Background and aims: We have recently reported that impaired adipose tissue (AT) lipid storage, but not altered lipolysis, contributes to increased fatty acid levels in type 2 diabetes (T2D). CDKN2C (Cyclin Dependent Kinase Inhibitor 2C) is a cell growth regulator that controls cell cycle progression and has previously been associated with beta-cell differentiation, adipogenesis and obesity. A recent integrative genome-wide analysis study (GWAS) also implicates CDKN2C as a putative effector gene associated with insulin resistance phenotypes, risk for T2D and impaired peripheral AT storage capacity. This study aims to explore CDKN2C as a possible mediator for lipid storage defects in T2D subjects.

Materials and methods: 20 control and 20 metformin-treated T2D (HbA1c 6.6 ± 0.3%, mean±SD) subjects were matched for gender (10M/10F), age (58 ± 11 vs 58 ± 9 y) and BMI (30.8 ± 4.6 vs 30.7 ± 4.9 kg/m^2). Subcutaneous AT (SAT) samples were obtained by abdominal needle biopsies to measure mRNA of genes related to lipid storage and adipogenesis. In vivo lipolysis was assessed during a 3 h-OGTT with plasma glycerol and free-fatty-acids (FFA) levels. Magnetic resonance imaging (MRI) was performed for body fat measurements.

Results: *CDKN2C* mRNA expression in SAT was down-regulated in the T2D group compared with the control group (P<0.05). In the T2D group, *CDKN2C* expression was negatively correlated with FFA AUC during OGTT (r=-0.57, P<0.01) and with glycemia and insulin resistance (HbA1C, glucose AUC during OGTT, QUICKI; all P<0.05). In addition, there was a negative association with WHR, visceral AT (VAT) volume, VAT/SAT ratio and liver fat percentage (P<0.01) in the T2D group, but no association with BMI was found. In the control group, only VAT volume (P=0.001) and VAT/SAT (P<0.05) were negatively correlated with *CDKN2C* expression. In multivariate analyses, VAT/SAT (st beta coeffi= -0.674, P<0.001) and FFA AUC (st beta coeffi = -0.486, P<0.001) were significantly associated with *CDKN2C* expression (P<0.001, adjusted R^2 for model=0.79) in the T2D group, suggesting a link between CDKN2C and higher circulating levels of FFA, as well as preferential fat deposition in visceral rather than subcutaneous stores. Furthermore, *CDKN2C* expression positively correlated with the expression of genes promoting lipid storage (e.g. *CIDEC*, *FASN*, *DGAT1/2*, *FABP4*, *PC, PPARG*, *LPL*, *LIPE*, *CD36*; all P<0.01). Look-up in GWAS databases showed that a common variant in *CDKN2C* (rs12855, C-allele) was nominally associated with lower body weight (P<0.001), BMI (P<0.01), but with higher HbA1c (P<0.001), WHR adjusted for BMI (P<0.01), and risk for T2D (P<0.001) and coronary artery disease (P<0.01). In publicly available datasets, CDKN2C is highly expressed in AT compared to other tissues (GEO database), and shows increasing expression during adipocyte differentiation (FANTOM5 database).

Conclusion: *CDKN2C* gene expression is down-regulated in T2D and is associated with elevated plasma fatty acids and visceral adiposity. Our findings suggest that CDKN2C might be an important regulator of lipid storage and fatty acid turnover. Its downregulation in T2D might contribute to insulin resistance, impaired SAT lipid storage and to redistribution of AT from subcutaneous to visceral depots.

Global protein profiling of visceral adipose tissue among type 2 diabetic and non-diabetic morbidly obese patients

B. Seyoum, Z. Yi;
Wayne State University, Detroit, USA.

Background and aims: The accumulation of visceral fat has been shown to be highly associated with increased risk of obesity, metabolic dysregulation and type 2 diabetes (T2D). Proteomic analysis of visceral fat from obese non-diabetic (Non-T2D) and obese T2D subjects might identify factors in visceral adipose tissue linked to diabetes.

