

# Implementing Public-Key Infrastructure for Sensor Networks

DAVID J. MALAN, MATT WELSH, and MICHAEL D. SMITH  
Harvard University

---

We present a critical evaluation of the first known implementation of elliptic curve cryptography over  $\mathbb{F}_{2^p}$  for sensor networks based on the 8-bit, 7.3828-MHz MICA2 mote. We offer, along the way, a primer for those interested in the field of cryptography for sensor networks. We discuss, in particular, the decisions underlying our design and alternatives thereto. And we elaborate on the methodologies underlying our evaluation.

Through instrumentation of UC Berkeley's TinySec module, we argue that, although symmetric cryptography has been tractable in this domain for some time, there has remained a need, unfulfilled until recently, for an efficient, secure mechanism for distribution of secret keys among nodes. Although public-key infrastructure has been thought impractical, we show, through analysis of our original implementation for TinyOS of point multiplication on elliptic curves, that public-key infrastructure is indeed viable for TinySec keys' distribution, even on the MICA2. We demonstrate that public keys can be generated within 34 seconds and that shared secrets can be distributed among nodes in a sensor network within the same time, using just over 1 kilobyte of SRAM and 34 kilobytes of ROM. We demonstrate that communication costs are minimal, with only 2 packets required for transmission of a public key among nodes. We make available all of our source code for other researchers to download and use. And we discuss recent results based on our work that corroborate and improve upon our conclusions.

Categories and Subject Descriptors: C.2.0 [Computer-Communication Networks]: General—Security and protection; C.2.4 [Computer-Communication Networks]: Distributed Systems—Network operating systems; C.4 [Performance of Systems]:—Performance attributes; D.2.8 [Software Engineering]: Metrics—Performance measures; D.4.6 [Operating Systems]: Security and Protection—Cryptographic controls; E.3 [Data Encryption]:—Public key cryptosystems

General Terms: Algorithms, Design, Experimentation, Measurement, Performance, Security

Additional Key Words and Phrases: Diffie-Hellman, DLP, ECDLP, ECC, elliptic curve cryptography, MICA2, motes, sensor networks, TinyOS, TinySec

## 1. INTRODUCTION

Wireless sensor networks have been proposed for such applications as habitat monitoring [Cerpa et al. 2001], structural health monitoring [Kottapalli et al. 2003], emergency medical care [Malan et al. 2004a], and vehicular tracking [NEST Challenge Architecture 2002], all of which demand some combination of authentication, integrity, privacy, and security, implementation of which tends to require cryptographic primitives. Unfortunately, until recently, the state of the art in cryptography for sensor networks offered weak, if any, guarantees of these needs.

The limited resources boasted by today's sensor networks appear to render them ill-suited for the most straightforward implementations of security protocols. Consider the MICA2 mote [Crossbow Technology, Inc. 2004], designed by researchers at the University of California at Berkeley and fabricated by Crossbow Technology, Inc. Supported by Berkeley's TinyOS operating system [Hill et al. 2000] and the nesC programming language [Gay et al. 2003], this device offers an 8-bit, 7.3828-MHz ATmega 128L processor, 4 kilobytes (KB) of primary memory (SRAM), and 128 KB of program space (ROM). Such a device, given these resources, is seemingly unfit for computationally expensive or energy-intensive operations. For this reason public-key cryptography has often been ruled out for sensor networks as an infrastructure for authentication, integrity, privacy, and security [Karlof et al. 2004a, 2004b; Perrig et al. 2001, 2004], even despite its allowance for secure rekeying of mobile devices.

But such conclusions have been backed by actual data too infrequently. In fact, prior to our original work [Malan 2004b], little empirical research had been published to our knowledge, on the viability of public-key infrastructure (PKI) for the MICA2, save for a cursory analysis of an implementation of RSA [Watro 2003].

Our work has aspired to fill this void. This article in particular expands on our own prior work [Malan et al. 2004b], providing not only a primer for those interested in cryptography for sensor networks but also additional details on our own experience. Moreover, rather than present results in isolation, we expose in greater detail our motivation for various design decisions and elaborate on the methodologies underlying our evaluation.

Through instrumentation of TinyOS, we first demonstrate that symmetric cryptography is tractable on the MICA2. By way of our own implementation of multiplication of points on elliptic curves, we then argue that PKI for secret keys' distribution is, in fact, tractable as well. We do not dwell in this work on tradeoffs one might need to make in order to integrate PKI with particular applications but, rather, on whether PKI is viable at all. With elliptic curves over  $\mathbb{F}_{2^p}$ , generation of public keys requires no more than 34 seconds, and distribution of shared secrets requires no more than that, using just over 1 KB

of SRAM and 34 KB of ROM [Malan 2004b; Malan et al. 2004b]. With elliptic curves over  $\mathbb{F}_p$  (and AVR assembly), the same operations can be implemented in far less time [Gura et al. 2004]. Communication costs, meanwhile, are minimal, with only 2 packets required for transmission of a public key among nodes.

To be sure, not all sensor networks (nor their applications) require PKI, let alone any form of security. But with PKI comes capabilities that can certainly prove useful, among them the abilities to distribute symmetric keys securely and to sign messages digitally. Per Section 6, our original work on PKI for sensor networks [Malan 2004b] is now part of a growing body of literature.

We begin this article own look at PKI for sensor networks in Section 2 with an analysis of TinySec [Karlof et al. 2004b], TinyOS's existing symmetric infrastructure for the MICA2 based on SKIPJACK [National Institute of Standards and Technology 1988]. In Section 3, we address shortcomings in that infrastructure with a look at an implementation of Diffie-Hellman for the MICA2 based on the Discrete Logarithm Problem (DLP) and expose weaknesses in its design for sensor networks. In Section 4, we redress those weaknesses with our own implementation of Diffie-Hellman based on the Elliptic Curve Discrete Logarithm Problem (ECDLP), the first such implementation to our knowledge [Malan 2004b; Malan et al. 2004b]. In Section 5, we discuss optimizations underlying our implementation. In Section 6, we discuss recent work by others that corroborates and improves upon our own findings. In Section 7, we propose directions for future work. In Section 8, we conclude.

Along the way, we offer a primer for those interested in this field of cryptography for sensor networks. In particular, we discuss the decisions underlying our design and possible alternatives. We also elaborate on the methodologies underlying our evaluations of SKIPJACK and Diffie-Hellman for sensor networks. Toward this article's end, we also provide a hyperlink to all of our source code for other researchers to download and use.

