## Abstract

To improve the quality of *Ginkgo biloba* leaves as biological feed additives, twelve *Aspergillus niger* strains were evaluated for their growth in the moisture ginkgo leaf meal media through solid-state fermentation. The results relating to flavor, flavonoids, enzymes, crude protein, and reducing sugars showed *A. niger* Gyx086 strain was capable of efficiently fermenting ginkgo leaves. The optimal cultural conditions were three loops of spores inoculation to every 75 g medium containing 60 % water, grew at 28°C for 48 h. The Gyx086 grew well in the medium. The fermented leaves generated a strong sweet-smelling odor, could be identified by electronic nose equipment using a cluster analysis, other than the original offensive smell from non-fermented ginkgo leaves. Each gram dried culture with Gyx086 showed  $2.83 \times 10^7$  CFU of *A. niger*;  $3.19 \pm 0.37$  FPU of acid-resistant filter paper activity. Its total contents of flavonoids, reducing sugars, and crude proteins were  $19.95 \pm 0.23$  mg,  $24.28 \pm 2.35$  mg, and  $162.81 \pm 3.46$  mg in each gram of leaves, 26.03 %, 62.73 %, and 14.58 % higher than the controls, respectively. The essential amino acids and total amino acids contents were 96.41 % and 16.49 % higher than the controls.

Key words: *Aspergillus niger*; *Ginkgo biloba* leaves; Solid-state fermentation; Biological feed additive; Filter paper activity; Flavonoids

## Introduction

*Ginkgo biloba* (*G. biloba*) is a well-known functional plant that has grown on Earth for 300 million years [1]. The components of ginkgo leaves (GLs) include terpenes, polyphenols, organic acids, carbohydrates, esters, mineral salts, and amino acids, among others [2, 3]. *G. biloba* extract (EGb) contains substances with extensive biological activity, such as antioxidant [4-6], anticancer [7, 8], anti-mutation [9], and antianxiety [10, 11] effects, as well as substance that display curative outcomes for thrombus [12-14], diabetes [15], ulcers [16, 17], epilepsy [18], and Alzheimer's disease [19, 20].

With the scaling-up of ginkgo cultivation and the corresponding price decrease in recent years, the use

of GLs as a functional feed additive has expanded for improving livestock and poultry products. Ginkgo leaf powder contains some other beneficial components, such as approximately 12 % protein content, and is being used as an additive in animal feed. However, a fermentation step is necessary before being fed to animals, without fermentation, the powder has a terrible odor and a bitter taste. Nonetheless, studies have shown that EGb can help to improve both the feed conversion rate and production performance of broiler chickens [21] as well as to enhance broiler chicken immunity [22, 23]. A few animal tests have been conducted that indicated GLs fermented by *A. niger* could improve broilers' growth

performance [24], reduce the feed: gain ratio [25], improve egg quality in laying hens [26], and benefit the immune function of weaned piglets [27]. Moreover, the fermented additive can increase duodenal villous height and crypt depth of birds compared to the control of non-fermented leaves [24]. However, it is not clear why the FGLs bring better benefit than unfermented GLs and there is little literature focusing on the processing program provides suggestions for the feed production.

Solid-state fermentation (SSF) is most suitable for filamentous fungi growth under low-moisture conditions and is a cost-effective technology for the production of bioproducts [28]; thus, SSF appears appropriate for fermenting GLs with *A. niger*. Unfortunately, GLs contain significant anti-microbial components such as flavonoids and polyphenols with antibacterial or antifungal activity [29-31] that inhibits/delays the growth of microorganisms. Some additives have been supplied in the medium to support microbial growth [24-26], however, these additives raise production costs and reduce production efficiency. Therefore, it is critical to screen the strains considered for fermenting GLs: not only should the strain have a strong fermentation capacity in the GL medium, but the fermented product should also have higher feed quality [32]. The present study focused on studying *A. niger* strains in order to produce a GL bio-feed additive, using moisture GLs as the medium without any additive. Results related to fungal growth and bioproduct quality indicated that the Gyx086 strain is highly suitable for producing a GL biological feed additive.

## Materials and Methods

### *G. biloba* leaves

The *G. biloba* leaves were purchased in Pizhou City, Jiangsu Province, China. Leaves had been dried by hot air with a temperature less than 60 °C via a commercial production procedure. The dried leaves were ground into powder and sieved through a 0.71 mm screen. The dried leaves contain 8.9 % of water determined by a MA35m-00023V1 analyzer (Sartorius, Germany).

### Strains

Twelve strains of *A. niger* were used in this study. Seven of them, namely Gyx003, Gyx017, Gyx027, Gyx031, Gyx086, Gyx091, and Gyx105 were identified as *A. niger* or *A. niger var. awamori*, selected out of 76 fungal isolates originally obtained from soil samples under an ancient ginkgo tree in our previous study [32]. The other five *A. niger* strains, XA-8, XA-10, Tu-A, Tu-B, and Tu-C, were stored in our lab. These strains did not produce *ochratoxin A* toxin in

fermented ginkgo leaves (FGLs).

### Fungi amplification

Rose Bengal agar medium (Shengsi, China) was used as an amplification medium. 0.3 ml of dense conidium suspension was applied to the surface in a 10cm petri dish using sterile glass bar. The conidium suspension was prepared by washing a plate incubated for four days at 28 °C with 20.0 ml sterile water. The conidia suspension was homogenized on a vortex mixer (XW-80A, China) for 15 s before inoculation. Then the plate incubated at 28 °C for 4 days was inoculated with a metal loop of 0.5 cm diameter.

