We examine how differences in language models, learned by different data-driven systems performing the same NLP task, can be exploited to yield a higher accuracy than the best individual system. We do this by means of experiments involving the task of morphosyntactic word class tagging, on the basis of three different tagged corpora. Four well-known tagger generators (hidden Markov model, memory-based, transformation rules, and maximum entropy) are trained on the same corpus data. After comparison, their outputs are combined using several voting strategies and second-stage classifiers. All combination taggers outperform their best component. The reduction in error rate varies with the material in question, but can be as high as 24.3% with the LOB corpus.

1. Introduction

In all natural language processing (NLP) systems, we find one or more language models that are used to predict, classify, or interpret language-related observations. Because most real-world NLP tasks require something that approaches full language understanding in order to be perfect, but automatic systems only have access to limited (and often superficial) information, as well as limited resources for reasoning with that information, such language models tend to make errors when the system is tested on new material. The engineering task in NLP is to design systems that make as few errors as possible with as little effort as possible. Common ways to reduce the error rate are to devise better representations of the problem, to spend more time on encoding language knowledge (in the case of hand-crafted systems), or to find more training data (in the case of data-driven systems). However, given limited resources, these options are not always available.

Rather than devising a new representation for our task, in this paper, we combine different systems employing known representations. The observation that suggests this approach is that systems that are designed differently, either because they use a different formalism or because they contain different knowledge, will typically produce different errors. We hope to make use of this fact and reduce the number of errors with

very little additional effort by exploiting the disagreement between different language models. Although the approach is applicable to any type of language model, we focus on the case of statistical disambiguators that are trained on annotated corpora. The examples of the task that are present in the corpus and its annotation are fed into a learning algorithm, which induces a model of the desired input-output mapping in the form of a **classifier**. We use a number of different learning algorithms simultaneously on the same training corpus. Each type of learning method brings its own "inductive bias" to the task and will produce a classifier with slightly different characteristics, so that different methods will tend to produce different errors.

We investigate two ways of exploiting these differences. First, we make use of the **gang effect**. Simply by using more than one classifier, and voting between their outputs, we expect to eliminate the quirks, and hence errors, that are due to the bias of one particular learner. However, there is also a way to make better use of the differences: we can create an **arbiter effect**. We can train a second-level classifier to select its output on the basis of the patterns of co-occurrence of the outputs of the various classifiers. In this way, we not only counter the bias of each component, but actually exploit it in the identification of the correct output. This method even admits the possibility of correcting collective errors. The hypothesis is that both types of approaches can yield a more accurate model from the same training data than the most accurate component of the combination, and that given enough training data the arbiter type of method will be able to outperform the gang type.[1]

In the machine learning literature there has been much interest recently in the theoretical aspects of classifier combination, both of the gang effect type and of the arbiter type (see Section 2). In general, it has been shown that, when the errors are uncorrelated to a sufficient degree, the resulting combined classifier will often perform better than any of the individual systems. In this paper we wish to take a more empirical approach and examine whether these methods result in substantial accuracy improvements in a situation typical for statistical NLP, namely, learning morphosyntactic word class tagging (also known as part-of-speech or POS tagging) from an annotated corpus of several hundred thousand words.

Morphosyntactic word class tagging entails the classification (tagging) of each token of a natural language text in terms of an element of a finite palette (**tagset**) of word class descriptors (**tags**). The reasons for this choice of task are several. First of all, tagging is a widely researched and well-understood task (see van Halteren [1999]). Second, current performance levels on this task still leave room for improvement: "state-of-the-art" performance for data-driven automatic word class taggers on the usual type of material (e.g., tagging English text with single tags from a low-detail tagset) is at 96–97% correctly tagged words, but accuracy levels for specific classes of ambiguous words are much lower. Finally, a number of rather different methods that automatically generate a fully functional tagging system from annotated text are available off-the-shelf. First experiments (van Halteren, Zavrel, and Daelemans 1998; Brill and Wu 1998) demonstrated the basic validity of the approach for tagging, with the error rate of the best combiner being 19.1% lower than that of the best individual tagger (van Halteren, Zavrel, and Daelemans 1998). However, these experiments were restricted to a single language, a single tagset and, more importantly, a limited amount of training data for the combiners. This led us to perform further, more extensive,

1 In previous work (van Halteren, Zavrel, and Daelemans 1998), we were unable to confirm the latter half of the hypothesis unequivocally. As we judged this to be due to insufficient training data for proper training of the second-level classifiers, we greatly increase the amount of training data in the present work through the use of cross-validation.

tagging experiments before moving on to other tasks. Since then the method has also been applied to other NLP tasks with good results (see Section 6).

In the remaining sections, we first introduce classifier combination on the basis of previous work in the machine learning literature and present the combination methods we use in our experiments (Section 2). Then we explain our experimental setup (Section 3), also describing the corpora (3.1) and tagger generators (3.2) used in the experiments. In Section 4, we go on to report the overall results of the experiments, starting with a comparison between the component taggers (and hence between the underlying tagger generators) and continuing with a comparison of the combination methods. The results are examined in more detail in Section 5, where we discuss such aspects as accuracy on specific words or tags, the influence of inconsistent training data, training set size, the contribution of individual component taggers, and tagset granularity. In Section 6, we discuss the results in the light of related work, after which we conclude (Section 7) with a summary of the most important observations and interesting directions for future research.

2. Combination Methods

In recent years there has been an explosion of research in machine learning on finding ways to improve the accuracy of supervised classifier learning methods. An important finding is that a set of classifiers whose individual decisions are combined in some way (an **ensemble**) can be more accurate than any of its component classifiers if the errors of the individual classifiers are sufficiently uncorrelated (see Dietterich [1997], Chan, Stolfo, and Wolpert [1999] for overviews). There are several ways in which an ensemble can be created, both in the selection of the individual classifiers and in the way they are combined.

One way to create multiple classifiers is to use subsamples of the training examples. In **bagging**, the training set for each individual classifier is created by randomly drawing training examples with replacement from the initial training set (Breiman 1996a). In **boosting**, the errors made by a classifier learned from a training set are used to construct a new training set in which the misclassified examples get more weight. By sequentially performing this operation, an ensemble is constructed (e.g., ADABOOST, [Freund and Schapire 1996]). This class of methods is also called **arcing** (for adaptive resampling and combining). In general, boosting obtains better results than bagging, except when the data is noisy (Dietterich 1997). Another way to create multiple classifiers is to train classifiers on different sources of information about the task by giving them access to different subsets of the available input features (Cherkauer 1996). Still other ways are to represent the output classes as bit strings where each bit is predicted by a different component classifier (error correcting output coding [Dietterich and Bakiri 1995]) or to develop learning-method-specific methods for ensuring (random) variation in the way the different classifiers of an ensemble are constructed (Dietterich 1997).

In this paper we take a multistrategy approach, in which an ensemble is constructed by classifiers resulting from training different learning methods on the same data (see also Alpaydin [1998]).

Methods to combine the outputs of component classifiers in an ensemble include **simple voting** where each component classifier gets an equal vote, and **weighted voting**, in which each component classifier's vote is weighted by its accuracy (see, for example, Golding and Roth [1999]). More sophisticated weighting methods have been designed as well. Ali and Pazzani (1996) apply the Naive Bayes' algorithm to learn weights for classifiers. Voting methods lead to the gang effect discussed earlier. The

Let T_i be the component taggers, $S_i(tok)$ the most probable tag for a token *tok* as suggested by T_i, and let the quality of tagger T_i be measured by

- the precision of T_i for tag *tag*: $Prec(T_i, tag)$
- the recall of T_i for tag *tag*: $Rec(T_i, tag)$
- the overall precision of T_i: $Prec(T_i)$

Then the vote $V(tag, tok)$ for tagging token *tok* with tag *tag* is given by:

- **Majority:**
$$\sum_i IF \;\; S_i(tok) = tag \;\; THEN \;\; 1 \;\; ELSE \;\; 0$$
- **TotPrecision:**
$$\sum_i IF \;\; S_i(tok) = tag \;\; THEN \;\; Prec(T_i) \;\; ELSE \;\; 0$$
- **TagPrecision:**
$$\sum_i IF \;\; S_i(tok) = tag \;\; THEN \;\; Prec(T_i, tag) \;\; ELSE \;\; 0$$
- **Precision-Recall:**
$$\sum_i IF \;\; S_i(tok) = tag \;\; THEN \;\; Prec(T_i, tag) \;\; ELSE \;\; 1 - Rec(T_i, tag)$$

Figure 1
Simple algorithms for voting between component taggers.

most interesting approach to combination is **stacking** in which a classifier is trained to predict the correct output class when given as input the outputs of the ensemble classifiers, and possibly additional information (Wolpert 1992; Breiman 1996b; Ting and Witten 1997a, 1997b). Stacking can lead to an arbiter effect. In this paper we compare voting and stacking approaches on the tagging problem.

In the remainder of this section, we describe the combination methods we use in our experiments. We start with variations based on weighted voting. Then we go on to several types of stacked classifiers, which model the disagreement situations observed in the training data in more detail. The input to the second-stage classifier can be limited to the first-level outputs or can contain additional information from the original input pattern. We will consider a number of different second-level learners. Apart from using three well-known machine learning methods, memory-based learning, maximum entropy, and decision trees, we also introduce a new method, based on grouped voting.

2.1 Simple Voting

The most straightforward method to combine the results of multiple taggers is to do an *n*-way vote. Each tagger is allowed to vote for the tag of its choice, and the tag with the highest number of votes is selected.[2] The question is how large a vote we allow each tagger (Figure 1). The most democratic option is to give each tagger one vote (**Majority**). This does not require any tuning of the voting mechanism on training data.