## 2. SKIPJACK AND THE MICA2

TinyOS offers the MICA2 access control, authentication, integrity, and confidentiality through TinySec, a link-layer security mechanism based on SKIPJACK in cipher-block chaining mode. An 80-bit symmetric cipher, SKIPJACK is the formerly classified algorithm behind the Clipper chip, approved by the National Institute for Standards and Technology (NIST) in 1994 for the Escrowed Encryption Standard [National Institute of Standards and Technology 1994]. TinySec supports message authentication and integrity with message authentication codes, confidentiality with encryption, and access control with shared, group keys. In this section we evaluate the performance of this mechanism, as the PKI we propose in later sections for symmetric keys' distribution will assume that we have access to efficient symmetric-key primitives.

The mechanism allows for an 80-bit key space, the benefit of which is that known attacks require as many  $2^{79}$  operations on average (assuming SKIPJACK isn't reduced from 32 rounds [Biham et al. 1999]).<sup>1</sup> Moreover, as

<sup>1</sup>Although TinySec allows for 80-bit keys, its original implementation actually relied on 64-bit keys that were extended with 16 bits of padding.

Field	Length	Field	Length
Destination Address	2 B	Destination Address	2 B
Active Message Type	1 B	Active Message Type	1 B
Group ID	1 B	Data Length	1 B
Data Length	1 B	Initialization Vector	4 B
Data	29 B (max)	Encrypted Data	29 B (max)
CRC	2 B	MAC	4 B
Total	36 B	Total	41 B

(a) (b)

Fig. 1. (a) TinyOS packet format without TinySec; (b) TinyOS packet format with TinySec.

packets under TinySec include a 4-byte message authentication code (MAC), the probability of blind forgery is only  $2^{-32}$ . This security comes at a cost of just five bytes (B); whereas transmission of some 29-byte plaintext and its cyclic redundancy check (CRC) requires a packet of 36 B. Transmission of that plaintext’s ciphertext and MAC under TinySec requires a packet of only 41 B, as the mechanism borrows TinyOS’s fields for Group ID (TinyOS’s weak, default mechanism for access control) and CRC for its MAC (Figure 1).

## 2.1 Performance

The impact of TinySec on the MICA2’s performance is reasonable. To assess TinySec’s impact on packets’ transmission time and round-trip time, we implemented BenchmarksM. A MICA2 running this TinyOS module forever transmits pings with 29-byte, random payloads to another mote running the same, which echoes the same in return. Each mote measures not only the time elapsed between `SendMsg.send(·,·,·)` and `SendMsg.sendDone()`, but also that between `SendMsg.send(·,·,·)` and `ReceiveMsg.receive()`. All such measurements are logged to `TOS_UART_ADDR` for analysis by our implementation in Java of a `MessageListener` with which we determined the median, mean, standard deviation, and standard error for the MICA2’s transmission and round-trip times, without and with TinySec, over 1,000 such measurements. A link to these tools’ source code is offered toward this article’s end.

On first glance, it would appear that TinySec adds under 2 milliseconds (ms) to a packet’s transmission time (Table I) and under 5 ms to a packet’s round-trip time to and from some neighbor (Table II). However, the apparent overhead of TinySec, 1,244 microseconds ( $\mu\text{sec}$ ) on average, as suggested by transmission times, is nearly subsumed by the data’s root mean square (1,094  $\mu\text{sec}$ ). Round-trip times exhibit less variance, but more precise analysis of TinySec requires tighter benchmarks.

We thus instrumented TinyOS’s TinySecM in order to measure the time required to invoke `encrypt()` and `computeMAC()` on 29-byte, random payloads, averaged over 1,000 trials. A link to our instrumentation’s source code appears at this article’s end. Table III offers our results, which exhibit far less variance—encryption of a 29-byte, random payload requires 2,190  $\mu\text{sec}$  on average, and computation of that payload’s MAC requires 3,049  $\mu\text{sec}$  on average.

Table I. Transmission Times Required to Transmit a 29-Byte, Random Payload, Averaged Over 1000 Trials, Without and With TinySec Enabled. Transmission Time is Defined Here as the Time Elapsed Between `SendMsg.send(.,.,.)` and `SendMsg.sendDone()`. The Implied Overhead of TinySec on Transmission Time is Given as the Difference of the Data's Means. The Root Mean Square is Defined as  $\sqrt{s_{w/o}^2/1,000 + s_{w/}^2/1,000}$ , Where  $s_{w/o}$  and  $s_{w/}$  are the Data's Standard Deviations

	without TinySec	with TinySec
Median	72,904 $\mu$ sec	74,367 $\mu$ sec
Mean	74,844 $\mu$ sec	76,088 $\mu$ sec
Standard Deviation	24,248 $\mu$ sec	24,645 $\mu$ sec
Standard Error	767 $\mu$ sec	779 $\mu$ sec

Implied Overhead of TinySec	1,244 $\mu$ sec
Root Mean Square	1,094 $\mu$ sec

Table II. Round-Trip Times Required to Transmit a 29-Byte, Random Payload, Without and With TinySec Enabled, From One Node to a Neighbor and Back Again, Averaged Over 1000 Trials. More Precisely, Round-Trip Time is Defined Here as the Time Elapsed Between `SendMsg.send(.,.,.)` and `ReceiveMsg.receive()`. The Implied Overhead of TinySec on Round-Trip Time is Given as the Difference of the Data's Means. The Root Mean Square is Defined as  $\sqrt{s_{w/o}^2/1,000 + s_{w/}^2/1,000}$ , Where  $s_{w/o}$  and  $s_{w/}$  are the Data's Standard Deviations

	without TinySec	with TinySec
Median	145,059 $\mu$ sec	149,290 $\mu$ sec
Mean	147,044 $\mu$ sec	152,015 $\mu$ sec
Standard Deviation	30,736 $\mu$ sec	31,466 $\mu$ sec
Standard Error	972 $\mu$ sec	995 $\mu$ sec

Implied Overhead of TinySec	4,971 $\mu$ sec
Root Mean Square	1,391 $\mu$ sec

Table III. Times Required to Encrypt a 29-Byte, Random Payload, and to Compute that Payload's MAC, Averaged Over 1000 Trials. The Implied Overhead of TinySec is Given as the Sum of the Data's Means. The Root Mean Square is Defined as  $\sqrt{s_{w/o}^2/1,000 + s_{w/}^2/1,000}$ , Where  $s_{w/o}$  and  $s_{w/}$  are the Data's Standard Deviations

	encrypt()	computeMAC()
Median	2,189 $\mu$ sec	3,038 $\mu$ sec
Mean	2,190 $\mu$ sec	3,049 $\mu$ sec
Standard Deviation	3 $\mu$ sec	281 $\mu$ sec
Standard Error	0 $\mu$ sec	9 $\mu$ sec

Implied Overhead of TinySec	5,239 $\mu$ sec
Root Mean Square	9 $\mu$ sec

Fig. 2. Actual throughput versus desired throughput for acknowledged (ACKed) and unacknowledged (unACKed) transmissions between a sender and a receiver, averaged over ten minutes of transmission per level of desired throughput, where desired throughput is the rate at which calls to `SendMsg.send(.,.,.)` were scheduled by `Timer.start(.,.)`. ACKed actual throughput is the rate at which 29-byte, random payloads from a sender were received and subsequently acknowledged by an otherwise passive recipient. UnACKed actual throughput is the rate at which the sender actually sent such packets, acknowledged or not (*i.e.*, the rate at which calls to `SendMsg.send(.,.,.)` were actually processed). For clarity, where ACKed and unACKed throughput begin to diverge points are labelled with values for actual throughput. In environments with less contention for medium access than in ours, higher throughput is possible, without and with TinySec enabled.

