concrete implementation $eq : T \times T \rightarrow \text{bool}$ such that the function eq reflects equality i.e.,

$$\forall x, y : T \cdot x = y \Leftrightarrow eq(x, y) = \mathbf{true} \quad . \quad (\text{DecSetoid}_{\text{char}})$$

Assume we have a suitable candidate for eq and let $f : \prod y : T \cdot C(y)$ be the function we want to update at position $x : T$ with $v : C(x)$ i.e. $f[x \mapsto v]$. Let y be an arbitrary element of the domain. Our task is to extract the appropriate element with type $C(y)$. We proceed by case analysis on whether x coincides with y . More precisely, we derive

$$\forall c : \text{bool} \cdot (eq(x, y) = c) \rightarrow C(y)$$

by induction on c with the help of the elimination principle

$$\frac{C : \text{bool} \rightarrow \text{Type} \quad C(\mathbf{false}) \quad C(\mathbf{true})}{\forall c : \text{bool} \cdot C(c)} \quad (\text{bool}_{\text{elim}})$$

Consider the case that $c = \mathbf{false}$. We ignore the additional input $eq(x, y) = \mathbf{false}$ and retrieve the original value $f(y)$.

The case $c = \mathbf{true}$ is more subtle, because the naïve solution v does not inhabit $C(y)$. But, in the presence of a proof of $eq(x, y) = \mathbf{true}$, eq 's characterisation lemma ($\text{DecSetoid}_{\text{char}}$) yields a proof that $x = y$ and we can use the axiom of substitutivity to coerce the type $C(y)$ to $C(x)$.

Thus, the recursion corresponds to the following elimination on booleans²:

$$\text{bool}_{\text{elim}} \left(\overbrace{(\lambda c : \text{bool} \cdot (eq(x, y) = c) \rightarrow C(y))}^{\text{need to be cut}} \right) \quad (\text{A.1})$$

$$\left(\lambda H : eq(x, y) = \mathbf{true} \cdot \underbrace{\text{Eq_subst}(x, y) (\text{snd}(\text{DecSetoid}_{\text{char}}(x, y))(H))}_{\text{coercing } v : C(x) \text{ to } C(y)} (v) \right) \quad (\text{A.2})$$

$$(\lambda _ : eq(x, y) = \mathbf{false} \cdot f(y)) \quad (\text{A.3})$$

$$(eq(x, y)) \quad (\text{A.4})$$

$$(\text{Eq_refl}(eq(x, y))) \quad (\text{A.5})$$

Expressions (A.2) and (A.3) correspond to the cases $eq(x, y)$ and $\neg eq(x, y)$, respectively. The terms (A.4) and (A.5) serve as a witness in order to cut the assumptions in term (A.1)

We can now establish the correctness of this implementation and show that both $f[x \mapsto v](x) = v$ and $f[x \mapsto v](y) = f(y)$ hold where $x \neq y$. Both proofs are easy to conduct by appealing to dependent substitution, replacing $eq(x, x)$ by **true**, and $eq(x, y)$ by **false**. We focus on the first property to clarify why ordinary substitution fails. The term $f[x \mapsto v](x)$ is obtained by replacing y with x yielding

$$\text{bool}_{\text{elim}} \left(\overbrace{(\lambda c : \text{bool} \cdot (eq(x, x) = c) \rightarrow C(x))}^{\text{need to be cut}} \right) \quad (\text{A.6})$$

$$\left(\lambda H : eq(x, x) = \mathbf{true} \cdot \underbrace{\text{Eq_subst}(x, y) (\text{snd}(\text{DecSetoid}_{\text{char}}(x, x))(H))}_{\text{coercing } v : C(x) \text{ to } C(x)} (v) \right) \quad (\text{A.7})$$

$$(\lambda _ : eq(x, x) = \mathbf{false} \cdot f(x)) \quad (\text{A.8})$$

$$(eq(x, x)) \quad (\text{A.9})$$

$$(\text{Eq_refl}(eq(x, x))) \quad (\text{A.10})$$

The substitutivity axioms are not strong enough to replace **true** for $eq(x, x)$ because, in case (A.7), the term $\text{Eq_subst}(x, y) (\text{snd}(\text{DecSetoid}_{\text{char}}(x, x))(H))$ requires an argument inhabiting the *type* $(eq(x, x) = \mathbf{true})$. Replacing $eq(x, x)$ by **true** would lead to an illegal term. As a consequence, we cannot replace $eq(x, x)$ in the term (A.6) either, for otherwise, the type of the argument (A.7) would violate the typing discipline of the

²Notice that in *extensional* type theory (Martin-Löf 1984), we may omit the coercion function $\text{Eq_subst}(x, y) (\text{snd}(\text{DecSetoid}_{\text{char}}(x, y))(H))$ because the equality reflection rule forces the identity of propositional and definitional equality. As a drawback, assuming this rule renders type-checking undecidable. We work in an *intensional* type theory. Type checking is decidable, but we cannot avoid equality bookkeeping in the constructed terms. Unfortunately, the current implementation of LEGO offers no help with this.

`boolelim` rule. Furthermore, if we were to replace $eq(x,x)$ with **true** in (A.9), the last argument must be a proof that $eq(x,x) = \mathbf{true}$, which cannot be fulfilled by a proof of reflexivity. We need dependent substitution to perform the desired substitution for the term (A.9) modifying the type of the term (A.6)–(A.8) accordingly.

Appendix B

Outline of LEGO Scripts

This appendix contains outlines of the actual LEGO scripts in which most of the proofs have been omitted. The full scripts and further modules from LEGO's library are available on-line (Lego 1998).