However, the component taggers can be distinguished by several figures of merit, and it appears more useful to give more weight to taggers that have proved their quality. For this purpose we use **precision** and **recall**, two well-known measures, which

2 In all our experiments, any ties are resolved by a random selection from among the winning tags.

can be applied to the evaluation of tagger output as well. For any tag X, precision measures which percentage of the tokens tagged X by the tagger are also tagged X in the benchmark. Recall measures which percentage of the tokens tagged X in the benchmark are also tagged X by the tagger. When abstracting away from individual tags, precision and recall are equal (at least if the tagger produces exactly one tag per token) and measure how many tokens are tagged correctly; in this case we also use the more generic term **accuracy**. We will call the voting method where each tagger is weighted by its general quality **TotPrecision**, i.e., each tagger votes its overall precision. To allow for more detailed interactions, each tagger is weighted by the quality in relation to the current situation, i.e., each tagger votes its precision on the tag it suggests (**TagPrecision**). This way, taggers that are accurate for a particular type of ambiguity can act as specialized experts. The information about each tagger's quality is derived from a cross-validation of its results on the combiner training set. The precise setup for deriving the training data is described in more detail below, in Section 3.

We have access to even more information on how well the taggers perform. We not only know whether we should believe what they propose (precision) but know as well how often they fail to recognize the correct tag (1 − recall). This information can be used by forcing each tagger to add to the vote for tags suggested by the opposition too, by an amount equal to 1 minus the recall on the opposing tag (**Precision-Recall**). As an example, suppose that the MXPOST tagger suggests DT and the HMM tagger TnT suggests CS (two possible tags in the LOB tagset for the token *that*). If MXPOST has a precision on DT of 0.9658 and a recall on CS of 0.8927, and TnT has a precision on CS of 0.9044 and a recall on DT of 0.9767, then DT receives a $0.9658 + 0.0233 = 0.9991$ vote and CS a $0.9044 + 0.1073 = 1.0117$ vote.

Note that simple voting combiners can never return a tag that was not suggested by a (weighted) majority of the component taggers. As a result, they are restricted to the combination of taggers that all use the same tagset. This is not the case for all the following (arbiter type) combination methods, a fact which we have recently exploited in bootstrapping a word class tagger for a new corpus from existing taggers with completely different tagsets (Zavrel and Daelemans 2000).

2.2 Stacked Probabilistic Voting

One of the best methods for tagger combination in (van Halteren, Zavrel, and Daelemans 1998) is the **TagPair** method. It looks at all situations where one tagger suggests tag_1 and the other tag_2 and estimates the probability that in this situation the tag should actually be tag_x. Although it is presented as a variant of voting in that paper, it is in fact also a stacked classifier, because it does not necessarily select one of the tags suggested by the component taggers. Taking the same example as in the voting section above, if tagger MXPOST suggests DT and tagger TnT suggests CS, we find that the probabilities for the appropriate tag are:

CS	subordinating conjunction	0.4623
CS22	second half of a two-token subordinating conjunction, e.g., *so that*	0.0171
DT	determiner	0.4966
QL	quantifier	0.0103
WPR	*wh*-pronoun	0.0137

When combining the taggers, every tagger pair is taken in turn and allowed to vote (with a weight equal to the probability $P(tag_x \mid tag_1, tag_2)$ as described above) for each possible tag (Figure 2). If a tag pair tag_1-tag_2 has never been observed in the training data, we fall back on information on the individual taggers, i.e., $P(tag_x \mid tag_1)$

Let T_i be the component taggers and $S_i(tok)$ the most probable tag for a token *tok* as suggested by T_i. Then the vote $V(tag, tok)$ for tagging token *tok* with tag *tag* is given by:

$$V(tag, tok) = \sum_{i,j|i<j} V_{i,j}(tag, tok)$$

where $V_{i,j}(tag, tok)$ is given by

$$IF\ frequency(\ S_i(tok_x) = S_i(tok),\ S_j(tok_x) = S_j(tok)\ ) > 0$$

$$THEN\ \ V_{i,j}(tag, tok) = P(tag \mid\ S_i(tok_x) = S_i(tok), S_j(tok_x) = S_j(tok)\ )$$

$$ELSE\ \ V_{i,j}(tag, tok) = \frac{1}{2}P(tag \mid\ S_i(tok_x) = S_i(tok)\ ) + \frac{1}{2}P(tag \mid\ S_j(tok_x) = S_j(tok)\ )$$

Figure 2
The TagPair algorithm for voting between component taggers.

If the case to be classified corresponds to the feature-value pair set

$$F_{case} = \{\{f_1 = v_1\}, \ldots, \{f_n = v_n\}\}$$

then estimate the probability of each class C_x for F_{case} as a weighted sum over all possible subsets F_{sub} of F_{case}:

$$\hat{P}(C_x) = \sum_{F_{sub} \subset F_{case}} W_{F_{sub}} P(C_x \mid F_{sub})$$

with the weight $W_{F_{sub}}$ for an F_{sub} containing n elements equal to $\frac{n!}{W_{norm}}$, where W_{norm} is a normalizing constant so that $\sum_{C_x} \hat{P}(C_x) = 1$.

Figure 3
The Weighted Probability Distribution Voting classification algorithm, as used in the combination experiments.

and $P(tag_x \mid tag_2)$. Note that with this method (and all of the following), a tag suggested by a minority (or even none) of the taggers actually has a chance to win, although in practice the chance to beat a majority is still very slight.

Seeing the success of TagPair in the earlier experiments, we decided to try to generalize this stacked probabilistic voting approach to combinations larger than pairs. Among other things, this would let us include word and context features here as well. The method that was eventually developed we have called **Weighted Probability Distribution Voting** (henceforth WPDV).

A WPDV classification model is not limited to pairs of features (such as the pairs of tagger outputs for TagPair), but can use the probability distributions for all feature combinations observed in the training data (Figure 3). During voting, we do not use a fallback strategy (as TagPair does) but use weights to prevent the lower-order combinations from excessively influencing the final results when a higher-order combination (i.e., more exact information) is present. The original system, as used for this paper, weights a combination of order n with a factor $n!$, a number based on the observation that a combination of order m contains m combinations of order $(m-1)$ that have to be competed with. Its only parameter is a threshold for the number of times a combination must be observed in the training data in order to be used, which helps prevent a combinatorial explosion when there are too many atomic features.[3]

3 In our experiments, this parameter is always set to 5. WPDV has since evolved, using more parameters and more involved weighting schemes, and also been tested on tasks other than tagger combination (van Halteren 2000a, 2000b).

- Tags suggested by the base taggers, used by all systems:

$$TagTBL = JJ \qquad TagMBT = VBN \qquad TagMXP = VBD \qquad TagHMM = JJ$$

- The focus token, used by stacked classifiers at level Tags+Word:

$$Word = restored$$

- Full form tags suggested by the base tagger for the previous and next token, used by stacked classifiers at level Tags+Context, except for WPDV:

$$PrevTBL = JJ \qquad PrevMBT = NN \qquad PrevMXP = NN \qquad PrevHMM = JJ$$

$$NextTBL = NN \qquad NextMBT = NN \qquad NextMXP = NN \qquad NextHMM = NN$$

- Compressed form of the context tags, used by WPDV(Tags+Context), because the system was unable to cope with the large number of features:

$$Prev = JJ + NN + NN + JJ \qquad Next = NN + NN + NN + NN$$

- Target feature, used by all systems:

$$Tag = VBD$$

Figure 4
Features used by the combination systems. Examples are taken from the LOB material.

In contrast to voting, stacking classifiers allows the combination of the outputs of component systems with additional information about the decision's context. We investigated several versions of this approach. In the basic version (Tags), each training case for the second-level learner consists of the tags suggested by the component taggers and the correct tag (Figure 4). In the more advanced versions, we add information about the word in question (Tags+Word) and the tags suggested by all taggers for the previous and the next position (Tags+Context). These types of extended second-level features can be exploited by WPDV, as well as by a wide selection of other machine learning algorithms.

2.3 Memory-based Combination

Our first choice from these other algorithms is a memory-based second-level learner, implemented in TiMBL (Daelemans et al. 1999), a package developed at Tilburg University and Antwerp University.[4]

Memory-based learning is a learning method that is based on storing all examples of a task in memory and then classifying new examples by similarity-based reasoning from these stored examples. Each example is represented by a fixed-length vector of feature values, called a **case**. If the case to be classified has been observed before, that is, if it is found among the stored cases (in the **case base**), the most frequent corresponding output is used. If the case is not found in the case base, k nearest neighbors are determined with some similarity metric, and the output is based on the observed outputs for those neighbors. Both the value of k and the similarity metric used can be selected by parameters of the system. For the Tags version, the similarity metric used is **Overlap** (a count of the number of matching feature values between a test and a training item) and k is kept at 1. For the other two versions (Tags+Word and Tags+Context), a value of $k = 3$ is used, and each overlapping feature is weighted by its **Information Gain** (Daelemans, Van den Bosch, and Weijters 1997). The Information

4 TiMBL is available from http://ilk.kub.nl/.

Gain of a feature is defined as the difference between the entropy of the a priori class distribution and the conditional entropy of the classes given the value of the feature.[5]

2.4 Maximum Entropy Combination

The second machine learning method, maximum entropy modeling, implemented in the Maccent system (Dehaspe 1997), does the classification task by selecting the most probable class given a maximum entropy model.[6] This type of model represents examples of the task (Cases) as sets of binary indicator features, for the task at hand conjunctions of a particular tag and a particular set of feature values. The model has the form of an exponential model:

$$p_\Lambda(tag \mid Case) = \frac{1}{Z_\Lambda(Case)}\, e^{\sum_i \lambda_i f_i(Case,tag)}$$

where i indexes all the binary features, f_i is a binary indicator function for feature i, Z_Λ is a normalizing constant, and λ_i is a weight for feature i. The model is trained by iteratively adding binary features with the largest gain in the probability of the training data, and estimating the weights using a numerical optimization method called improved iterative scaling. The model is constrained by the observed distribution of the features in the training data and has the property of having the maximum entropy of all models that fit the constraints, i.e., all distributions that are not directly constrained by the data are left as uniform as possible.[7]

The maximum entropy combiner takes the same information as the memory-based learner as input, but internally translates all multivalued features to binary indicator functions. The improved iterative scaling algorithm is then applied, with a maximum of one hundred iterations. This algorithm is the same as the one used in the MXPOST tagger described in Section 3.2.3, but without the beam search used in the tagging application.