Overall, TinySec adds  $5,239 \pm 18 \mu\text{sec}$  to a packet's computational requirements. It appears, then, that some of those cycles can be subsumed by delays in scheduling and medium access, at least for applications not operating at full duty. Figure 2, the results of an analysis of the MICA2's throughput, without and with TinySec enabled, puts the mechanism's computational overhead for such applications into perspective: on average, TinySec may lower throughput of acknowledged packets by only 0.28 packets per second. These results are in line with UC Berkeley's own evaluation of TinySec.<sup>2</sup>

## 2.2 Memory

Of course, TinySec's encryption and authentication does come at an additional cost in memory. To measure this cost, we utilized John Regehr's stack-tool [Regehr 2004] to determine a TinyOS module's memory usage without and with TinySec enabled. Per Table IV, TinySec adds 454 B to an application's `.bss` segment, 276 B to an application's `.data` segment, 7,076 B to an application's

<sup>2</sup>Per personal correspondence with Naveen Sastry, University of California at Berkeley.

Table IV. Memory Overhead of TinySec, Determined Through Instrumentation of CntToRfm, an Application that Simply Broadcasts a Counter's Values Over the MICA2's Radio. The .bss and .data Segments Consume SRAM While the .text Segment Consumes ROM. Stack is Defined Here as the Maximum of the Application's Stack Size During Execution

	without TinySec	with TinySec	Difference
.bss	384 B	838	454 B
.data	4 B	280 B	276 B
.text	9,220 B	16,296 B	7,076 B
stack	105 B	197 B	92 B

.text segment, and 92 B to an application's maximal stack size during execution. For applications that don't require the entirety of the MICA2's 128 KB of program memory and 4 KB of primary memory, TinySec is a viable addition.

### 2.3 Security

As with any cipher based only on shared secrets, TinySec is, of course, vulnerable to various attacks. After all, the MICA2 is intended for deployment in sensor networks. For reasons of cost and logistics, long term physical security of the devices is unlikely. Compromise of the network therefore, reduces to compromise of any one node, unless for instance, rekeying is possible. Pairwise keys among  $n$  nodes would certainly provide some defense against compromises of individual nodes. But  $n^2$  80-bit keys would more than exhaust a node's SRAM for  $n$  as small as 20. A more sparing use of secret keys is in order, but secure, dynamic establishment of those keys, particularly for networks in which the positions of sensors may be transient, requires a chain or infrastructure of trust. In fact, the very design of TinySec requires as much for rekeying as well. Though TinySec's 4-byte initialization vector (IV) allows for secure transmission of messages as many as  $2^{32}$  times, that bound may be insufficient for embedded networks whose lifespans demand longer lasting security.<sup>3</sup> Needless to say, TinySec's reliance on a single secret key prohibits the mechanism from securely rekeying itself.

Fortunately, these problems of secret keys' distribution are redressed by public-key infrastructure. The sections that follow explore options for that infrastructure's design and implementation on the MICA2.

## 3. DLP AND THE MICA2

With the utility of SKIPJACK-based TinySec thus motivated, and the mechanism's costs exposed, we next examine DLP, on which Diffie-Hellman [Diffie and Hellman 1976] is based, as an answer to the MICA2's problems of secret keys' distribution. DLP typically involves recovery of  $x \in \mathbb{Z}_p$ , given  $p$ ,  $g$ , and  $g^x \pmod{p}$ , where  $p$  is a prime integer, and  $g$  is a generator of  $\mathbb{Z}_p$ . By leveraging the presumed difficulty of DLP, Diffie-Hellman allows two parties

<sup>3</sup>To allow for secure transmission of as many as  $2^{32}$  packets, it is actually necessary to modify TinySec so that it no longer writes a mote's address into the third and fourth bytes of a mote's IV.

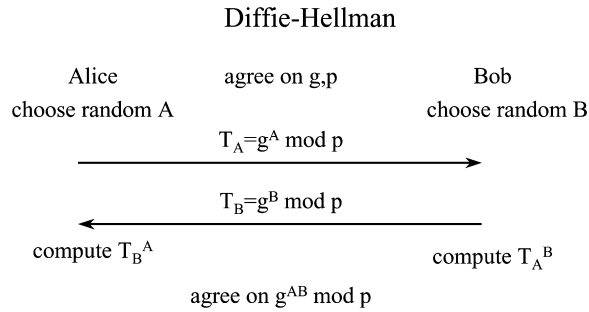

Fig. 3. Typical exchange of a shared secret under Diffie-Hellman based on DLP [Perlman 2003].

to agree, without prior arrangement, upon a shared secret, even in the midst of eavesdroppers, with perfect forward secrecy, as depicted in Figure 3. Authenticated exchanges are possible with STS [Diffie et al. 1992], a variant of Diffie-Hellman.

With a form of Diffie-Hellman, then, two nodes could thus establish a shared secret for use as TinySec’s key. At issue, though, is the cost of such establishment on the MICA2. Inasmuch as the goal at hand is distribution of 80-bit TinySec keys, any mechanism of exchange should provide at least as much security. According to NIST [National Institute of Standards and Technology 2003], the MICA2’s implementation of Diffie-Hellman should employ a modulus,  $p$ , of at least 1,024 bits and an exponent (private key),  $x$ , of at least 160 bits (Table V).

Unfortunately, on an 8-bit architecture, computations with 160-bit and 1,024-bit values are not inexpensive. However, modular exponentiation is not intractable on the MICA2. Figure 4 offers the results of our instrumentation of one implementation of Diffie-Hellman for the MICA2 by BBN Technologies. Computation of  $2^x \pmod{p}$ , where  $x$  is a pseudorandomly generated 160-bit integer and  $p$  is a 768-bit prime requires 31.0 sec on average; computation of the same, where  $p$  is a 1,024-bit prime, requires 54.9 sec. Assuming generously, that nodes sharing some key need only be rekeyed every  $2^{32}$  packets (at which time four-byte IVs are exhausted), this computation and that for  $y^x \pmod{p}$ , where  $y$  is another node’s public key, seem reasonable costs for an application’s longevity. Table VI details these operations’ memory usage, which we measured with *stacktool* [Regehr 2004].