### Culture preparation and GL SSF

The leaf powder and water were mixed with a shred to water mass ratio of 5:6 in the strain screening experiment. The mixture was divided into 39 of 250 ml triangular flasks with 65 g of the mixture in each bottle, consuming about 40 % of each bottle's volume. With hydrophobic fluoropore membranes (Tianke, China) covering the bottles, the cultures were sterilized at 115 °C for 15 min. Each bottle was inoculated with three loops of mycelium and thus triplicates for each fungal strain. The flask was inverted ten times to spread the spores and was then cultivated at 26 °C for seven days. The SSF samples were freeze-dried for analysis. For the humidity ratio experiment of Gyx086, each bottle contained 30 g in dry weight (dw) of GL powder but different water ratio to ensure uniform volume in each bottle.

### Extraction and assay of flavonoids

The extraction and assay method for flavonoids was implemented according to Wang's description [32]. In brief, 10.0 g GL sample was immersed in 100 ml of 70 % (v/v) ethanol, and an optimized ultrasonic-assisted program was carried out for 45 min at 60 °C using 100 W of power at 25 kHz. After filtration, the filtrate was extracted one more time. Twice-filtered liquids were combined for determining flavonoids. Total flavonoids assay: 0.5 ml of the extract or the quercetin standard solution was mixed with 3.0 ml of methanol, 0.2 ml of 10 % aluminum chloride (distilled water in blank control), 0.2 ml of 1 M potassium acetate, and 5.6 ml of distilled water. After 30 min of incubation, the absorbance was determined at 415 nm against a distilled water blank using a UV mini-1240 spectrophotometer (Shimadzu, Japan). Triplicates for each sample and the total flavonoid content are expressed as milligrams of quercetin equivalents per gram of dry weight. The flavonol aglycone assay was carried out using the Waters HPLC 2695 System (Waters, USA) with a Waters XBridge C18 column (5 mm, 150 mm × 4.6

mm) and 2489 UA detector. The HPLC column temperature was 40 °C with a wavelength determined at 370 nm. 45 % of mobile phase A (1 % phosphoric acid solution) and 55 % of mobile phase B (methanol) were run for 30 min with a constant flow rate of 0.8 ml/min. The standards of quercetin, kaempferol, and isorhamnetin (Generay Biotech Co., Ltd., China) were used for making a standard curve.

### Filter paper activity (FPA) and reducing sugar assay

A filter paper assay was followed the Chinese National Standard GB/T 23881-2009 [33]. In brief, 5.0 g of FGLs or unfermented GLs were extracted with 100 ml of citrate buffer (0.05 mol/l, pH 5.5), mixed for 30 min at room temperature and incubated for 24 h at 4 °C. The filtered liquid was used as an enzyme sample. A 25 ml test tube with 50 mg “Shuangquan” quantitative paper (Xinhua Paper Industry Co., Ltd., China), 1.0 ml of citrate buffer, and 0.5 ml of the diluted enzyme (0.04-0.18 U/ml) was incubated at 37 °C for 60 min. The reducing sugar content was estimated using the DNS method [34]. One unit of FPA is defined as the amount of enzyme required to release 1 μmol of reducing sugar per min.

### Assessment of the quality of fermented ginkgo leaves

A weighted mean was used for evaluating the dominant strain of *A. niger* according to both to fungal growth rates and to the quality of fermented GLs. The evaluation indicator included growth rate, flavor intension, FPA, flavonoid content, protein, and reducing sugar, weighted 15 %, 20 %, 20 %, 20 %, 15 %, and 10 %, respectively. Each index was graded from one to ten points, with the unfermented GLs (the control) defined as one, the best result defined as ten, and any value less than the control as zero. The total score of each sample was the sum of all indices with the graded value multiplied by the weight and the result expressed in a hundred-mark system.

### Smell and aroma character assay

The smell experiment was carried out by a team of eight assessors using a sensory analysis ranking method [35, 36]. Briefly, each FGLs and unfermented GLs sample was marked by a three-digit number for sensory analysis. All samples were randomly placed on a white plate. The assessor smelled the odors one by one and described the features and intensity of the sample odor under the marked number. The experimental data were analyzed by a sensory analysis ranking method. For the aroma character assay, an electronic nose instrument (Alpha FOX 3000, Germany) was used to analyze the flavor

characteristics. The apparatus is equipped with 12 electronic sensors with a special probing sensibility to different kinds of chemical compounds (Table 1). 120 s of response data were collected for each sample, then a flavor radar map and cluster analysis program (PCA) were constructed and plotted by the instrumentation procedure.

**Table 1.** Sensor and sensitive volatile chemical to the sensor.

Code	Sensor name designated by Alpha M.O.S	Sensitive chemical volatile substance indicated by Alpha M.O.S
1	LY2/LG	Chlorine, fluorine, oxynitride, sulfide
2	LY2/G	Ammonia, amines, carbon oxide
3	LY2/AA	Ethanol, acetone, ammonia
4	LY2/GH	Ammonia, amines
5	LY2/gCTL	hydrogen sulfide
6	LY2/gCT	Propane, butane
7	T30/1	polar compound, hydrogen sulfide
8	P10/1	Nonpolar: hydrocarbon, ammonia, chlorine
9	P10/2	nonpolar: methane, ethane
10	P40/1	Chlorine, fluorine
11	T70/2	Methylbenzene, xylene, carbon monoxide
12	PA/2	Ethanol, ammonium hydroxide, amines

### Protein and amino acid assay

Total crude protein was assessed according to the Kjeldahl method [37] using a set of Gerhardt Kjeldahl determination devices (Buchi, Switzerland). In brief, 1.0 g of GLs with 0.15 g CuSO<sub>4</sub>, 4.5 g K<sub>2</sub>SO<sub>4</sub>, and 15.0 ml of concentrated sulfuric acid were digested in a K-438 digestive tube at 200 °C for 30 min; the temperature was then raised to 400 °C until the liquid became light green. Then using a K-350 distilling apparatus, 200 ml of liquid was collected according to instrument instructions and titrated with 0.05 mol/L hydrochloric acid solution to light red with phenolphthalein as the endpoint indicator. The usage amount of hydrochloric acid was calculated and the content of crude protein was expressed as per centum. Three duplicates for each sample were performed.