2.5 Decision Tree Combination

The third machine learning method we used is C5.0 (Quinlan 1993), an example of top-down induction of decision trees.[8] A decision tree is constructed by recursively partitioning the training set, selecting, at each step, the feature that most reduces the uncertainty about the class in each partition, and using it as a split. C5.0 uses **Gain Ratio** as an estimate of the utility of splitting on a feature. Gain Ratio corresponds to the Information Gain measure of a feature, as described above, except that the measure is normalized for the number of values of the feature, by dividing by the entropy of the feature's values. After the decision tree is constructed, it is pruned to avoid overfitting, using a method described in detail in Quinlan (1993). A classification for a test case is made by traversing the tree until either a leaf node is found or all further branches do not match the test case, and returning the most frequent class at the last node. The case representation uses exactly the same features as the memory-based learner.

3. Experimental Setup

In order to test the potential of system combination, we obviously need systems to combine, i.e., a number of different taggers. As we are primarily interested in the

5 This is also sometimes referred to as mutual information in the computational linguistics literature.
6 Maccent is available from http://www.cs.kuleuven.ac.be/∼ldh.
7 For a more detailed discussion, see Berger, Della Pietra, and Della Pietra (1996) and Ratnaparkhi (1996).
8 c5.0 is commercially available from http://www.rulequest.com/. Its predecessor, c4.5, can be downloaded from http://www.cse.unsw.edu.au/∼quinlan/.

combination of classifiers trained on the same data sets, we are in fact looking for data sets (in this case, tagged corpora) and systems that can automatically generate a tagger on the basis of those data sets. For the current experiments, we have selected three tagged corpora and four tagger generators. Before giving a detailed description of each of these, we first describe how the ingredients are used in the experiments.

Each corpus is used in the same way to test tagger and combiner performance. First of all, it is split into a 90% training set and a 10% test set. We can evaluate the base taggers by using the whole training set to train the tagger generators and the test set to test the resulting tagger. For the combiners, a more complex strategy must be followed, since combiner training must be done on material unseen by the base taggers involved. Rather than setting apart a fixed combiner training set, we use a ninefold training strategy.[9] The 90% training set is split into nine equal parts. Each part is tagged with component taggers that have been trained on the other eight parts. All results are then concatenated for use in combiner training, so that, in contrast to our earlier work, all of the training set is effectively available for the training of the combiner. Finally, the resulting combiners are tested on the test set. Since the test set is identical for all methods, we can compute the statistical significance of the results using McNemar's chi-squared test (Dietterich 1998).

As we will see, the increase in combiner training set size (90% of the corpus versus the fixed 10% tune set in the earlier experiments) indeed results in better performance. On the other hand, the increased amount of data also increases time and space requirements for some systems to such a degree that we had to exclude them from (some parts of) the experiments.

The data in the training set is the only information used in tagger and combiner construction: all components of all taggers and combiners (lexicon, context statistics, etc.) are entirely data driven, and no manual adjustments are made. If any tagger or combiner construction method is parametrized, we use default settings where available. If there is no default, we choose intuitively appropriate values without preliminary testing. In these cases, we report such parameter settings in the introduction to the system.

3.1 Data

In the current experiments we make use of three corpora. The first is the LOB corpus (Johansson 1986), which we used in the earlier experiments as well (van Halteren, Zavrel, and Daelemans 1998) and which has proved to be a good testing ground. We then switch to *Wall Street Journal* material (WSJ), tagged with the Penn Treebank II tagset (Marcus, Santorini, and Marcinkiewicz 1993). Like LOB, it consists of approximately 1M words, but unlike LOB, it is American English. Furthermore, it is of a different structure (only newspaper text) and tagged with a rather different tagset. The experiments with WSJ will also let us compare our results with those reported by Brill and Wu (1998), which show a much less pronounced accuracy increase than ours with LOB. The final corpus is the slightly smaller (750K words) Eindhoven corpus (Uit den Boogaart 1975) tagged with the Wotan tagset (Berghmans 1994). This will let us examine the tagging of a language other than English (namely, Dutch). Furthermore, the Wotan tagset is a very detailed one, so that the error rate of the individual taggers

9 Compare this to the "tune" set in van Halteren, Zavrel, and Daelemans (1998). This consisted of 114K tokens, but, because of a 92.5% agreement over all four taggers, it yielded less than 9K tokens of useful training material to resolve disagreements. This was suspected to be the main reason for the relative lack of performance by the more sophisticated combiners.

tends to be higher. Moreover, we can more easily use projections of the tagset and thus study the effects of levels of granularity.

3.1.1 LOB. The first data set we use for our experiments consists of the tagged Lancaster-Oslo/Bergen corpus (LOB [Johansson 1986]). The corpus comprises about one million words of British English text, divided over 500 samples of 2,000 words from 15 text types.

The tagging of the LOB corpus, which was manually checked and corrected, is generally accepted to be quite accurate. Here we use a slight adaptation of the tagset. The changes are mainly cosmetic, e.g., nonalphabetic characters such as "$" in tag names have been replaced. However, there has also been some retokenization: genitive markers have been split off and the negative marker *n't* has been reattached.

An example sentence tagged with the resulting tagset is:

The	ATI	singular or plural article
Lord	NPT	singular titular noun
Major	NPT	singular titular noun
extended	VBD	past tense of verb
an	AT	singular article
invitation	NN	singular common noun
to	IN	preposition
all	ABN	pre-quantifier
the	ATI	singular or plural article
parliamentary	JJ	adjective
candidates	NNS	plural common noun
.	SPER	period

The tagset consists of 170 different tags (including ditto tags), and has an average ambiguity of 2.82 tags per wordform over the corpus.[10] An impression of the difficulty of the tagging task can be gained from the two baseline measurements in Table 2 (in Section 4.1 below), representing a completely random choice from the potential tags for each token (Random) and selection of the lexically most likely tag (LexProb).[11]

The training/test separation of the corpus is done at utterance boundaries (each 1st to 9th utterance is training and each 10th is test) and leads to a 1,046K token training set and a 115K token test set. Around 2.14% of the test set are tokens unseen in the training set and a further 0.37% are known tokens but with unseen tags.[12]

3.1.2 WSJ. The second data set consists of 1M words of *Wall Street Journal* material. It differs from LOB in that it is American English and, more importantly, in that it is completely made up of newspaper text. The material is tagged with the Penn Treebank tagset (Marcus, Santorini, and Marcinkiewicz 1993), which is much smaller than the LOB one. It consists of only 48 tags.[13] There is no attempt to annotate compound words, so there are no ditto tags.

10 Ditto tags are used for the components of multitoken units, e.g. if *as well as* is taken to be a coordinating conjunction, it is tagged "as_CC-1 well_CC-2 as_CC-3", using three related but different ditto tags.

11 These numbers are calculated on the basis of a lexicon derived from the whole corpus. An actual tagger will have to deal with unknown words in the test set, which will tend to increase the ambiguity and decrease Random and LexProb. Note that all actual taggers and combiners in this paper do have to cope with unknown words as their lexicons are based purely on their training sets.

12 Because of the way in which the tagger generators treat their input, we do count tokens as different even though they are the same underlying token, but differ in capitalization of one or more characters.

13 In the material we have available, quotes are represented slightly differently, so that there are only 45 different tags. In addition, the corpus contains a limited number of instances of 38 "indeterminate" tags, e.g., JJ|VBD indicates a choice between adjective and past participle which cannot be decided or about which the annotator was unsure.

An example sentence is:

By	IN	preposition/subordinating conjunction
10	CD	cardinal number
a.m.	RB	adverb
Tokyo	NNP	singular proper noun
time	NN	singular common noun
,	,	comma
the	DT	determiner
index	NN	singular common noun
was	VBD	past tense verb
up	RB	adverb
435.11	CD	cardinal number
points	NNS	plural common noun
,	,	comma
to	TO	"to"
34903.80	CD	cardinal number
as	IN	preposition/subordinating conjunction
investors	NNS	plural common noun
hailed	VBD	past tense verb
New	NNP	singular proper noun
York	NNP	singular proper noun
's	POS	possessive ending
overnight	JJ	adjective
rally	NN	singular common noun
.	.	sentence-final punctuation

Mostly because of the less detailed tagset, the average ambiguity of the tags is lower than LOB's, at 2.34 tags per token in the corpus. This means that the tagging task should be an easier one than that for LOB. This is supported by the values for Random and LexProb in Table 2. On the other hand, the less detailed tagset also means that the taggers have less detailed information to base their decisions on. Another factor that influences the quality of automatic tagging is the consistency of the tagging over the corpus. The WSJ material has not been checked as extensively as the LOB corpus and is expected to have a much lower consistency level (see Section 5.3 below for a closer examination).

The training/test separation of the corpus is again done at utterance boundaries and leads to a 1,160K token training set and a 129K token test set. Around 1.86% of the test set are unseen tokens and a further 0.44% are known tokens with previously unseen tags.

3.1.3 Eindhoven. The final two data sets are both based on the Eindhoven corpus (Uit den Boogaart 1975). This is slightly smaller than LOB and WSJ. The written part, which we use in our experiments, consists of about 750K words, in samples ranging from 53 to 451 words. In variety, it lies between LOB and WSJ, containing 150K words each of samples from Dutch newspapers (subcorpus CDB), weeklies (OBL), magazines (GBL), popular scientific writings (PWE), and novels (RNO).

The tagging of the corpus, as used here, was created in 1994 as part of a master's thesis project (Berghmans 1994). It employs the Wotan tagset for Dutch, newly designed during the project. It is based on the classification used in the most popular descriptive grammar of Dutch, the *Algemene Nederlandse Spraakkunst* (ANS [Geerts et al. 1984]). The actual distinctions encoded in the tagset were selected on the basis of their importance to the potential users, as estimated from a number of in-depth interviews with interested parties in the Netherlands. The Wotan tagset is not only very large (233 base tags, leading to 341 tags when counting each ditto tag separately), but furthermore contains distinctions that are very difficult for automatic taggers, such as verb transitivity, syntactic use of adjectives, and the recognition of multitoken units. It has an average ambiguity of 7.46 tags per token in the corpus. For our experiments,

we also designed a simplification of the tagset, dubbed WotanLite, which no longer contains the most problematic distinctions. WotanLite has 129 tags (with a complement of ditto tags leading to a total of 173) and an average ambiguity of 3.46 tags per token.