Of course, these measurements assume operation at full duty cycle, the energy requirements of which may be unacceptable, as the MICA2’s lifetime decreases to just a few days at maximal duty cycle. To measure the cost in energy of modular exponentiation on the MICA2, we further instrumented the same implementation of Diffie-Hellman to raise and lower a general-purpose I/O pin at the start and end, respectively, of the primitive’s execution. We then measured both time and average power consumption using an oscilloscope, in order to calculate, using the frequency of the MICA2’s clock, the primitive’s total energy consumption [Shnayder et al. 2004].

Table VII reveals the MICA2’s energy consumption for modular exponentiation: computation of  $2^x \pmod{p}$  appears to require 1.185 (J).

Table V. Strength in Bits (b) of Diffie-Hellman Based on DLP for Moduli and Exponents of Various Sizes. “An Algorithm that has a ‘Y’ Bit Key, but Whose Strength is Equivalent to an ‘X’ Bit Key of Such a Symmetric Algorithm is Said to Provide ‘X Bits of Security’ or to Provide ‘X-bits of Strength.’ An Algorithm that Provides X Bits of Strength Would, on Average, Take  $2^{X-1}T$  to Attack, Where  $T$  is the Amount of Time that is Required to Perform One Encryption of a Plaintext Value and Comparison of the Result Against the Corresponding Ciphertext Value.” [National Institute of Standards and Technology 2003]

Bits of Security	Modulus	Exponent
80 b	1,024 b	160 b
112 b	2,048 b	224 b
128 b	3,072 b	256 b
192 b	7,680 b	384 b
256 b	15,360 b	512 b

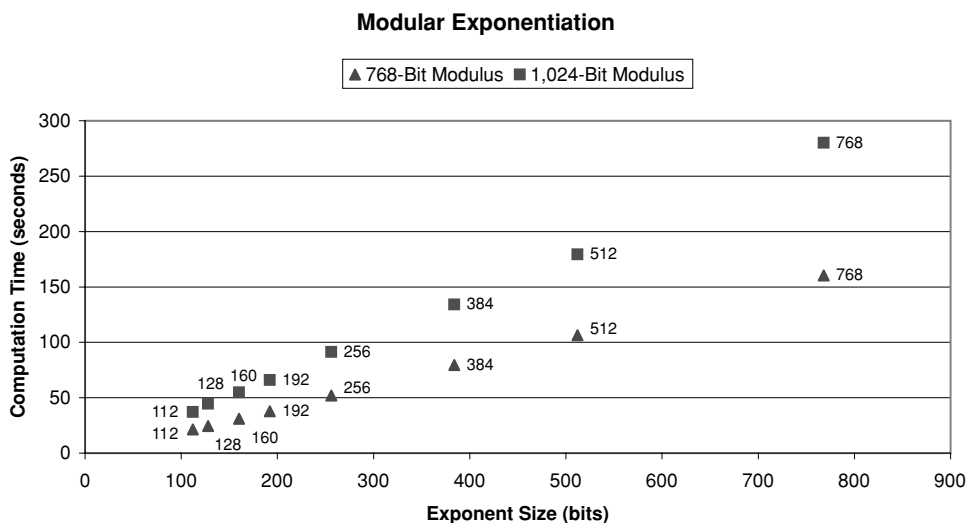

Fig. 4. Time required to compute  $2^x \pmod p$ , where  $p$  is prime, on the MICA2.

Roughly speaking, a mote could devote its lifetime to 51,945 such computations.<sup>4</sup>

Of course, the implementation could be tuned for better performance. However, its computations ultimately require not only time but also memory. Mere

<sup>4</sup>For instance, Energizer No. E91, an AA battery, offers an average capacity of 2,850 mAh [Eveready Battery Company 2004]; it follows that no more than  $2 \times 2,850 \text{ mAh} \times 3600 \text{ sec/h} \div (7.3 \text{ mA} \times 54.1144 \text{ sec}) \approx 51,945$  modular exponentiations would be possible with two AA batteries on the MICA2. Of course, this bound is generous, as the MICA2 effectively dies once voltage drops below 2 volts.

Table VI. Memory Overhead of Modular Exponentiation, Determined Through Our Instrumentation of an Implementation of Diffie-Hellman Based on DLP on the MICA2 that Computes  $2^x \pmod{p}$ , Where  $x$  is a 512-bit Integer and  $p$  is Prime. The `.bss` and `.data` Segments Consume SRAM While the `.text` Segment Consumes ROM. Stack is Defined Here as the Maximum of the Application's Stack Size During Execution

	768-Bit Modulus	1,024-Bit Modulus
<code>.bss</code>	852 B	980 B
<code>.data</code>	102 B	134 B
<code>.text</code>	11,334 B	11,350 B
<code>stack</code>	136 B	136 B

Table VII. Energy Consumption of Modular Exponentiation, Determined Through Our Instrumentation of an Implementation of Diffie-Hellman Based on DLP on the MICA2 that Computes  $2^x \pmod{p}$ , Where  $x$  is a 160-Bit Integer and  $p$  is a 1,024-Bit Prime

	1,024-Bit Modulus, 160-Bit Exponent
Total Time	54.1144 sec
Total CPU Utilization	$3.9897 \times 10^8$ cycles
Total Energy	1.185 Joules

storage of a public key requires as many bits as the modulus in use. Accordingly,  $n$  1,024-bit keys would more than exhaust a node's SRAM for  $n$  as small as 32. Although a node is unlikely to have—or, at least, need—so many neighbors or certificate authorities for whom it needs public keys, Diffie-Hellman's relatively large key sizes are unfortunate in the MICA2's resource-constrained environment. A key of this size would not even fit in a pair of TinyOS packets.

#### 4. ECDLP AND THE MICA2

With ECC, secure distribution of 80-bit TinySec keys is possible using public keys with fewer bits than 1,024; 163 bits are sufficient (Figure 5). Indeed, elliptic curves are believed to offer security computationally equivalent to that of Diffie-Hellman, based on DLP with remarkably smaller key sizes insofar as subexponential algorithms exist for DLP [Adleman 1979; Gordon 1993; LaMacchia and Odlyzko 1991; Rabin 1979], but no such algorithm is known or thought to exist for ECDLP over certain fields [Certicom Corporation 2000; Gaudry et al. 2000].