Free and total amino acids were analyzed using an S433D automatic amino acid analyzer (Sykam, Germany). In brief, extraction was carried out by boiling 2.0 g of GLs were extracted by boiling them three times for 20 min with 100 ml of 75 % ethanol solution in a 250 ml conical flask. The filtrates were combined and ethanol was removed by evaporation. The residuum was transferred into a 25 ml volumetric flask in divided doses used 0.02 mol/L hydrochloric acid solution and constant volume. The supernatant was used for analysis of free amino acids: 0.15 g GLs with 10.0 ml 6 mol/L was hydrolyzed at 110 °C for 22 h in the sealed digestion tube. After filtering, 1.0 ml of filtrate was dried under vacuum conditions and diluted appropriately for the analysis of total amino acids by the automated program.

## Gas chromatographic-mass spectrometer (GC-MS) and scanning electron microscope (SEM) assay

2.0 g GLs were placed into a 15 ml closed sample bottle; after 3 h, the volatile matter in the bottle headspace was gathered using a 57310-U solid phase microextraction needle (Sigma-Aldrich, U.S.A.) for 30 min. The GC-MS analysis was conducted using a Thermo Fisher Trace ISQ-LT instrument (U.S.A.) with a DB-5MS column (30 m × 0.25 mm × 0.25 μm). The carrier gas was helium (99.999 %), and with a constant flow of 1.0 mL/min. GC analysis conditions included an initial temperature of 40 °C for three min, first rising to 150 °C by 5 °C/min, then rising to 250 °C by 10 °C/min and waiting for five min. MS conditions included electron ionization, an interface temperature of 250 °C, electron impact at 70 eV, and a quality range of 35 ~ 450 m/z for the full scan. The NIST library was used as the mass spectrum retrieval library.

For the SEM observations, first water was removed from the sample by a freezer drying program for 48 h. The samples were then sputter-coated with gold and observed using the FEI Quanta200 SEM instrument (FEI, U.S.A.).

## Statistical analysis

Variance analysis was carried out by the one-way ANOVA program of the SAS system for Windows 8.02 (SAS Institute Inc., U.S.A.). Duncan's multiple-range test was selected as the comparison method in the program, and the significance level was set at 0.05 or 0.01. The correlation analyses were carried out by Origin 8.5 software (Origin Lab, U.S.A.) using either the linear fit or the polynomial fit program.

## Results and Discussion

### Adaptability and growth of fungi in ginkgo leaf medium

First and foremost, the selected fungal strain used for fermenting ginkgo leaves should have the strong growing ability in the GL medium. Twelve *A. niger* strains were evaluated: five from our lab and seven others separated from the ancient ginkgo tree soil in our previous work [32], including five *A. niger* and two *A. niger var. awamori* (Table 1). Eleven of the twelve strains except Gyx031 were able to survive in the ginkgo leaf medium with a 54.5 % humidity ratio, without adding any other component. The medium was used mainly for screening strong adaptability of the strain and simultaneously for inducing production inputs and enhancing throughput of the FGL product. After five days, the fungal mycelia had covered the entire medium at 26 °C; however, the

microbes grew with different speeds in the culture. The translucent mycelia of Gyx017 and Gyx086 covered the entire medium after 24 h; Gyx003, Gyx105, Gyx091, Gyx027, Tu-A, and Tu-C took 36 h; the others required over 48 h. The result indicated that ginkgo leaves supplied enough substances for the growth of all fungal strains except Gyx031, which could not survive in the medium, possibly because of sensitivity to anti-microbial medium components such as flavonoids [38] and ginkgolic acids [39]; a lack of other organisms in the medium whose coexistence facilitates survival in the soil [40]; or nutrient deficiency for that strain in the medium. In the published studies, the good growth of *A. niger* in GL medium usually required adding some additives, such as wheat bran [24], nutritive salt [24, 25, 41], maltose and peptone [27]. In this work, the medium is moisture GLs without any additive which could simplify production program and reduce cost, and the fast growth, especially Gyx017 and Gyx086, is very benefit for increasing production efficiency.

### Quality of FGL and strain assessment

To select the dominant strain, the 11 remaining *A. niger* strains were employed in fermenting GLs (Table 2). A series of quality indexes, including FPA, flavonoid content, protein, reducing sugar, and flavor were determined for each strain. Cellulase is an important additive to facilitate digestion of lignocellulose, decreasing the intestinal viscosity and increasing the nutritional value of feed [42]. The FPA reflects total cellulase activity, including endo- and exo-cellulase and β-glucosidase [43, 44]. The highest FPA value of 3.01 ± 0.19 U/g dw FGL, which was significantly higher than the others (p < 0.05), was obtained by the Gyx086 strain. Flavonoids are one of the important functional components in GLs, and comprise the major quality indexes of GLs [45]. *Aspergillus* spp. improves flavonoid extraction from GLs via solid-state fermentation more effectively than other species such as *Penicillium* spp. and *Mucor* spp. [32]. All GLs fermented by *A. niger* had a higher mean of flavonoid content than the control. Gyx017 resulted in the highest flavonoid content of 19.17 ± 0.22 mg/g dw, with the Gyx086 and Tu-A strains following. Reducing sugar is a beneficial component in the feed which can be directly absorbed in an animal's small intestine and contributes sweetness to improve GL taste. The reducing sugar content varies significantly in the GLs fermented by *A. niger*. The highest reducing sugar content, 66.2 % higher than the control, was found in the culture fermented by Gyx086. This may explain the origin of this strain's significantly high FPA value, of note because ruminant animals first digest cellulose into