An example of Wotan tagging is given below (only underlined parts remain in WotanLite):[14]

Mr. (*Master*, title)	N(eigen,ev,neut):1/2	first part of singular neutral case proper noun
Rijpstra	N(eigen,ev,neut):2/2	second part of singular neutral case proper noun
heeft (*has*)	V(hulp,ott,3,ev)	3rd person singular present tense auxiliary verb
de (*the*)	Art(bep,zijd-of-mv,neut)	neutral case non-neuter or plural definite article
Commissarispost (*post of Commissioner*)	N(soort,ev,neut)	singular neutral case common noun
in (*in*)	Prep(voor)	adposition used as preposition
Friesland	N(eigen,ev,neut)	singular neutral case proper noun
geambieerd (*aspired to*)	V(trans,verl-dw,onverv)	base form of past participle of transitive verb
en (*and*)	Conj(neven)	coordinating conjunction
hij (*he*)	Pron(per,3,ev,nom)	3rd person singular nominative personal pronoun
moet (*should*)	V(hulp,ott,3,ev)	3rd person singular present tense auxiliary verb
dus (*therefore*)	Adv(gew,aanw)	demonstrative non-pronominal adverb
alle (*all*)	Pron(onbep,neut,attr)	attributively used neutral case indefinite pronoun
kans (*opportunity*)	N(soort,ev,neut)	singular neutral case common noun
hebben (*have*)	V(trans,inf)	infinitive of transitive verb
er (*there*)	Adv(pron,er)	pronominal adverb "er"
het (*the*)	Art(bep,onzijd,neut)	neutral case neuter definite article
beste (*best*)	Adj(zelfst,overtr,verv-neut)	nominally used inflected superlative form of adjective
van (*of*)	Adv(deel-adv)	particle adverb
te (*to*)	Prep(voor-inf)	infinitival "te"
maken (*make*)	V(trans,inf)	infinitive of transitive verb
.	Punc(punt)	period

The annotation of the corpus was realized by a semiautomatic upgrade of the tagging inherited from an earlier project. The resulting consistency has never been exhaustively measured for either the Wotan or the original tagging.

The training/test separation of the corpus is done at sample boundaries (each 1st to 9th sample is training and each 10th is test). This is a much stricter separation than applied for LOB and WSJ, as for those two corpora our test utterances are related to the training ones by being in the same samples. Partly as a result of this, but also very much because of word compounding in Dutch, we see a much higher percentage of new tokens—6.24% tokens unseen in the training set. A further 1.45% known tokens have new tags for Wotan, and 0.45% for WotanLite. The training set consists of 640K tokens and the test set of 72K tokens.

3.2 Tagger Generators

The second ingredient for our experiments is a set of four tagger generator systems, selected on the basis of variety and availability.[15] Each of the systems represents a

14 The example sentence could be rendered in English as *Master Rijpstra has aspired to the post of Commissioner in Friesland and he should therefore be given every opportunity to make the most of it.*

15 The systems have to differ as much as possible in their learning strategies and biases, as otherwise there will be insufficient differences of opinion for the combiners to make use of. This was shown clearly in early experiments in 1992, where only *n*-gram taggers were used, and which produced only a very limited improvement in accuracy (van Halteren 1996).

Table 1
The features available to the four taggers in our study. Except for MXPOST, all systems use different models (and hence features) for known (k) and unknown (u) words. However, Brill's transformation-based learning system (TBL) applies its two models in sequence when faced with unknown words, thus giving the unknown-word tagger access to the features used by the known-word model as well. The first five columns in the table show features of the focus word: capitalization (C), hyphen (H), or digit (D) present, and number of suffix (S) or prefix (P) letters of the word. Brill's TBL system (for unknown words) also takes into account whether the addition or deletion of a suffix results in a known lexicon entry (indicated by an L). The next three columns represent access to the actual word (W) and any range of words to the left (W_{left}) or right (W_{right}). The last three columns show access to tag information for the word itself (T) and any range of words left (T_{left}) or right (T_{right}). Note that the expressive power of a method is not purely determined by the features it has access to, but also by its algorithm, and what combinations of the available features this allows it to consider.

	Features										
System	C	D	N	S	P	W	W_{left}	W_{right}	T	T_{left}	T_{right}
TBL (k)						x	1–2	1–2	x	1–3	1–3
TBL (u)	x	x	x	4,L	4,L		1–2	1–2		1–3	1–3
MBT (k)						x			x	1–2	1–2
MBT (u)	x	x	x	3						1	1
MXP (all)	x	x	x	4	4	x	1–2	1–2		1–2	
TNT (k)	x					x			x	1–2	
TNT (u)	x			10						1–2	

popular type of learning method, each uses slightly different features of the text (see Table 1), and each has a completely different representation for its language model. All publicly available systems are used with the default settings that are suggested in their documentation.

3.2.1 Error-driven Transformation-based Learning. This learning method finds a set of rules that transforms the corpus from a baseline annotation so as to minimize the number of errors (we will refer to this system as TBL below). A tagger generator using this learning method is described in Brill (1992, 1994). The implementation that we use is Eric Brill's publicly available set of C programs and Perl scripts.[16]

When training, this system starts with a baseline corpus annotation A_0. In A_0, each known word is tagged with its most likely tag in the training set, and each unknown word is tagged as a noun (or proper noun if capitalized). The system then searches through a space of transformation rules (defined by rule templates) in order to reduce the discrepancy between its current annotation and the provided correct one. There are separate templates for known words (mainly based on local word and tag context), and for unknown words (based on suffix, prefix, and other lexical information). The exact features used by this tagger are shown in Table 1. The learner for the unknown words is trained and applied first. Based on its output, the rules for context disambiguation are learned. In each learning step, all instantiations of the rule templates that are present in the corpus are generated and receive a score. The rule that corrects the highest number of errors at step n is selected and applied to the corpus to yield an annotation A_n, which is then used as the basis for step $n+1$. The process stops when no rule reaches a score above a predefined threshold. In our experiments this has usually yielded several hundreds of rules. Of the four systems, TBL has access to

16 Brill's system can be downloaded from ftp://ftp.cs.jhu.edu/pub/brill/Programs/RULE_BASED_TAGGER_V.1.14.tar.Z.

the most features: contextual information (the words and tags in a window spanning three positions before and after the focus word) as well as lexical information (the existence of words formed by the addition or deletion of a suffix or prefix). However, the conjunctions of these features are not all available in order to keep the search space manageable. Even with this restriction, the search is computationally very costly. The most important rule templates are of the form

$$\texttt{if } \textit{context} = x \texttt{ change } \textit{tag}_i \texttt{ to } \textit{tag}_j$$

where *context* is some condition on the tags of the neighbouring words. Hence learning speed is roughly cubic in the tagset size.[17]

When tagging, the system again starts with a baseline annotation for the new text, and then applies all rules that were derived during training, in the sequence in which they were derived. This means that application of the rules is fully deterministic. Corpus statistics have been at the basis of selecting the rule sequence, but the resulting tagger does not explicitly use a probabilistic model.

3.2.2 Memory-Based Learning. Another learning method that does not explicitly manipulate probabilities is machine-based learning. However, rather than extracting a concise set of rules, memory-based learning focuses on storing all examples of a task in memory in an efficient way (see Section 2.3). New examples are then classified by similarity-based reasoning from these stored examples. A tagger using this learning method, MBT, was proposed by Daelemans et al. (1996).[18]

During the training phase, the training corpus is transformed into two case bases, one which is to be used for known words and one for unknown words. The cases are stored in an IGTree (a heuristically indexed version of a case memory [Daelemans, Van den Bosch, and Weijters 1997]), and during tagging, new cases are classified by matching cases with those in memory going from the most important feature to the least important. The order of feature relevance is determined by Information Gain.

For known words, the system used here has access to information about the focus word and its potential tags, the disambiguated tags in the two preceding positions, and the undisambiguated tags in the two following positions. For unknown words, only one preceding and following position, three suffix letters and information about capitalization and presence of a hyphen or a digit are used as features. The case base for unknown words is constructed from only those words in the training set that occur five times or less.

3.2.3 Maximum Entropy Modeling. Tagging can also be done using maximum entropy modeling (see Section 2.4): a maximum entropy tagger, called MXPOST, was developed by Ratnaparkhi (1996) (we will refer to this tagger as MXP below).[19] This system uses a number of word and context features rather similar to system MBT, and trains a maximum entropy model using the improved iterative scaling algorithm for one hundred iterations. The final model has a weighting parameter for each feature value that is relevant to the estimation of the probability $P(\textit{tag} \mid \textit{features})$, and combines the evidence from diverse features in an explicit probability model. In contrast to the other taggers, both known and unknown words are processed by the same

17 Because of the computational complexity, we have had to exclude the system from the experiments with the very large Wotan tagset.
18 An on-line version of the tagger is available at http://ilk.kub.nl/.
19 Ratnaparkhi's Java implementation of this system is freely available for noncommercial research purposes at ftp://ftp.cis.upenn.edu/pub/adwait/jmx/.

model. Another striking difference is that this tagger does not have a separate storage mechanism for lexical information about the focus word (i.e., the possible tags). The word is merely another feature in the probability model. As a result, no generalizations over groups of words with the same set of potential tags are possible. In the tagging phase, a beam search is used to find the highest probability tag sequence for the whole sentence.

3.2.4 Hidden Markov Models. In a Hidden Markov Model, the tagging task is viewed as finding the maximum probability sequence of states in a stochastic finite-state machine. The transitions between states emit the words of a sentence with a probability $P(w \mid S_t)$, the states S_t themselves model tags or sequences of tags. The transitions are controlled by Markovian state transition probabilities $P(S_{t_i} \mid S_{t_{i-1}})$. Because a sentence could have been generated by a number of different state sequences, the states are considered to be "Hidden." Although methods for unsupervised training of HMM's do exist, training is usually done in a supervised way by estimation of the above probabilities from relative frequencies in the training data. The HMM approach to tagging is by far the most studied and applied (Church 1988; DeRose 1988; Charniak 1993).