Elliptic curves offer an alternative foundation for the exchange of shared secrets among eavesdroppers with perfect forward secrecy, as depicted in Figure 6. ECDLP, on which ECC [Koblitz 1987; Miller 1986a] is based, typically involves recovery over some Galois (*i.e.*, finite) field,  $\mathbb{F}$ , of  $k \in \mathbb{F}$ , given (at least)  $k \cdot G$ ,  $G$ , and  $E$ , where  $G$  is a point on an elliptic curve,  $E$ , a smooth curve of the long Weierstrass form

$$y^2 + a_1xy + a_3y \equiv x^3 + a_2x^2 + a_4x + a_6, \quad (1)$$

Size of SKIPJACK Key	Recommended Size of ECC Private Key	
	over $\mathbb{F}_p$	over $\mathbb{F}_{2^p}$
80 b	192 b	163 b
112 b	224 b	233 b
128 b	256 b	283 b
192 b	384 b	409 b
256 b	521 b	571 b

Fig. 5. Sizes in bits (b) of private keys necessary to exchange SKIPJACK keys securely using ECC over two different fields [National Institute of Standards and Technology 1999]. With ECC over  $\mathbb{F}_{2^p}$ , 163-bit keys are sufficient for the secure exchange of 80-bit SKIPJACK keys.

Fig. 6. Typical exchange of a shared secret under Diffie-Hellman based on ECDLP.

where  $a_i \in \mathbb{F}$ . Of recent interest to cryptographers are such curves over  $\mathbb{F}_p$  and  $\mathbb{F}_{2^p}$  (Figure 7), where  $p$  is prime, as neither appears vulnerable to subexponential attack [Gaudry et al. 2000]. Though once popular, extension fields of composite degree over  $\mathbb{F}_2$  are vulnerable by reduction with Weil descent [Frey and Gangl 1998] of ECDLP to DLP over hyperelliptic curves [Gaudry et al. 2000]. But  $\mathbb{F}_{2^p}$ , a binary extension field, remains popular among implementations of ECC, especially those in hardware, as it allows for particularly space- and time-efficient algorithms. In light of its applications in coding, the field has also received more attention in the literature than those of other characteristics [Paar 1999].

It was with this history in mind that we proceeded with our implementation of ECC over  $\mathbb{F}_{2^p}$  toward the goal of smaller public keys for the MICA2.

#### 4.1 Elliptic Curves over $\mathbb{F}_{2^p}$

It turns out that, over  $\mathbb{F}_{2^p}$ , Equation 1 simplifies to

$$y^2 + xy \equiv x^3 + ax^2 + b, \quad (2)$$

where  $a, b \in \mathbb{F}_{2^p}$ , upon substitution of  $a_1^2 x + \frac{a_3}{a_1}$  for  $x$  and  $a_1^3 y + \frac{a_1^2 a_4 + a_3^2}{a_1^3}$  for  $y$ , if we consider only nonsupersingular curves, for which  $a_1 \neq 0$ . It is the set of solutions to Equation 2 and, more generally, Equation 1 (the points on  $E$ ), that actually provides the foundation for smaller public keys on the MICA2. All that remains is specification of some algebraic structure over that set. An Abelian

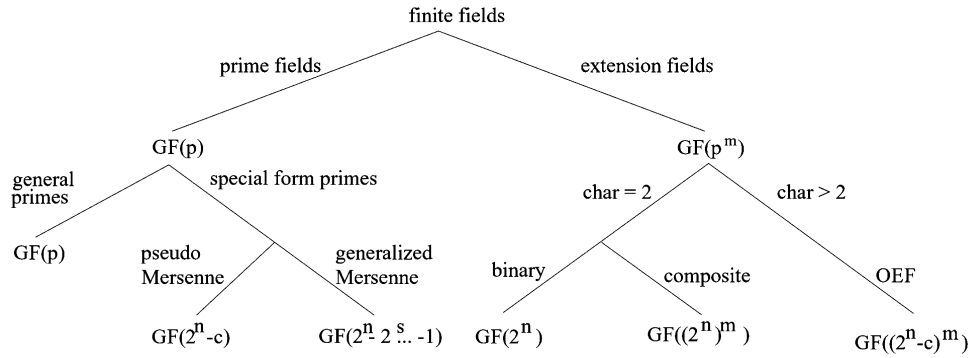

Fig. 7. Finite fields proposed for use in public-key schemes [Paar 1999]. Of recent interest to cryptographers are  $\mathbb{F}_p$  and  $\mathbb{F}_{2^p}$ , where  $p$  is prime, as neither appears vulnerable to subexponential attack [Gaudry et al. 2000].

group suffices but requires provision of some binary operator offering closure, associativity, identity, inversion, and commutativity. As suggested by ECDLP's definition, that operator is to be addition.

The addition of two points on a curve over  $\mathbb{F}_{2^p}$  is defined as

$$(x_1, y_1) + (x_2, y_2) = (x_3, y_3),$$

such that

$$(x_3, y_3) = (\lambda^2 + \lambda + x_1 + x_2 + a, \lambda(x_1 + x_3) + x_3 + y_1),$$

where

$$\lambda = (y_1 + y_2)(x_1 + x_2)^{-1}.$$

However, so that the group is Abelian, it is necessary to define a point at infinity,  $\mathcal{O}$ , whereby

$$\begin{aligned} \mathcal{O} + \mathcal{O} &= \mathcal{O}, \\ (x, y) + \mathcal{O} &= (x, y), \text{ and} \\ (x, y) + (x, -y) &= \mathcal{O}. \end{aligned}$$

Doubling of some point, meanwhile, is defined as

$$(x_1, y_1) + (x_1, y_1) = (x_3, y_3),$$

such that

$$(x_3, y_3) = (\lambda^2 + \lambda + a, x_1^2 + (\lambda + 1)x_3),$$

where

$$\lambda = x_1 + y_1 x_1^{-1},$$

provided  $x_1 \neq 0$ .

With these primitives point multiplication is also possible [Gordon 1998]. With an algebraic structure on the points of elliptic curves over  $\mathbb{F}_{2^p}$  thus defined, implementation of a cryptosystem is possible.

#### 4.2 ECC over $\mathbb{F}_{2^p}$

Implementation of ECC over  $\mathbb{F}_{2^p}$  first requires choice of a basis for points' representation, insofar as each  $a \in \mathbb{F}_{2^p}$  can be written as

$$a = \sum_{i=0}^{m-1} a_i \alpha_i,$$

where  $a_i \in \{0, 1\}$ . Thus defined,  $a$  can be represented as a binary vector,  $\{a_0, a_1, \dots, a_{p-1}\}$ , where  $\{\alpha_0, \alpha_1, \dots, \alpha_{p-1}\}$  is its basis over  $\mathbb{F}_2$ . Most common for bases over  $\mathbb{F}_2$  are polynomial bases and normal bases, though dual, triangular, and other bases exist.