monosaccharide via rumen microorganisms then absorb them in the small intestine, but mono-gastric animals cannot utilize lignocellulose [46]. Therefore the reducing sugar content is more important to monogastric animals than to ruminant animals. However, a few strains such as Gyx105 and Tu-B resulted in lower reducing sugar contents than the control. Protein is an important parameter to consider in the feed. Fungal growth increases the protein content; therefore, SSF has been used to improve the nutritional value of feed [28]. Unfermented GLs contain 14.26 % crude protein, while FGLs have relatively higher crude protein content of 16.28 %. Fungus growth increases the protein content as the partial degradation of lignocellulose raises the proportion of protein [28, 42]. FGLs' sweet smell is far preferable to the control's highly unpleasant smell. Up to now no physical equipment method can replace humans in describing the feel feature of a sample, so the GL aroma and intensity were evaluated by a group of eight assessors using a sensory analysis of ranking method [35]. The aroma intensity was greatest in the samples fermented by Gyx091 and Tu-C, with a thick, sweet aroma. Lighter sweet aromas were given out from the GLs fermented by Gyx017, Gyx086, XA-10, and Tu-A. Other samples gave out a light, sweet aroma tainted by the unpleasant nature of the GL odor. The results discussed above were all used for strain assessment.

Traditional feed additives mainly supplement deficiencies in animal nutrition such as limited amino acids, mineral elements, and vitamins [28, 47]. GLs are a raw material for functional food or medical supplementation due to the biological activities of their natural components. FGLs contain not only these original ingredients but also microorganisms and enzymes, which are mainly functional, versus nutritional, feed additive. So the biological components, namely enzymes and flavonoids, were weighted more in evaluating the quality of FGL products. The weighted mean is widely used for dealing with such complex assessments involving multiple indicators and different contributions [35]. Thus the strain assessment score was calculated by the weighted arithmetic mean [36]; Gyx086 obtained the highest score of 79.5 and was thus selected for further experimentation as shown in Table 2.

### Temperature effect on growth, enzymes, flavonoids, and reducing sugar

The temperature caused great fluctuation in fungus growth, enzyme activity, flavonoids, and sugar content during fermentation, as shown in Figure 1. Between 28 and 34 °C, the respiratory intensity did not significantly differ ( $p < 0.05$ );

however, it was significantly higher than the intensity at 25 °C, which indicated that higher temperature promoted fungal growth in the beginning. The increased white fungal mycelia were also confirmed visually. *A. niger* had lower respiratory intensity after 48 h at 25-28 °C, which revealed maturing and older mycelia. Black spores could be observed after 72 h at 34 °C and after 96 h at 31 °C, but at 120 h for 25 °C and 28 °C. Interestingly, the second germinate of *A. niger* appeared after 96 h at a temperature of 34 °C. The preferred temperature was 28-31 °C for FPA, demonstrating a higher and longer value under these temperature conditions. The content of flavonoids had a similar variation to FPA because of their positive relation and the release of flavonoids caused by cellulase decomposing cellulose in the cell wall [32, 48]. The flavonoids may have been used as a carbon source during fermentation as indicated by their gradual decrease in later stages of fermentation. During fermentation, a similar but more dramatic change was present in the content of reducing sugar in GLs. High FPA is beneficial to accumulate reducing sugar, but more is also consumed by the rapid growth of the fungus. The temperature from 28 to 31 °C is relatively favorable for fungal fermentation of GLs in terms of growth, enhancing FPA, and the content of flavonoids and reducing sugar.

**Table 2.** FPA, total flavonoids, reducing sugar, crude protein, smell and score by the weighted mean in the FGLs and the control.

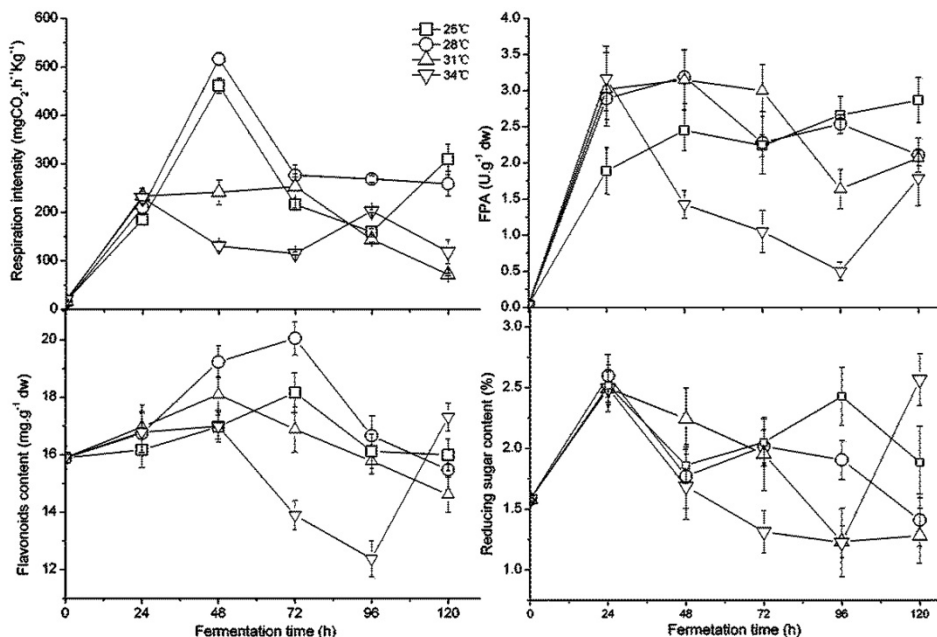

Code*	Species	FPA* (U/g dw)	Total flavonoids* (mg/g dw)	Reduci ng sugar* (%)	Crude Protein * (%)	Sweet aroma intensit y	Scor e
Control		0	15.81 ± 0.12 <sup>e</sup>	1.51 ± 0.13 <sup>e</sup>	14.26 ± 0.11 <sup>e</sup>	-	10.0

Notes: The control is an unfermented ginkgo leaves samples; the different superscript letters in each column represent significant differences of mean values by Duncan's multiple-range test with  $\alpha = 0.05$ .