In van Halteren, Zavrel, and Daelemans (1998) we used a straightforward implementation of HMM's, which turned out to have the worst accuracy of the four competing methods. In the present work, we have replaced this by the TnT system (we will refer to this tagger as HMM below).[20] TnT is a trigram tagger (Brants 2000), which means that it considers the previous two tags as features for deciding on the current tag. Moreover, it considers the capitalization of the previous word as well in its state representation. The lexical probabilities depend on the identity of the current word for known words and on a suffix tree smoothed with successive abstraction (Samuelsson 1996) for guessing the tags of unknown words. As we will see below, it shows a surprisingly higher accuracy than our previous HMM implementation. When we compare it with the other taggers used in this paper, we see that a trigram HMM tagger uses a very limited set of features (Table 1). On the other hand, it is able to access some information about the rest of the sentence indirectly, through its use of the Viterbi algorithm.

4. Overall Results

The first set of results from our experiments is the measurement of overall accuracy for the base taggers. In addition, we can observe the agreement between the systems, from which we can estimate how much gain we can possibly expect from combination. The application of the various combination systems, finally, shows us how much of the projected gain is actually realized.

4.1 Base Tagger Quality

An additional benefit of training four popular tagging systems under controlled conditions on several corpora is an experimental comparison of their accuracy. Table 2 lists the accuracies as measured on the test set.[21] We see that TBL achieves the lowest accuracy on all data sets. MBT is always better than TBL, but is outperformed by both MXP and HMM. On two data sets (LOB and Wotan) the Hidden Markov Model system (TnT) is better than the maximum entropy system (MXPOST). On the other two

20 The TnT system can be obtained from its author through http://www.coli.uni-sb.de/~thorsten/tnt/.
21 In this and several following tables, the best performance is indicated with bold type.

Table 2
Baseline and individual tagger test set accuracy for each of our four data sets. The bottom four rows show the accuracies of the four tagging systems on the various data sets. In addition, we list two baselines: the selection of a completely random tag from among the potential tags for the token (Random) and the selection of the lexically most likely tag (LexProb).

	LOB	WSJ	Wotan	WotanLite
Baseline				
Random	61.46	63.91	42.99	54.36
LexProb	93.22	94.57	89.48	93.40
Single Tagger				
TBL	96.37	96.28	–*	94.63
MBT	97.06	96.41	89.78	94.92
MXP	97.52	**96.88**	91.72	**95.56**
HMM	**97.55**	96.63	**92.06**	95.26

*The training of TBL on the large Wotan tagset was aborted after several weeks of training failed to produce any useful results.

Table 3
Pairwise agreement between the base taggers. For each base tagger pair and data set, we list the percentage of tokens in the test set on which the two taggers select the same tag.

	Tagger Pair					
Data Set	MXP HMM	MXP MBT	MXP TBL	HMM MBT	HMM TBL	MBT TBL
LOB	97.56	96.70	96.27	97.27	96.96	96.78
WSJ	97.41	96.85	96.90	97.18	97.39	97.21
Wotan	93.02	90.81	–	92.06	–	–
WotanLite	95.74	95.12	95.00	95.48	95.36	95.52

(WSJ and WotanLite) MXPOST is the better system. In all cases, except the difference between MXP and HMM on LOB, the differences are statistically significant ($p < 0.05$, McNemar's chi-squared test).

We can also see from these results that WSJ, although it is about the same size as LOB, and has a smaller tagset, has a higher difficulty level than LOB. We suspect that an important reason for this is the inconsistency in the WSJ annotation (cf. Ratnaparkhi 1996). We examine this effect in more detail below. The Eindhoven corpus, both with Wotan and WotanLite tagsets, is yet more difficult, but here the difficulty lies mainly in the complexity of the tagset and the large percentage of unknown words in the test sets. We see that the reduction in the complexity of the tagset from Wotan to WotanLite leads to an enormous improvement in accuracy. This granularity effect is also examined in more detail below.

4.2 Base Tagger Agreement

On the basis of the output of the single taggers we can also examine the feasibility of combination, as combination is dependent on different systems producing different errors. As expected, a large part of the errors are indeed uncorrelated: the agreement between the systems (Table 3) is at about the same level as their agreement with the benchmark tagging. A more detailed view of intertagger agreement is shown in Table 4, which lists the (groups of) patterns of (dis)agreement for the four data sets.

Table 4
The presence of various tagger (dis)agreeement patterns for the four data sets. In addition to the percentage of the test sets for which the pattern is observed (%), we list the cumulative percentage (%Cum).

	LOB		WSJ		Wotan		WotanLite	
Pattern	%	%Cum	%	%Cum	%	%Cum	%	%Cum
All taggers agree and are correct.	93.93	93.93	93.80	93.80	85.68	85.68	90.50	90.50
A majority is correct.	3.30	97.23	2.64	96.44	6.54	92.22	4.73	95.23
Correct tag is present but is tied.	1.08	98.31	1.07	97.51	0.82	93.04	1.59	96.82
A minority is correct.	0.91	99.22	1.12	98.63	2.62	95.66	1.42	98.24
The taggers vary, but are all wrong.	0.21	99.43	0.26	98.89	1.53	97.19	0.46	98.70
All taggers agree but are wrong.	0.57	100.00	1.11	100.00	2.81	100.00	1.30	100.00

It is interesting to see that although the general accuracy for WSJ is lower than for LOB, the intertagger agreement for WSJ is on average higher. It would seem that the less consistent tagging for WSJ makes it easier for all systems to fall into the same traps. This becomes even clearer when we examine the patterns of agreement and see, for example, that the number of tokens where all taggers agree on a wrong tag is practically doubled.

The agreement pattern distribution enables us to determine levels of combination quality. Table 5 lists both the accuracies of several ideal combiners (%) and the error reduction in relation to the best base tagger for the data set in question (Δ_{Err}).[22] For example, on LOB, "All ties correct" produces 1,941 errors (corresponding to an accuracy of 98.31%), which is 31.3% less than HMM's 2,824 errors. A minimal level of combination achievement is that a majority or better will lead to the correct tag and that ties are handled appropriately about 50% of the time for the (2–2) pattern and 25% for the (1–1–1–1) pattern (or 33.3% for the (1–1–1) pattern for Wotan). In more optimistic scenarios, a combiner is able to select the correct tag in all tied cases, or even in cases where a two- or three-tagger majority must be overcome. Although the possibility of overcoming a majority is present with the arbiter type combiners, the situation is rather improbable. As a result, we ought to be more than satisfied if any combiners approach the level corresponding to the projected combiner which resolves all ties correctly.[23]

22 We express the error reduction in the form of a percentage, i.e., a relative measure, instead of by an absolute value, because we feel this is the more informative of the two. After all, there is a vast difference between an accuracy improvement of 0.5% from 50% to 50.5% (a Δ_{Err} of 1%) and one of 0.5% from 99% to 99.5% (a Δ_{Err} of 50%).

23 The bottom rows of Table 5 might be viewed in the light of potential future extremely intelligent combination systems. For the moment, however, it is better to view them as containing recall values for *n*-best versions of the combination taggers, e.g., an *n*-best combination tagger for LOB, which simply provides all tags suggested by its four components, will have a recall score of 99.22%.

Table 5
Projected accuracies for increasingly successful levels of combination achievement. For each level we list the accuracy (%) and the percentage of errors made by the best individual tagger that can be corrected by combination (Δ_{Err}).

	LOB		WSJ		Wotan		WotanLite	
Pattern	%	Δ_{Err}	%	Δ_{Err}	%	Δ_{Err}	%	Δ_{Err}
Best Single Tagger	HMM		MXP		HMM		MXP	
	97.55	–	96.88	–	92.06	–	95.56	–
Ties randomly correct.	97.77	9.0	96.97	2.8	92.49	5.5	96.01	10.1
All ties correct.	98.31	31.3	97.50	19.9	93.04	12.4	96.82	28.3
Minority vs. two-tagger correct.	98.48	48.5	97.67	25.4	95.66	45.3	97.09	34.3
Minority vs three-tagger correct.	99.22	68.4	98.63	56.0	–	–	98.24	60.3

Table 6
Accuracies of the combination systems on all four corpora. For each system we list its accuracy (%) and the percentage of errors made by the best individual tagger that is corrected by the combination system (Δ_{Err}).

	LOB		WSJ		Wotan		WotanLite

Maccent(Tags)	98.03	19.6	97.10	7.1	92.76	8.9	96.29	16.4
Maccent(Tags+Word)	98.02	19.3	97.09	6.6	92.63	7.2	96.27	16.0
Maccent(Tags+Context)	98.12	23.5	97.10	7.0	**93.25**	**15.0**	96.37	18.2

*c5.0 was not able to cope with the large amount of data involved in all Tags+Word experiments and the Tags+Context experiment with Wotan.

4.3 Results of Combination

In Table 6 the results of our experiments with the various combination methods are shown. Again we list both the accuracies of the combiners (%) and the error reduction in relation to the best base tagger (Δ_{Err}). For example, on LOB, TagPair produces 2,321 errors (corresponding to an accuracy of 97.98%), which is 17.8% less than HMM's 2,824 errors.

Although the combiners generally fall short of the "All ties correct" level (cf. Table 5), even the most trivial voting system (Majority), significantly outperforms the best individual tagger on all data sets. Within the simple voting systems, it appears that use of more detailed voting weights does not necessarily lead to better results. TagPrecision is clearly inferior to TotPrecision. On closer examination, this could have been expected. Looking at the actual tag precision values (see Table 9 below), we see that the precision is generally more dependent on the tag than on the tagger, so that TagPrecision always tends to select the easier tag. In other words, it uses less specific rather than more specific information. Precision-Recall is meant to correct this behavior by the involvement of recall values. As intended, Precision-Recall generally has a higher accuracy than TagPrecision, but does not always improve on TotPrecision.

Our previously unconfirmed hypothesis, that arbiter-type combiners would be able to outperform the gang-type ones, is now confirmed. With the exception of several of the Tags+Word versions and the Tags+Context version for WSJ, the more sophisticated modeling systems have a significantly better accuracy than the simple voting systems on all four data sets. TagPair, being somewhere between simple voting and stacking, also falls in the middle where accuracy is concerned. In general, it can at most be said to stay close to the real stacking systems, except for the cleanest data set, LOB, where it is clearly being outperformed. This is a fundamental change from our earlier experiments, where TagPair was significantly better than MBL and Decision Trees. Our explanation at the time, that the stacked systems suffered from a lack of training data, appears to be correct. A closer investigation below shows at which amount of training data the crossover point in quality occurs (for LOB).