When represented with a polynomial basis, each  $a \in \mathbb{F}_{2^p}$  corresponds to a binary polynomial of degree less than  $p$ , whereby

$$a = a_{p-1}x^{p-1} + a_{p-2}x^{p-2} + \dots + a_0x^0,$$

where, again,  $a_i \in \{0, 1\}$ . Accordingly, each  $a \in \mathbb{F}_{2^p}$  can be represented in the MICA2's SRAM as a bit string,  $a_{p-1}a_{p-2} \dots a_0$ . All operations on these elements are performed modulo an irreducible reduction polynomial,  $f$ , of degree  $p$  over  $\mathbb{F}_2$ , such that  $f(x) = x^p + \sum_{i=0}^{p-1} f_i x^i$ , where  $f_i \in \{0, 1\}$  for  $i \in \{0, 1, \dots, p-1\}$ . Typically, if an irreducible trinomial,  $x^p + x^k + 1$ , exists over  $\mathbb{F}_{2^p}$ , then  $f(x)$  is chosen to be that with smallest  $k$ ; if no such trinomial exists, then  $f(x)$  is chosen to be a pentanomial,  $x^p + x^{k_3} + x^{k_2} + x^{k_1} + 1$ , such that  $k_1$  is minimal,  $k_2$  is minimal given  $k_1$ , and  $k_3$  is minimal given  $k_1$  and  $k_2$  [López and Dahab 2000a].

In a polynomial basis, addition of two elements,  $a$  and  $b$ , is defined as  $a + b = c$ , where  $c_i \equiv a_i + b_i \pmod{2}$  (a sequence of XORs). Multiplication of  $a$  and  $b$ , meanwhile, is defined as  $a \cdot b = c$ , where  $c(x) \equiv (\sum_{i=0}^{p-1} a_i x^i)(\sum_{i=0}^{p-1} b_i x^i) \pmod{f(x)}$ .

We selected a polynomial basis for our implementations of point multiplication on the MICA2, as it tends to allow for more efficient implementations in software [Barwood 1997].

#### 4.3 First Implementation

Our first implementation of ECC on the MICA2 (EccM 1.0), a TinyOS module based on code by Michael Rosing [Rosing 1999] (whose *Implementing Elliptic Curve Cryptography* is a popular starting point for any implementation of ECC) ultimately reinforced prevailing wisdom: it was a failure.

EccM 1.0 first selected a random curve in the form of Equation 2, such that  $a = 0$  and  $b \in \mathbb{F}_{2^p}$ . It next selected a random point,  $G \in \mathbb{F}_{2^p} \times \mathbb{F}_{2^p}$ , from that curve as well as a random  $k \in \mathbb{F}_{2^p}$ , the node's private key. Finally, it computed  $k \cdot G$ , the node's public key.

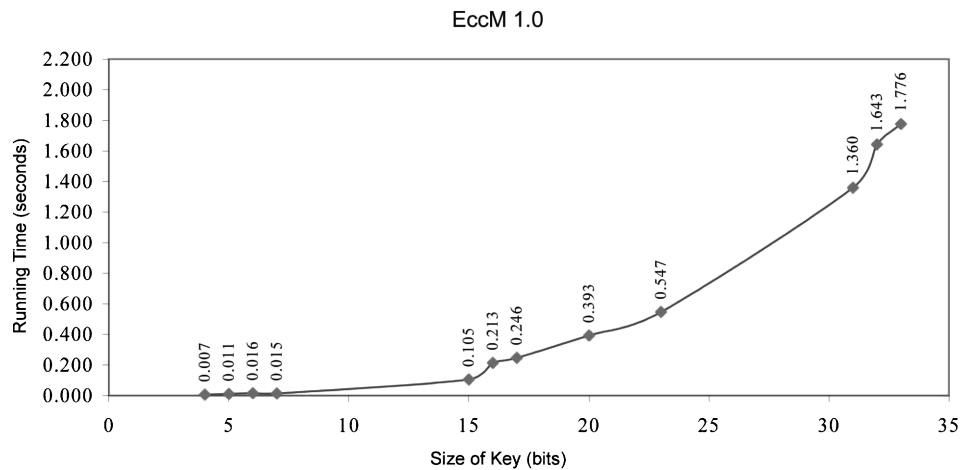

Fig. 8. Running time for EccM 1.0, a TinyOS module that selected for a node at random, using a polynomial basis over  $\mathbb{F}_{2^p}$ , a curve, a point, and a private key, thereafter computing the node's public key. Points are labelled with running times. For larger keys (*e.g.*, 63-bit), the module failed to produce results.

As in Rosing's code, this implementation employed a number of optimizations. Addition of points was implemented in accordance with Schroepel et al. [1995]; multiplication of points followed Koblitz [1992]; conversion of integers to nonadjacent form was accomplished as in Solinas [1997]. Generation of pseudorandom numbers, meanwhile, was achieved with Marsaglia [1994].

On first glance, the results (Figure 8) were encouraging, with generation of 33-bit keys requiring just 1.776 sec. (The module itself performed these measurements.) Unfortunately, for larger keys (*e.g.*, 63-bit), the module failed to produce results, instead causing the mote to reset as a result of stack overflow. Although none of the module's functions were recursive, several utilized a good deal of memory for multi-word arithmetic. Figure 9 offers the results of an analysis of EccM 1.0's usage of SRAM, determined with stacktool [Regehr 2004].

#### 4.4 Second Implementation

Since optimizations of EccM 1.0 failed to render it possible to generate even 63-bit keys an overhaul of this popular implementation proved necessary for realization of 163-bit keys. Inspired by the design of Dragongate Technologies Limited's Java-based jBorZoi 0.9 [Dragongate Technologies Limited 2003], EccM 2.0 similarly implements ECC but with far greater success. EccM 2.0 selects for a node, Alice, a private key,  $k_A$ , using a polynomial basis over  $\mathbb{F}_{2^p}$ , thereafter computing with a Koblitz curve and base point,  $G$ , Alice's public key,  $T_A$ . Alice's public key is then broadcast in two, 22-byte payloads to any node, Bob, with whom secure communication is desired. Provided Alice receives Bob's public key,  $T_B$ , from Bob in this same manner, each can compute a shared secret,  $k_A \cdot k_B \cdot G$ , where  $k_B$  is Bob's private key. If so desired, this secret could be massaged into compliance with a standard like the Elliptic Curve Key Agreement Scheme, Diffie-Hellman 1 (ECKAS-DH1) [IEEE Computer Society 2000].