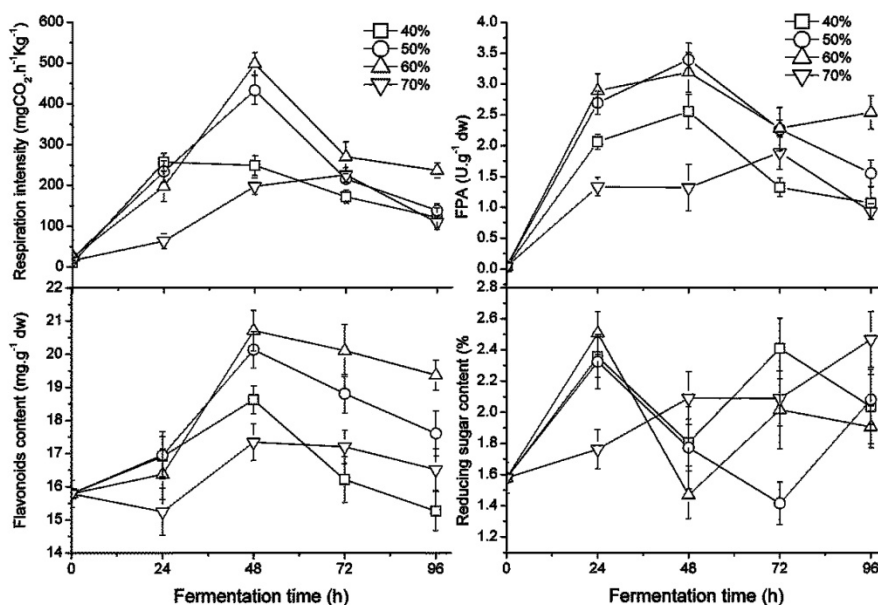

### Effect of GL humidity ratio on growth, enzymes, flavonoids, and reducing sugar

The growth of the fungus was greatly affected by the humidity ratio of the GL medium, which ranged from 40 % to 70 % as shown in Figure 2. Sequentially the FPA and the content of flavonoids and reducing sugar were also affected. The respiration intensity at 40 % and 50 % water ratios in the medium was significantly higher than at 60 % or 70 % ( $p < 0.05$ ). In particular, the white hyphae covered on the former were obviously greater than the latter, perhaps due to

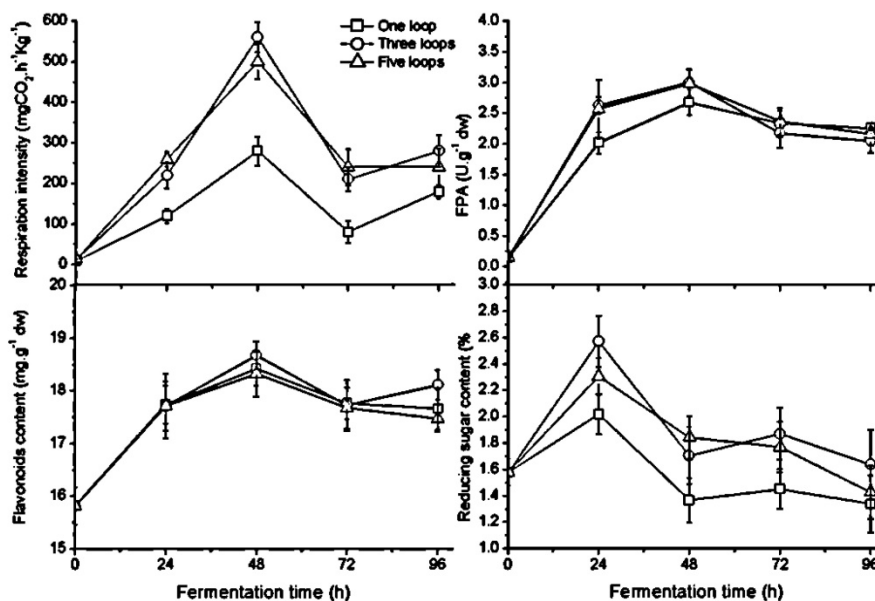

a higher air capacity. Beyond a 50 % water ratio, the highest fungal rate of respiration intensity was found in the culture with a 60 % humidity ratio. A greater humidity ratio, e.g. 70 %, reduced the oxygen in the culture, which delayed fungal growth. The FPA and flavonoid content in the medium appear to be increasing early on and later appear to decline during the fermenting period; higher values were present in the medium with 50 % - 60 % of humidity content, proving better for fungal growth, improving FPA, and releasing flavonoids.

**Figure 1.** Changes in the fungal growth, FPA, flavonoids, and reducing sugar content during fermentation by Gyx086 at temperatures from 25 °C to 34 °C with humidity 54 % by inoculating three loops of agar culture.

**Figure 2.** Changes in fungal growth, FPA, flavonoids and reducing sugar content during fermentation with different humidity ratio in GLs cultures at 28 °C by inoculating three loops of plate culture.