Another unresolved issue from the earlier experiments is the effect of making word or context information available to the stacked classifiers. With LOB and a single 114K tune set (van Halteren, Zavrel, and Daelemans 1998), both MBL and Decision Trees degraded significantly when adding context, and MBL degraded when adding the word.[24] With the increased amount of training material, addition of the context generally leads to better results. For MBL, there is a degradation only for the WSJ data, and of a much less pronounced nature. With the other data sets there is an improvement, significantly so for LOB. For Decision Trees, there is also a limited degradation for WSJ and WotanLite, and a slight improvement for LOB. The other two systems appear to be able to use the context more effectively. WPDV shows a relatively constant significant improvement over all data sets. Maccent shows more variation, with a comparable improvement on LOB and WotanLite, a very slight degradation on WSJ, and a spectacular improvement on Wotan, where it even yields an accuracy higher than the "All ties correct" level.[25] Addition of the word is still generally counterproductive. Only WPDV sometimes manages to translate the extra information into an improvement in accuracy, and even then a very small one. It would seem that vastly larger amounts of training data are necessary if the word information is to become useful.

5. Combination in Detail

The observations about the overall accuracies, although the most important, are not the only interesting ones. We can also examine the results of the experiments above in more detail, evaluating the results of combination for specific words and tags, and

24 Just as in the current experiments, the Decision Tree system could not cope with the amount of data when the word was added.

25 We have no clear explanation for this exceptional behavior, but conjecture that Maccent is able to make optimal use of the tagging differences caused by the high error rate of all four taggers.

Table 7
Error rates for the most confusing words. For each word, we list the total number of instances in the test set (n), the number of tags associated with the word (tags), and then, for each base tagger and WPDV(Tags+Context), the rank in the error list (rank), the absolute number of errors (err), and the percentage of instances that is mistagged (%).

		MXP		HMM		MBT		TBL		WPDV(T+C)	
Word	n/tags	rank: err	%	rank: err	%	rank: err	%	rank: err	%	rank: err	%
as	719/17	1: 102	14.19	1: 130	18.08	3: 120	16.69	1: 167	23.23	1: **82**	**11.40**

trying to discover why such disappointing results are found for WSJ. Furthermore, we can run additional experiments, to determine the effects of the size of the training set, the number of base tagger components involved, and the granularity of the tagset.

5.1 Specific Words

The overall accuracy of the various tagging systems gives a good impression of relative performance, but it is also useful to have a more detailed look at the tagging results. Most importantly for this paper, the details give a better feel for the differences between the base taggers and for how well a combiner can exploit these differences. More generally, users of taggers or tagged corpora are rarely interested in the whole corpus. They focus rather on specific words or word classes, for which the accuracy of tagging may differ greatly from the overall accuracy.

We start our detailed examination with the words that are most often mistagged. We use the LOB corpus for this evaluation, as it is the cleanest data set and hence the best example. For each base tagger, and for WPDV(Tags+Context), we list the top seven mistagged words, in terms of absolute numbers of errors, in Table 7. Although the base taggers have been shown (in Section 4.2) to produce different errors, we see that they do tend to make errors on the same words, as the five top-sevens together contain only nine words.

A high number of errors for a word is due to a combination of tagging difficulty and frequency. Examples of primarily difficult words are *much* and *more*. Even though they have relatively low frequencies, they are ranked high on the error lists. Words whose high error rate stems from their difficulty can be recognized by their high error percentage scores. Examples of words whose high error rate stems from their frequency are *to* and *in*. The error percentages show that these two words are actually tagged surprisingly well, as *to* is usually quoted as a tough case and for *in* the taggers have to choose between 14 possible tags. The first place on the list is taken by *as*, which has both a high frequency and a high difficulty level (it is also the most ambiguous word with 17 possible tags in LOB).

Table 7 shows yet again that there are clear differences between the base taggers, providing the opportunity for effective combination. For all but one word, *in*, the combiner manages to improve on the best tagger for that specific word. If we compare to the overall best tagger, HMM, the improvements are sometimes spectacular. This is

Table 8
Confusion rates for the tag pairs most often confused. For each pair (tagger, correct), we first take the two possible confusion directions separately and list the corresponding error list ranks (rank) and absolute number of errors (err) for the four base taggers and for WPDV(Tags+Context). Then we list the same information for the pair as a whole, i.e., for the two directions together.

		MXP		HMM		MBT		TBL		WPDV(T+C)	
Tagger	Correct	rank	err	rank	err	rank	err	rank	err	rank	err
VBN	VBD	6	**92**	1	154	1	205	1	236	3	102
VBD	VBN	3	118	3	117	3	152	3	149	4	**100**
	pair		210		271		357		385		**202**
JJ	NN	2	132	2	150	2	168	2	205	2	**109**
NN	JJ	1	153	6	**75**	4	148	4	148	1	110
	pair		285		225		316		353		**219**
IN	CS	4	105	4	93	5	122	8	97	5	**79**
CS	IN	10	55	7	70	10	64	6	122	8	**48**
	pair		160		163		186		219		**127**
NN	VB	5	98	5	78	6	116	5	132	6	**59**
VB	NN	25	**28**	14	45	12	60	7	100	15	35
	pair		126		123		176		232		**94**
IN	RP	7	59	10	61	7	99	12	83	7	**50**
RP	IN	24	**30**	18	38	27	34	21	42	18	**30**
	pair		89		99		133		125		**80**

of course especially the case where HMM has particular difficulties with a word, e.g., *about* with a 46.3% reduction in error rate, but in other cases as well, e.g., *to* with a 32.2% reduction, which is still well above the overall error rate reduction of 24.3%.

5.2 Specific Tags

We can also abstract away from the words and simply look at common word class confusions, e.g., a token that should be tagged VBD (past tense verb) is actually tagged VBN (past participle verb). Table 8 shows the tag confusions that are present in the top seven confusion list of at least one of the systems (again the four base taggers and WPDV(Tags+Context) used on LOB). The number on the right in each system column is the number of times the error was made and the number on the left is the position in the confusion list. The rows marked with tag values show the individual errors.[26] In addition, the "pair" rows show the combined value of the two inverse errors preceding it.[27]

As with the word errors above, we see substantial differences between the base taggers. Unlike the situation with words, there are now a number of cases where base taggers perform better than the combiner. Partly, this is because the base tagger is outvoted to such a degree that its quality cannot be maintained, e.g., NN → JJ. Furthermore, it is probably unfair to look at only one half of a pair. Any attempt to decrease the number of errors of type X → Y will tend to increase the number of errors of type Y → X. The balance between the two is best shown in the "pair" rows, and

26 The tags are: CS = subordinating conjunction, IN = preposition, JJ = adjective, NN = singular common noun, RP = adverbial particle, VB = base form of verb, VBD = past tense of verb, VBN = past participle.
27 RP → IN is not actually in any top seven, but has been added to complete the last pair of inverse errors.

Table 9
Precision and recall for tags involved in the tag pairs most often confused. For each tag, we list the percentage of tokens in the test set that are tagged with that tag (%test), followed by the precision (Prec) and recall (Rec) values for each of the systems.

		MXP	HMM	MBT	TBL	WPDV(T+C)
Tag	%test	Prec/Rec	Prec/Rec	Prec/Rec	Prec/Rec	Prec/Rec
CS	1.48	92.69/90.69	90.14/91.10	89.46/89.05	84.85/91.51	**93.11/93.38**
IN	10.57	97.58/98.95	97.83/98.59	97.14/98.17	97.33/97.62	**98.37/99.03**
JJ	5.58	94.52/94.55	94.07/95.61	92.79/94.38	90.66/94.06	**95.64/96.00**
NN	13.11	96.68/97.85	**97.91**/97.24	96.59/97.22	96.00/96.31	97.66/**98.25**
RP	0.79	95.74/91.82	94.78/92.27	95.26/88.84	93.05/90.28	**95.95/94.14**
VB	2.77	98.04/95.55	97.95/95.99	96.79/94.55	95.09/93.36	**98.13/97.06**
VBD	2.17	94.20/**95.22**	94.23/93.06	92.48/90.29	91.74/87.40	**95.26**/95.14
VBN	2.30	94.07/93.29	90.93/93.37	89.59/90.54	87.09/90.99	**94.25/94.50**

Table 10
A comparison of benchmark consistency on a small sample of WSJ and LOB. We list the reasons for differences between WPDV(Tags+Context) output and the benchmark tagging, both in terms of absolute numbers and percentages of the whole test set.

	WSJ		LOB	
	tokens	%	tokens	%
Tagger wrong, benchmark right	250	1.97	200	1.75
Benchmark wrong, tagger right	90	0.71	11	0.10
Both wrong	7	0.06	1	0.01
Benchmark left ambiguous, tagger right	2	0.02	–	–

here the combiner is again performing excellently, in all cases improving on the best base tagger for the pair.

For an additional point of view, we show the precision and recall values of the systems on the same tags in Table 9, as well as the percentage of the test set that should be tagged with each specific tag. The differences between the taggers are again present, and in all but two cases the combiner produces the best score for both precision and recall. Furthermore, as precision and recall form yet another balanced pair, that is, as improvements in recall tend to decrease precision and vice versa, the remaining two cases (NN and VBD), can be considered to be handled quite adequately as well.

5.3 Effects of Inconsistency

Seeing the rather bad overall performance of the combiners on WSJ, we feel the need to identify a property of the WSJ material that can explain this relative lack of success. A prime candidate for this property is the allegedly very low degree of consistency of the WSJ material. We can investigate the effects of the low consistency by way of comparison with the LOB data set, which is known to be very consistent.

We have taken one-tenth of the test sets of both WSJ and LOB and manually examined each token where the WPDV(Tags+Context) tagging differs from the benchmark tagging. The first indication that consistency is a major factor in performance is found in the basic correctness information, given in Table 10. For WSJ, there is a much higher percentage where the difference in tagging is due to an erroneous tag in the benchmark. This does not mean, however, that the tagger should be given a higher accuracy score, as it may well be that the part of the benchmark where tagger and

benchmark do agree contains a similar percentage of benchmark errors. It does imply, though, that the WSJ tagging contains many more errors than the LOB tagging, which is likely to be detrimental to the derivation of automatic taggers.