Fig. 9. Primary memory used by EccM 1.0, a TinyOS module that, using a polynomial basis over  $\mathbb{F}_{2^p}$ , selected for a node at random a curve, a point, and a private key, thereafter computing the node's public key. Although the sizes of the `.bss` and `.data` segments are fixed during execution, the stack is defined here as the maximum of the application's stack size during execution. Keys of 63 bits or more exhaust the MICA2's 4,096 KB of SRAM.

In EccM 2.0, multiplication of points is achieved with Algorithm IV.1 in Blake et al. [1999], while addition of points is achieved with Algorithm 7 in López and Dahab [2000a]. Multiplication of elements in  $\mathbb{F}_{2^p}$ , meanwhile, is implemented as Algorithm 4 in López and Dahab [2000b], while inversion is implemented as Algorithm 8 in Hankerson et al. [2001].

Beyond rendering 163-bit public keys feasible, EccM 2.0 also redresses another shortcoming in EccM 1.0. Inasmuch as EccM 1.0 selects curves at random, it risks (albeit with exponentially small probability) selection of supersingular curves that are vulnerable to subexponential attack via MOV reduction [Menezes et al. 1991] with index-calculus methods [Silverman and Suzuki 1998]. EccM 2.0 thus obeys NIST's recommendation for ECC over  $\mathbb{F}_{2^p}$  [National Institute of Standards and Technology 1999], selecting, for the results

$$f(x) = x^{163} + x^7 + x^6 + x^3 + 1$$

for the reduction polynomial,

$$y^2 + xy \equiv x^3 + x^2 + 1$$

for the curve,  $E$ , the order of (*i.e.*, number of points on) which is `0x4000000000000000000020108a2e0cc0d99f8a5ef`, and, for the point  $G = (G_x, G_y)$ ,

$$G_x = 0x2fe13c0537bbc11acaa07d793de4e6d5e5c94eee8$$

and

$$G_y = 0x289070fb05d38ff58321f2e800536d538ccdaa3d9.$$

Table VIII. Memory Usage of EccM 1.0 Versus EccM 2.0. With EccM 2.0, We Obtain Significantly More Bits of Security Using a Reasonable Footprint in Memory. The .bss and .data Segments Consume SRAM While the .text Segment Consumes ROM. Stack is Defined Here as the Maximum of the Application's Stack Size During Execution. Much of the Increase of ROM's Consumption is the Result of EccM 2.0's Additional Functionality

	EccM 1.0 (32-bit key)	EccM 2.0 (163-bit key)
.bss	826 B	1,055 B
.data	6 B	4 B
.text	17,544 B	34,342 B
stack	976 B	81 B

Table IX. Energy Consumption of EccM 2.0, a TinyOS Module that Allows Two Nodes to Generate Public and Private Keys (and, Thereafter, to Use the Same to Exchange a Shared Secret), During Generation of a Node's Public and Private Keys

	Private-Key Generation	Public-Key Generation
Total Time	0.229 sec	34.161 sec
Total CPU Utilization	$1.690 \times 10^6$ cycles	$2.512 \times 10^8$ cycles
Total Energy	0.00549 Joules	0.816 Joules

Ultimately, EccM 2.0 employs much less memory than does EccM 1.0 (Table VIII), per stacktool [Regehr 2004], and its running time bests that for Diffie-Hellman based on DLP, using keys an order of magnitude smaller in size but no less secure. (The module itself measures the times required to generate keys and to generate shared secrets.) The time required to generate a private and public key pair with this module, averaged over 100 trials, is just 34.161 sec, with a standard deviation of 0.921 sec. The time required to generate a shared secret, given one's private key and another's public key, averaged over 100 trials, is 34.173 sec, with a standard deviation of 0.934 sec. In short, distribution of some shared secret using ECC over  $\mathbb{F}_{2^p}$  requires no more than a minute or so of computation per node in total. Table IX details the module's energy consumption, measured as before for Diffie-Hellman over DLP. Although such performance might prove unacceptable for some applications of PKI, it appears quite reasonable for infrequent distribution of TinySec keys. As more recent work confirms (Section 6), it is also an upper bound on the time required.

Since the release of its source code, EccM 2.0 has been incorporated into, or been a point of comparison for, a variety of projects [Arazi and Qi 2006; Blass and Zitterbart 2005; Benenson et al. 2005; Deng et al. 2006; Rochester Institute of Technology 2005; Seo et al. 2006; Wang and Li 2006]. A link to EccM 2.0's source code is offered toward the end of this article.

## 5. DISCUSSION

EccM 2.0's average running time of roughly 34 seconds for point multiplication was the result of several iterations of optimization. In fact, this module initially clocked 7.782 minutes for this computation, well beyond any reasonable bound. To be sure, we spent some cycles foolishly (*e.g.*, unnecessarily recomputing the terminal condition for some loop). But other waste was less obvious. Apparent only to us (and not to nesC's compiler), certain loops were simply better off iterating from high to low rather than from low to high, given the expected lengths of various multiprecision intermediates. Other loops proved better off once manually unrolled.

Rather than handle multiprecision bit shifts with a generalized implementation, we were able to shave seconds off the running time by special-casing the most common of shifts (namely left shifts by one bit and by two bits), albeit at a cost of a larger `.bss` segment.

Consider that for with inlining disabled, even the second version of this module induced hundreds of thousands of function calls, largely the result of the module's requirement for multiprecision arithmetic. Even the slightest of improvements in some function's performance, then, can effect significant overall gains.

Other optimizations were grounded in published, theoretical results. Using Algorithm 4 in López and Dahab [2000b] instead of Algorithm 2 in Hankerson et al. [2001], offered several seconds of improvement, as did implementation of Algorithm 7 in López and Dahab [2000a]. But the art of source-level, hand optimizations, so infrequently deployed for modern systems, proved remarkably helpful, daresay necessary, for an environment so constrained as the MICA2.

## 6. RELATED WORK

Studied by mathematicians for more than a century, elliptic curves have significant coverage in the literature and ECC has received much attention since its discovery in 1985.

Since completion of our earliest work [Malan 2004b], the viability of PKI for sensor networks has received significantly more attention. Gura et al. offer significant improvement over our earlier results using  $\mathbb{F}_p$  instead of  $\mathbb{F}_{2^p}$  [Gura et al. 2004; Wander et al. 2005]. Ning and Liu [2005] now offer TinyECC 0.1 which Wang compares to EccM 2.0 [Wang and Li 2006], while Gupta et al. [2005] offer Sizzle (ECC-based SSL), both over  $\mathbb{F}_p$  [Ning and Liu 2005]. Du et al. [2005] investigate alternatives to expensive public-key operations. Gaubatz et al. [2004] propose a hardware-assisted approach to PKI. Benenson et al. [2005] meanwhile, implement digital signatures atop EccM 2.0 Watro et al. [2004] on the other hand, explore RSA as a PKI foundation.