**Figure 3.** Changes in fungal growth, FPA, flavonoids and reducing sugar content during fermentation with different inoculum size in GLs cultures with humidity ratio of 60 % at 28 °C

Pairwise correlation analyses were carried out by the linear fit or the polynomial fit program of Origin 8.5. There was not always a correlation between two factors. A linear positive correlation only appeared between growth and FPA in the culture of 40 % or 50 %, with an adj. R-square of 0.928 for the former ( $p < 0.01$ ) and 0.862 for the later ( $p < 0.05$ ). A polynomial correlation presented between FPA and flavonoid content in the 40 % culture, with an adj. R-square of 0.907 ( $p < 0.05$ ). Reducing sugar content had no linear correlation with other factors. It was difficult to establish a model among these factors, likely because SSF is a complicated, heterogeneous system that includes multiple phases of mass transfer among gas-liquid, gas-solid, and liquid-solid [49]. Therefore there is great non-uniformity in many aspects, such as fungi distribution, median temperature and humidity, and secreted metabolic products and substrate content with degradation, which prevents confirmation of the relevancy among factors.

### Effect of inoculum size on growth, enzymes, flavonoids, and reducing sugar

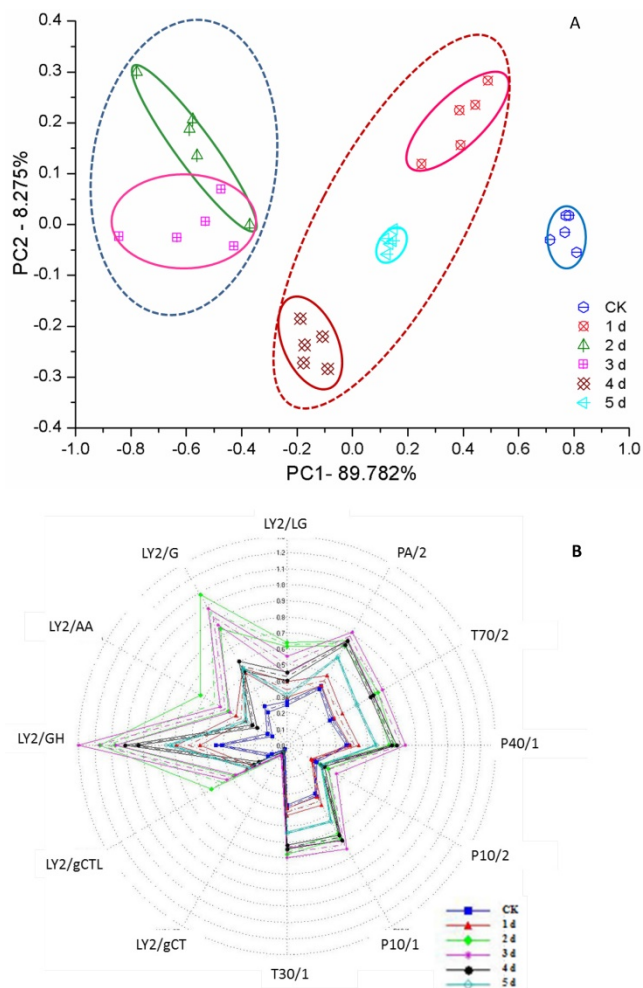

Unlike the temperature and the humidity ratio, the inoculum size doesn't affect fermentation progress. Fungal growth, FPA, flavonoids, and reducing sugar demonstrated a similar change pattern with different inoculum sizes during fermentation (Figure 3). A significantly higher respiration rate appeared in the culture inoculating three and five loops of *A. niger* compared to a single loop ( $p < 0.05$ ). The respiratory crest of the polygonal line appears at 48 h in all three cultures and subsequently declines,

indicating the aging mycelium with black sporangia observed in the medium at 72 h. The FPA and sugar content have uniform peak times compared to the growth peak but have small differences among the three different inoculum sizes. FPA is not significantly different in the culture of one loop versus the other two in the later stage of fermentation; the values of flavonoid content were no different during the period of 72 h fermentation. Three and five loops of inoculum size gave rise to relatively higher sugar content than one loop did; there was no significant difference between the two during fermentation. Thus according to respiration rate, the results suggested that one loop of inoculum size was too little and three loops were sufficient for each bottle with 65 grams of GL medium.

### Aroma of GL fermented by Gyx086

Voluntary intake studies have been used to form indices of forage quality and have found that adding flavor into feed leads to an increase in animal weight gain [50, 51]. However, unfermented GLs have a very unpleasant odor, denoted ginkgo leaf odor (GLO). With active enzyme systems, fermentation usually changes the flavor of food or feed [52]. All fermented ginkgo leaves gave off a pleasantly fragrant and sweet odor during mycelium growth according to nose sniffing, but delayed fermentation was disadvantageous to the improved aroma, which was subsequently slowly reduced and even lost when fungal spores formed. This flavor features unfermented and fermented GLs could be determined by the e-nose and clearly distinguished by the PCA

from days 0 to 5 (Figure 4A). Three regions can be determined: the left region including the 2<sup>nd</sup> and 3<sup>rd</sup> days shows an excellent, sweet aroma; the middle region including the 1<sup>st</sup>, 4<sup>th</sup> and 5<sup>th</sup> days shows a light, sweet aroma accompanied by the slight unpleasant odor of GLs; and the unfermented GLs have GLO but no sweet aroma. Furthermore, a few fungi belonging to *Penicillium* spp. and *Mucor* spp. were also used to ferment ginkgo leaves and presented a consistent PCA result, supporting the use of PCA for assessing the aroma character and quality of FGLs.