The cases where the tagger is found to be wrong provide interesting information as well. Our examination shows that 109 of the 250 erroneous tags occur in situations that are handled rather inconsistently in the corpus.

In some of these situations we only have to look at the word itself. The most numerous type of problematic word (21 errors) is the proper noun ending in *s*. It appears to be unclear whether such a word should be tagged NNP or NNPS. When taking the words leading to errors in our 1% test set and examining them in the training data, we see a near even split for practically every word. The most frequent ones are *Securities* (146 NNP vs. 160 NNPS) and *Airlines* (72 NNP vs. 83 NNPS). There are only two very unbalanced cases: *Times* (78 NNP vs. 6 NNPS) and *Savings* (76 NNP vs. 21 NNPS). A similar situation occurs, although less frequently, for common nouns, for example, *headquarters* gets 67 NN and 21 NNS tags.

In other cases, difficult words are handled inconsistently in specific contexts. Examples here are *about* in cases such as *about 20* (405 IN vs. 385 RB) or *about $20* (243 IN vs. 227 RB), *ago* in cases such as *years ago* (152 IN vs. 410 RB) and *more* in *more than* (558 JJR vs. 197 RBR).

Finally, there are more general word class confusions, such as adjective/particle or noun/adjective in noun premodifying positions. Here it is much harder to provide numerical examples, as the problematic situation must first be recognized. We therefore limit ourselves to a few sample phrases. The first is *stock-index*, which leads to several errors in combinations like *stock-index futures* or *stock-index arbitrage*. In the training set, *stock-index* in premodifying position is tagged JJ 64 times and NN 69 times. The second phrase *chief executive officer* has three words so that we have four choices of tagging: JJ-JJ-NN is chosen 90 times, JJ-NN-NN 63 times, NN-JJ-NN 33 times, and NN-NN-NN 30 times.

Admittedly, all of these are problematic cases and many other cases are handled quite consistently. However, the inconsistently handled cases do account for 44% of the errors found for our best tagging system. Under the circumstances, we feel quite justified in assuming that inconsistency is the main cause of the low accuracy scores.[28]

5.4 Size of the Training Set

The most important result that has undergone a change between van Halteren, Zavrel, and Daelemans (1998) and our current experiments is the relative accuracy of TagPair and stacked systems such as MBL. Where TagPair used to be significantly better than MBL, the roles are now well reversed. It appears that our hypothesis at the time, that the stacked systems were plagued by a lack of training data, is correct, since they can now hold their own. In order to see at which point TagPair is overtaken, we have trained several systems on increasing amounts of training data from LOB.[29] Each increment is one of the 10% training corpus parts described above. The results are shown in Figure 5.

28 Another property that might contribute to the relatively low scores for the WSJ material is the use of a very small tagset. This makes annotation easier for human annotators, but it provides much less information to the automatic taggers and combiners. It may well be that the remaining information is insufficient for the systems to discover useful disambiguation patterns in. Although we cannot measure this effect for WSJ, because of the many differences with the LOB data set, we feel that it has much less influence than the inconsistency of the WSJ material.

29 Only combination uses a variable number of parts. The base taggers are always trained on the full 90%.

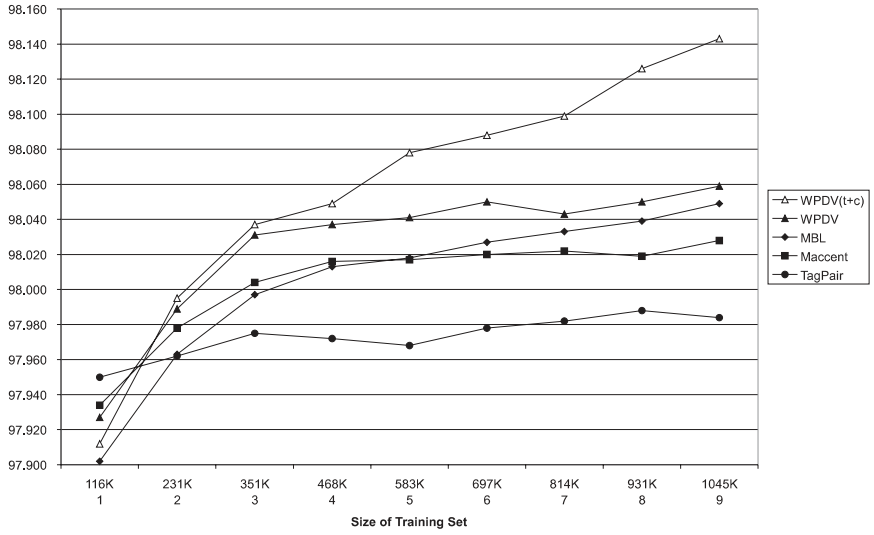

Figure 5
The accuracy of combiner methods on LOB as a function of the number of tokens of training material.

TagPair is only best when a single part is used (as in the earlier experiments). After that it is overtaken and quickly left behind, as it is increasingly unable to use the additional training data to its advantage.

The three systems using only base tagger outputs have comparable accuracy growth curves, although the initial growth is much higher for WPDV. The curves for WPDV and Maccent appear to be leveling out towards the right end of the graph. For MBL, this is much less clear. However, it would seem that the accuracy level at 1M words is a good approximation of the eventual ceiling.

The advantage of the use of context information becomes clear at 500K words. Here the tags-only systems start to level out, but WPDV(Tags+Context) keeps showing a constant growth. Even at 1M words, there is no indication that the accuracy is approaching a ceiling. The model seems to be getting increasingly accurate in correcting very specific contexts of mistagging.

5.5 Interaction of Components

Another way in which the amount of input data can be varied is by taking subsets of the set of component taggers. The relation between the accuracy of combinations for LOB (using WPDV(Tags+Context)) and that of the individual taggers is shown in Table 11. The first three columns show the combination, the accuracy, and the improvement in relation to the best component. The other four columns show the further improvement gained when adding yet another component.

The most important observation is that every combination outperforms the combination of any strict subset of its components. The difference is always significant, except in the cases MXP+HMM+MBT+TBL vs. MXP+HMM+MBT and HMM+MBT+TBL vs. HMM+MBT.

We can also recognize the quality of the best component as a major factor in the quality of the combination results. HMM and MXP always add more gain than MBT, which always adds more gain than TBL. Another major factor is the difference in

Table 11
WPDV(Tags+Context) accuracy measurements for various component tagger combinations. For each combination, we list the tagging accuracy (Test), the error reduction expressed as a percentage of the error count for the best component base tagger ($\Delta_{Err}(best)$) and any subsequent error reductions when adding further components (Gain).

Combination	Test	$\Delta_{Err}(best)$	Gain +TBL	Gain +MBT	Gain +MXP	Gain +HMM
TBL	96.37	–	–	29.1	**40.2**	38.9
MBT	97.06	–	12.5	–	**28.4**	26.0
MBT+TBL	97.43	12.5 (MBT)	–	–	**20.6**	17.2
MXP	97.52	–	12.3	15.0	–	**16.2**
HMM	97.55	–	9.5	11.3	**15.3**	–
HMM+TBL	97.78	9.5 (HMM)	–	4.0	**11.8**	–
HMM+MBT	97.82	11.3 (HMM)	2.0	–	**13.7**	–
MXP+TBL	97.83	12.3 (MXP)	–	6.0	–	**9.9**
HMM+MBT+TBL	97.87	13.1 (HMM)	–	–	**12.9**	–
MXP+MBT	97.89	15.0 (MXP)	3.0	–	–	**10.8**
MXP+HMM	97.92	15.3 (HMM)	5.7	**9.6**	–	–
MXP+MBT+TBL	97.96	17.6 (MXP)	–	–	–	**9.1**
MXP+HMM+TBL	98.04	20.1 (HMM)	–	**5.2**	–	–
MXP+HMM+MBT	98.12	23.4 (HMM)	**1.1**	–	–	–
MXP+HMM+MBT+TBL	98.14	24.3 (HMM)	–	–	–	–

language model. MXP, although having a lower accuracy by itself than HMM, yet leads to better combination results, again witnessed by the Gain columns. In some cases, MXP is even able to outperform pairs of components in combination: both MXP+MBT and MXP+HMM are better than HMM+MBT+TBL.

5.6 Effects of Granularity

The final influence on combination that we measure is that of the granularity of the tagset, which can be examined with the highly structured Wotan tagset. Part of the examination has already taken place above, as we have added the WotanLite tagset, a less granular projection of Wotan. As we have seen, the WotanLite taggers undeniably have a much higher accuracy than the Wotan ones. However, this is hardly surprising, as they have a much easier task to perform. In order to make a fair comparison, we now measure them at their performance of the same task, namely, the prediction of WotanLite tags. We do this by projecting the output of the Wotan taggers (i.e., the base taggers, WPDV(Tags), and WPDV(Tags+Context)) to WotanLite tags. Additionally, we measure all taggers at the main word class level, i.e., after the removal of all attributes and ditto tag markers.

All results are listed in Table 12. The three major horizontal blocks each represent a level at which the correctness of the final output is measured. Within the lower two blocks, the three rows represent the type of tags used by the base taggers. The rows for Wotan and WotanLite represent the actual taggers, as described above. The row for BestLite does not represent a real tagger, but rather a virtual tagger that corresponds to the best tagger from among Wotan (with its output projected to WotanLite format) and WotanLite. This choice for the best granularity is taken once for each system as a whole, not per individual token. This leads to BestLite being always equal to WotanLite for TBL and MBT, and to projected Wotan for MXP and HMM.

The three major vertical blocks represent combination strategies: no combination, combination using only the tags, and combination using tags and direct context. The two combination blocks are divided into three columns, representing the tag level

Table 12
Accuracy for base taggers and different levels combiners, as measured at various levels of granularity. The rows are divided into blocks, each listing accuracies for a different comparison granularity. Within a block, the individual rows list which base taggers are used as ingredients in the combination. The columns contain, from left to right, the accuracies for the base taggers, the combination accuracies when using only tags (WPDV(Tags)) at three different levels of combination granularity (Full, Lite, and Main) and the combination accuracies when adding context (WPDV(Tags+Context)), at the same three levels of combination granularity.