Though less recent, of particular relevance to our work, is Woodbury's recommendation of an optimal extension field,  $\mathbb{F}_{(2^8-17)^{17}}$ , for low-end, 8-bit processors [Woodbury 2001]. Ernst et al. [2002] propose supplementary hardware for AVR implementing operations over binary fields. Handschuh and Paillier [2000] propose cryptographic coprocessors for smart cards, whereas Woodbury et al. [2000] describe ECC for smart cards without coprocessors. Albeit for a

different target, Hasegawa et al. [1999] provide a “small and fast” implementation of ECC in software over  $\mathbb{F}_p$  for a 16-bit microcomputer. Messerges et al. [2003] call for ECC with 163-bit keys for mobile, ad hoc networks. Guajardo et al. [2001] describe an implementation of ECC for the 16-bit TI MSP430x33x family of microcontrollers. Weimerskirch et al. [2001] meanwhile, offer an implementation of ECC for Palm OS and Brown et al. [2000] offer the same for Research In Motion’s RIM pager [Brown et al. 2000].

ZigBee, on the other hand, shares this work’s aim of wireless security for sensor networks albeit not with ECC but with AES-128 [ZigBee Alliance 2004], a shared-key protocol. Meanwhile, recommendations for ECC’s parameters abound, among academics [Lenstra and Verheul 1999], among corporations [Certicom Corporation 2004], and within government [IEEE Computer Society 2000; National Institute of Standards and Technology 1999].

A number of implementations of ECC in software are freely available in languages other than nesC. Rosing [1999] offers his C-based implementation of ECC over  $\mathbb{F}_{2^p}$  with both polynomial and normal bases. ECC-LIB [Zaroliagis 2004] and pegwit [Barwood 2006] offer their own C-based implementations over  $\mathbb{F}_{2^p}$  with polynomial bases. MIRACL [Shamus Software Ltd 2004] provides the same, with an additional option for curves over  $\mathbb{F}_p$ . LibTomCrypt [Denis 2004], also in C, focuses on  $\mathbb{F}_p$ . Dragongate Technologies Limited [2003], meanwhile, offers borZoi and jBorZoi implementations of ECC over  $\mathbb{F}_{2^p}$  with polynomial bases in C++ and Java, respectively. Another implementation in C++, also using a polynomial basis over  $\mathbb{F}_{2^p}$ , is available through libecc [Wood 2004].

## 7. FUTURE WORK

Opportunities for future work certainly remain. Reduction of EccM 2.0’s ROM requirements is certainly of interest, as the module currently consumes a non-trivial amount (34 KB) of the MICA2’s 128-KB ROM. Optimizations of the module’s nesC source code might allow us to reclaim some of those bytes; reimplementing of one or more functions in AVR assembly might allow us to reclaim even more. Of course, as expectations of secure communications rise, cryptographic primitives like those in TinySec and EccM 2.0 could simply be integrated into hardware (much like Texas Instruments has done with AES in its CC2420 transceiver [Texas Instruments 2007]), thereby reserving nodes’ own resources for actual applications.

Further reduction of EccM 2.0’s running time, through source- or assembly-level enhancements, is also of interest, wherever the module happens to be housed, particularly in light of others’ recent results [Gura et al. 2004; Gupta et al. 2005; Ning and Liu 2005; Wander et al. 2005]. Use of wNAF (width nonadjacent form) or wMOF (width mutual opposite form) might also help to reduce our numbers of scalar multiplications [Okeya et al. 2004a].<sup>5</sup> Worthy of consideration for future versions of this module is a normal basis, an advantage of which would be its implementation using only ANDs, XORs, and cyclic shifts, beneficiaries of which are multiplication and squaring. (For this reason, normal bases tend to be popular in implementations of ECC in hardware.) Also of

<sup>5</sup>Personal correspondence with Seog Chung of the Gwangju Institute of Science and Technology.

value, might be a hybrid of polynomial and normal bases, which is thought to simultaneously leverage the advantages of each [Rosing 1999].

Of course, work by Gura et al. [2004] and Gupta et al. [2005] suggests that the module might offer even better performance if reimplemented over  $\mathbb{F}_p$ , especially as expensive inversions could be avoided through use of projective, as opposed to affine, coordinates. Although relatively efficient algorithms exist for modular reduction (*e.g.*, those of Montgomery [1985] or Barrett [1987]), selection of a generalized Mersene number for  $p$  would also allow modular reduction to be executed as a more efficient sequence of three additions (mod  $p$ ) [Solinas 1999]. Also of potential benefit are mixed coordinates [Cohen et al. 1998], nonadjacent form [Miller 1986b], mutual opposite form [Okeya et al. 2004b], fractional windows [Möller 2004], and signed binary representations [Kong and Li 2005; Joye and Yen 2000].

Performance aside, EccM 2.0's reliance on TinyOS's RandomLFSR module is troubling cryptographically, as this pseudo-random number generator (PRNG) relies solely upon a mote's unique ID for seeding, rather than upon any physical source of randomness. Implementation of a superior PRNG is necessary for our module's security. Truly random bits might be captured from such sources as local sensor readings, interrupt and packet-arrival times, and other physical sources.

It also remains to define the protocol according to which a module like EccM 2.0 would operate to rekey nodes. Prerequisite, for instance, will be some form of authentication, lest adversaries be able to trigger rekeyings, thereby sapping motes' energy and otherwise interfering with communication.

## 8. CONCLUSION

Despite claims to the contrary, public-key infrastructure is viable on the MICA2, certainly for infrequent distribution of shared secrets. Although our implementation of ECC in 4 KB of primary memory on this 8-bit, 7.3828-MHz device offers room for further optimization, its successors corroborate and demonstrate ECC's viability as a foundation for PKI for sensor networks.

The need for PKI's success on the MICA2 seems clear. TinySec's shared secrets do allow for efficient, secure communications among nodes. But such devices as those in sensor networks, for which physical security is unlikely, require some mechanism for secret keys' distribution.

In that it offers equivalent security at lower cost to memory and bandwidth than does Diffie-Hellman based on DLP, a public-key infrastructure for key distribution based on elliptic curves is an apt and increasingly viable choice for sensor networks.

## SOURCE CODE

Source code for EccM 2.0, BenchmarksM (plus its `MessageListener`), and our instrumented TinySecM is available for download from <http://www.eecs.harvard.edu/~malan/>.

## ACKNOWLEDGMENTS

Many thanks to Breanne Duncan, Mark Hempstead, Glenn Holloway, Michael Mitzenmacher, and Victor Shnayder of Harvard University and to David van Dyk of the University of California at Irvine for their assistance with this work.