**Figure 4.** PCA (A) and radar (B) map of smell analysis of unfermented and fermented ginkgo leaves by the electrical nose

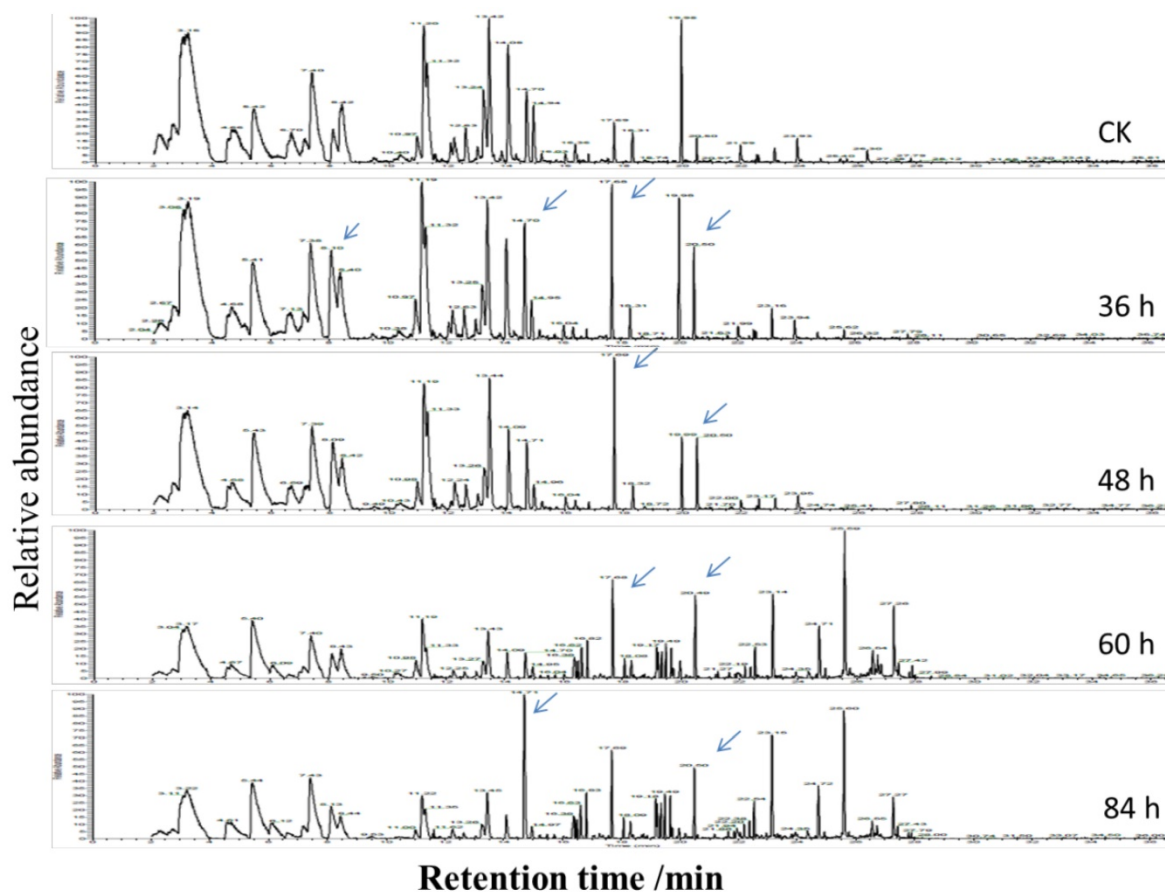

To investigate volatile matter compounds, various sensors' electric signal strengths were plotted as a radar map. As shown in Figure 4B, all FGLs demonstrated relatively higher response values on the sensors than the unfermented GLs. The sensor for LY2/G and LY2/GH compounds, which is also very sensitive to small molecules of ammonia, amines, and carbon oxide, showed a particularly strong signal for the 2<sup>nd</sup> and 3<sup>rd</sup>-day samples, suggesting that the sweet aroma likely originates from these compounds.

GC-MS analysis usually helps to identify volatile compounds [53-55], and the chromatogram of GC-MS showed component variations after fermenting GLs (Figure 5). However, according to GC-MS analysis, there were fewer than five compounds from each sample that could be identified using the NIST standard reference.

### Appropriate conditions for fermenting GLs using Gyx086

The quality of FGLs was determined according to a multi-index, including sensory index, functional components, enzymes, and nutritive index. These, in turn, were determined by fermenting conditions including temperature, water ratio, inoculum size, and fermentation time in natural pH conditions. However, the mathematical system of multiple independent and dependent variables is very complex, and there was a time difference between high FPA and high flavonoid content results; thus, it was very difficult to find a model for optimizing fermentation conditions. This study split the difference among FGL quality indices according to the above progressive single factor experiments. From the temperature experiment, 28 °C was selected as the optimal fermentation temperature based the higher level of FPA and flavonoids. At this temperature, the humidity ratio of 60 % is beneficial for higher growth, FPA, and flavonoids. When fermenting at 28 °C with 60 % water to GL ratio, the inoculum size experiment indicated that three loops of spores for every 30 g of GLs (dw) is appropriate. Fermentation time is most difficult to confirm because the best fermentation times are different for FPA (< 48 h) and flavonoids (> 48 h), as shown when comparing Figures 1 - 3. This time asynchronization derives from the causality between enzymes and flavonoids. The cellulosic degradation by cellulase enzymes accelerates flavonoid release from GL cells [56]; thus, a higher FPA is usually followed by relatively high flavonoid content in this study. In our previous study, the optimized time for flavonoid extraction from GLs was 61 h with a water ratio of 64.2 % in the culture and fermentation at 27.8 °C [32]. Notably, this time is different from that of high FPA. FPA and flavonoids were equally weighted in terms of biological functionality of the GL feed additive. A balanced time for fermentation was thus selected as 48 h. The optimal fermentation conditions for temperature, humidity ratio, inoculum size, and fermentation time are  $28 \pm 0.5$  °C,  $60 \pm 1$  %, 3 loops for 30 g (dw) medium, and 48 h, respectively. Under these conditions, the quality indices of FGLs were further investigated.