	Base Taggers				WPDV(Tags)			WPDV(Tags+Context)		
	TBL	MBT	MXP	HMM	Full	Lite	Main	Full	Lite	Main
Measured as Wotan Tags										
Wotan	–	89.78	91.72	92.06	92.83	–	–	93.03	–	–
Measured as WotanLite Tags										
Wotan	–	94.56	95.71	95.98	96.50	96.49	–	96.53	96.54	–
WotanLite	94.63	94.92	95.56	95.26	–	96.32	–	–	96.42	–
BestLite	94.63	94.92	95.71	95.98	–	96.58	–	–	96.64	–
Measured as Main Word Class Tags										
Wotan	–	96.55	97.23	97.54	97.88	97.87	97.85	97.88	97.89	97.91
WotanLite	96.37	96.76	97.12	96.96	–	97.69	97.71	–	97.76	97.77
BestLite	96.37	96.76	97.23	97.54	–	97.91	97.90	–	97.94	97.93

at which combination is performed, for example, for the Lite column the output of the base taggers is projected to WotanLite tags, which are then used as input for the combiner.

We hypothesized beforehand that, in general, the more information a system can use, the better its results are. Unfortunately, even for the base taggers, reality is not that simple. For both MXP and HMM, the Wotan tagger indeed yields a better WotanLite tagging than the WotanLite tagger itself, thus supporting the hypothesis. On the other hand, the results for MBT do not confirm this, as here the WotanLite tagger is more accurate. However, we have already seen that MBT has severe problems in dealing with the complex Wotan data. Furthermore, the lowered accuracy of the MBL combiners when provided with words (see Section 4.3) also indicate that memory-based learning sometimes has problems in coping with a surplus of information. This means that we have to adjust our hypothesis: more information is better, but only up to the point where the wealth of information overwhelms the machine learning system. Where this point is found obviously differs for each system.

For the combiners, the situation is rather inconclusive. In some cases, especially for WPDV(Tags), combining at a higher granularity (i.e., using more information) produces better results. In others, combining at a lower granularity works better. In all cases, the difference in scores between the columns is extremely small and hardly supports any conclusions either way. What is obviously much more important for the combiners is the quality of the information they can work with. Here, higher granularity on the part of the ingredients is preferable, as combiners based on Wotan taggers perform better than those based on WotanLite taggers,[30] and ingredient performance seems to be even more useful, as BestLite yields yet better results in all cases.

30 However, this comparison is not perfect, as the combination of Wotan tags does not include TBL. On the one hand, this means the combination has less information to go on and we should hence be even more impressed with the better performance. On the other hand, TBL is the lowest scoring base tagger, so maybe the better performance is due to not having to cope with a flawed ingredient.

Table 13
A comparison of our results for WSJ with those by Brill and Wu (1998).

Brill and Wu		Our Experiments	
Training/Test Split	80/20	Training/Test Split	90/10
Unigram	93.26	LexProb	94.57
Trigram	96.36	TnT	96.63
–		MBT	96.41
Transformation	96.61	Transformation	96.28
Maximum Entropy	96.83	Maximum Entropy	96.88
Transformation-based combination	97.16	WPDV(Tags+Context)	97.23
Error rate reduction	10.4%	Error rate reduction	11.3%

6. Related Research

Combination of ensembles of classifiers, although well-established in the machine learning literature, has only recently been applied as a method for increasing accuracy in natural language processing tasks. There has of course always been a lot of research on the combination of different methods (e.g., knowledge-based and statistical) in hybrid systems, or on the combination of different information sources. Some of that work even explicitly uses voting and could therefore also be counted as an ensemble approach. For example, Rigau, Atserias, and Agirre (1997) combine different heuristics for word sense disambiguation by voting, and Agirre et al. (1998) do the same for spelling correction evaluation heuristics. The difference between single classifiers learning to combine information sources, i.e., their input features (see Roth [1998] for a general framework), and the combination of ensembles of classifiers trained on subsets of those features is not always very clear anyway.

For part-of-speech tagging, a significant increase in accuracy through combining the output of different taggers was first demonstrated in van Halteren, Zavrel, and Daelemans (1998) and Brill and Wu (1998). In both approaches, different tagger generators were applied to the same training data and their predictions combined using different combination methods, including stacking. Yet the latter paper reported much lower accuracy improvement figures. As we now apply the methods of van Halteren, Zavrel, and Daelemans (1998) to WSJ as well, it is easier to make a comparison. An exact comparison is still impossible, as we have not used the exact same data preparation and taggers, but we can put roughly corresponding figures side by side (Table 13). As for base taggers, the first two differences are easily explained: Unigram has to deal with unknown words, while LexProb does not, and TnT is a more advanced trigram system. The slight difference for Maximum Entropy might be explained by the difference in training/test split. What is more puzzling is the substantial difference for the transformation-based tagger. Possible explanations are that Brill and Wu used a much better parametrization of this system or that they used a different version of the WSJ material. Be that as it may, the final results are comparable and it is clear that the lower numbers in relation to LOB are caused by the choice of test material (WSJ) rather than by the methods used.

In Tufiş (1999), a single tagger generator is trained on different corpora representing different language registers. For the combination, a method called **credibility profiles** worked best. In such a profile, for each component tagger, information is kept about its overall accuracy, its accuracy for each tag, etc. In another recent study, Màrquez et al. (1999) investigate several types of ensemble construction in a decision tree learning framework for tagging specific classes of ambiguous words (as opposed

to tagging all words). The construction of ensembles was based on bagging, selection of different subsets of features (e.g., context and lexical features) in decision tree construction, and selection of different splitting criteria in decision tree construction. In all experiments, simple voting was used to combine component tagger decisions. All combination approaches resulted in a better accuracy (an error reduction between 8% and 12% on average compared to the basic decision tree trained on the same data). But as these error reductions refer to only part of the tagging task (18 ambiguity classes), they are hard to compare with our own results.

In Abney, Schapire, and Singer (1999), ADABOOST variants are used for tagging WSJ material. Component classifiers here are based on different information sources (subsets of features), e.g., capitalization of current word, and the triple "string, capitalization, and tag" of the word to the left of the current word are the basis for the training of some of their component classifiers. Resulting accuracy is comparable to, but not better than, that of the maximum entropy tagger. Their approach is also demonstrated for prepositional phrase attachment, again with results comparable to but not better than state-of-the-art single classifier systems. High accuracy on the same task is claimed by Alegre, Sopena, and Lloberas (1999) for combining ensembles of neural networks. ADABOOST has also been applied to text filtering (Schapire, Singer, and Singhal 1998) and text categorization (Schapire and Singer 1998).

In Chen, Bangalore, and Vijay-Shanker (1999), classifier combination is used to overcome the sparse data problem when using more contextual information in **supertagging**, an approach in which parsing is reduced to tagging with a complex tagset (consisting of partial parse trees associated with lexical items). When using pairwise voting on models trained using different contextual information, an error reduction of 5% is achieved over the best component model. Parsing is also the task to which Henderson and Brill (1999) apply combination methods with reductions of up to 30% precision error and 6% recall error compared to the best previously published results of single statistical parsers.

This recent research shows that the combination approach is potentially useful for many NLP tasks apart from tagging.

7. Conclusion

Our experiments have shown that, at least for the word class tagging task, combination of several different systems enables us to raise the performance ceiling that can be observed when using data-driven systems. For all tested data sets, combination provides a significant improvement over the accuracy of the best component tagger. The amount of improvement varies from 11.3% error reduction for WSJ to 24.3% for LOB. The data set that is used appears to be the primary factor in the variation, especially the data set's consistency.

As for the type of combiner, all stacked systems using only the set of proposed tags as features reach about the same performance. They are clearly better than simple voting systems, at least as long as there is sufficient training data. In the absence of sufficient data, one has to fall back to less sophisticated combination strategies. Addition of word information does not lead to improved accuracy, at least with the current training set size. However, it might still be possible to get a positive effect by restricting the word information to the most frequent and ambiguous words only. Addition of context information does lead to improvements for most systems. WPDV and Maccent make the best use of the extra information, with WPDV having an edge for less consistent data (WSJ) and Maccent for material with a high error rate (Wotan).

Although the results reported in this paper are very positive, many directions for research remain to be explored in this area. In particular, we have high expectations for the following two directions. First, there is reason to believe that better results can be obtained by using the probability distributions generated by the component systems, rather than just their best guesses (see, for example, Ting and Witten [1997a]). Second, in the present paper we have used disagreement between a fixed set of component classifiers. However, there exist a number of dimensions of disagreement (inductive bias, feature set, data partitions, and target category encoding) that might fruitfully be searched to yield large ensembles of modular components that are evolved to cooperate for optimal accuracy.

Another open question is whether and, if so, when, combination is a worthwile technique in actual NLP applications. After all, the natural language text at hand has to be processed by each of the base systems, and then by the combiner. Now none of these is especially bothersome at run-time (most of the computational difficulties being experienced during training), but when combining N systems, the time needed to process the text can be expected to be at least a factor $N+1$ more than when using a single system. Whether this is worth the improvement that is achieved, which is as yet expressed in percents rather than in factors, will depend very much on the amount of text that has to be processed and the use that is made of the results. There are a few clear-cut cases, such as a corpus annotation project where the CPU time for tagging is negligible in relation to the time needed for manual correction afterwards (i.e., do use combination), or information retrieval on very large text collections where the accuracy improvement does not have enough impact to justify the enormous amount of extra CPU time (i.e., do not use combination). However, most of the time, the choice between combining or not combining will have to be based on evidence from carefully designed pilot experiments, for which this paper can only hope to provide suggestions and encouragement.

Acknowledgments

The authors would like to thank the creators of the tagger generators and classification systems used here for making their systems available, and Thorsten Brants, Guy De Pauw, Erik Tjong Kim Sang, Inge de Mönnink, the other members of the CNTS, ILK, and TOSCA research groups, and the anonymous reviewers for comments and discussion.

This research was done while the second and third authors were at Tilburg University. Their research was done in the context of the Induction of Linguistic Knowledge (ILK) research program, supported partially by the Netherlands Organization for Scientific Research (NWO).