**Figure 5.** The chromatogram of GC-MS of the volatile compounds of unfermented and fermented ginkgo leaves. The significant changes of component peaks are directed by the arrows.

### Small-scale production test of fermented GLs by Gyx086

Based on the fermentation conditions established above, a small-scale production test of 15 kg of GLs was carried out; 12.25 kg of FGLs were harvested, and the physical, chemical and biological qualities were investigated (Figure 6 and Table 3). Figure 6 shows that the biomass of GL tissue was partly degraded and consumed after fermentation, which is likely responsible for the lost weight. The FGL product was smaller and more malleable than unfermented GLs, which is advantageous for the additives to be scattered into feed materials. The extracellular cellulase activity of exo- and endo- cellulase and  $\beta$ -glucosidase was  $0.13 \pm 0.01$ ,  $5.11 \pm 0.29$ , and  $8.36 \pm 0.33$  U/g dw, respectively (Table 3). The total cellulase activity, FPA, was  $3.19 \pm 0.37$  U/g dw; the cellulase had excellent acid resistance in a lower pH of 2.0 in our other study of enzyme characteristics (data not yet published). The feed additive of cellulase can eliminate anti-nutritional factors, supply animals' own digestive enzymes and improve the feed utilization for mono-gastric or ruminant animals [42]. This is the likely reason that the feed/gain ratio of

broiler chicks is significantly higher by intake FGLs than un-FGLs [24, 25]. The total flavonoid content is  $19.95 \pm 0.23$  mg per gram dry FGLs, which is 26 % higher than unfermented GLs, and also greatly higher than the previous studies [24, 26]. Broken cell walls (Figure 6) can improve flavonoid extraction by an enzyme or microbial pretreatment [32, 56]. The main aglycone flavonoids in GLs are quercetin, kaempferol, and isorhamnetin, but the content of these three aglycones was less than 0.1 %, indicating that flavonoids mainly exist as glycosides [32], which are more advantageous for absorption in the intestinal tract [56]. Flavonoids are likely the main factor helping improve animal's intestinal and immune function [24, 27]. Reducing sugar and organic acids (pH 3.54) can supply sweet and sour flavors to improve FGL taste and enhance feed intake [28, 35, 50]. Fermentation is very beneficial for improving GL aroma; the unpleasant odor of unfermented GLs was eliminated during fermentation, and FGLs demonstrated a pleasant, thick, sweet-smelling odor. This is an expressly desired change brought about by the fermenting process for feed and food [52]. The CFU amount of *A. niger* was  $2.83 \times 10^9$  per gram dried FGL. *A. niger*, including its secreted enzyme, has already

been accepted since 1972 by FAO/WHO experts, and the FDA has considered *A. niger* to be “generally regarded as safe” (GRAS) [57]. This fungus is currently listed under direct-fed microbes (DFMS) by China and U.S.A. Furthermore, the GLs fermented by *A. niger* and used for feed additive has been certified as safe in our previous studies [24-26, 41]. However, further research is needed to determine if the benefit of the feed additive is mainly contributed by *A. niger* or flavonoids. The crude protein content is also significantly higher in FGLs than in unfermented GLs, at 14.5 % above the control, but the balance of amino acids is more important for animal nutrition [47].

**Figure 6.** SEM of unfermented GLs and FGLs (a) unfermented GLs 100×, (b) unfermented GLs 2400×, (c) FGLs 100×, (d) FGLs 2400×.

### Amino acids of GLs fermented by Gyx086

Animal feed requires certain crude protein levels to meet animal production performance, particularly for non-ruminants due to their unavailability of inorganic-N [28, 47]. Moreover, the efficiency of utilization of protein depends on digestible essential amino acids [47]; thus the content and composition of amino acids is an important factor for animal feed. The amount of free and total amino acids in the GLs fermented by Gyx086 were 14.77 and 95.07 mg per gram, respectively, (Table 4) which was 96.41 % and 16.49 % higher than the control, respectively. These results indicated that fermentation processing enhanced GL amino acid content, particularly free amino acids that are more beneficial for animal absorption. The total aromatic amino acids, isoleucine and valine, were plentiful with content more than 62.6 mg ( only Phe. and Tyr. ), 31 mg, and 39 mg per gram crude protein, respectively, compared to minimum requirements of 63 mg, 28 mg, and 35 mg per gram

crude protein, respectively [58]. On the other hand, leucine, lysine, threonine, and total sulfur amino acid results are less than the required 66 mg, 58 mg, 63 mg, and 25 mg per gram crude protein in GLs, with the FGLs demonstrating a smaller gap than the control (Table 4).

**Table 3.** Cellulase activities, flavonoids, flavonoid aglycone, crude protein and *A. niger* in the FGLs fermented by Gyx086 with water ratio 60 % at 28 ± 0.5 °C for 48 h.

	Control	FGLs		Control	FGLs
FPA (U/g dw)	0	3.19 ± 0.37	Isorhamnetin (µg/g dw)	1.82 ± 0.25	2.57 ± 0.41*

Note: \* α = 0.05, \*\* α = 0.01, significantly higher than unfermented GLs; The bold type mark for essential amino acid; <sup>#</sup> FAO/WHO/UNU amino acid requirement pattern based on amino acid requirements of preschool-age child [58], moreover, the total sulfur amino acids and total aromatic amino acids are 25 and 63.

Animals not only have dietary requirements for essential amino acids but also need nutritionally nonessential amino acids to achieve maximum growth and production performance [59]. Therefore increasing nonessential amino acids is very important and beneficial for animals. In addition to the myriad other benefits, almost all of the total nonessential amino acid content was also improved through GL fermentation by the Gyx086 strain.

## Abbreviations