Materials and methods: In this study, we used a straightforward label-free quantitative proteomics approach to analyze visceral fat tissue in type 2 diabetic and non-diabetic participants that are morbidly obese with body mass index above 40 kg/m2. A total of 18 biopsies, including 9 Non-T2D and 9 T2D, age, sex and BMI matched were analyzed.

Results: Proteomics analysis identified more than 1500 unique protein groups in our study with FDR at 0.01 and minimum 2 unique peptides. One hundred thirty-three protein groups show at least 2-fold differences between Non-T2D visceral fat and T2D visceral, including 53 protein groups with significant change (pglt 0.05). Of particular interest, we identified 6 proteins (Proteasomal ubiquitin receptor ADRM1, Signal recognition particle 14 kDa protein, Fatty acid synthase, Proteasome inhibitor PI31 subunit, Serine/threonine-protein kinase OSR1, and Switch-associated protein 70) with 4-7 fold increase in the visceral adipose tissue of patients with T2D when compared to viscera fat from non-diabetic controls. Pathway analysis for these 53 proteins indicated that multiple pathways in involved in oxidative stress, proten synthesis and degradation are significantly enriched, such as NRF2-mediated Oxidative Stress Response, mTOR Signaling, EIF2 Signaling and Protein Ubiquitination Pathway.

Conclusion: We have performed proteomics analysis on visceral fat tissues in non-T2D and T2D subjects, and identified new abnormality in multiple proteins and pathways in T2D visceral fat, which may increase our understanding of the pathogenesis of type 2 diabetes and insulin resistance.

Negative effect of exogenous methylglyoxal on metabolic changes in visceral adipose tissue of metabolic syndrome model

M. Hüttl[1], H. Malinska[1], I. Markova[1], O. Oliyarnyk[1], J. Trnovska[1], V. Škop[1], O. Šeda[2], L. Kazdova[1], M. Haluzík[1];
[1]Institute for Clinical and Experimental Medicine, Prague 4, [2]Institute of Biology and Medical Genetics, Charles University, Prague, Czech Republic.

Background and aims: Methylglyoxal (MG) is a highly reactive metabolite excessively produced in connection with metabolic disoders such as hyperglycaemia and dyslipidemia. Excessive dicarbonyl production contributes to metabolic and vascular changes in many tissues through participation in inflammatory processes, disturbed regulatory mechanisms and contribution to the development of organ complications. Recent studies suggest that MG accumulation in adipocytes may lead to structural and functional changes in adipose tissue. Here, we used transcriptomic analysis to investigate the effect of MG on metabolic changes in visceral adipose tissue of Hereditary Hypetriglyceridemic (HHTg) rats, a non-obese metabolic syndrome model with dyslipidemia, insulin resistance and ectopic lipid deposition.
Materials and methods: 5-month-old male HHTg rats were fed standard diet and treated with MG intragastrically (0.5 mg/kg b.wt., 3x/week) for 4 weeks. Commercial/ELISA kits, Multiplex Assay, HPLC-method and gass chromatography were used for analysis. Transcriptomic analysis was performed using microarray, gene expressions by RT-PCR.
Results: MG administration was associated with increased glyceamia (+23.8 %, $p<0.001$), insulinaemia (+109.3 %, $p<0.05$), cholesterolaemia (1.19 ± 0.07 *vs* 1.59 ± 0.99 mmol/l, $p<0.05$), and impaired glucose tolerance ($AUC_{0\text{-}120}$: + 8.2%, $p<0.05$). Compared to controls, MG increased serum levels of pro-inflammatory factors MCP-1 and TNF-alpha, while serum adiponectin and leptin levels were not affected. Adipose tissue insulin sensitivity, measured *ex vivo* according to basal and insulin-stimulated ^{14}C-U-glucose incorporation into lipids, was markedly impaired ($p<0.05$) after MG administration. MG-treated rats exhibited strongly impaired fatty acid composition in visceral adipose tissue phospholipids. The proportion of saturated fatty acids, especially palmitic (16:00) and myristic (14:00) acid, was significantly increased together with decreased proportion of PUFA n-3 ($p<0.001$) suggesting a possible negative influence on the membrane fluidity and insulin signaling. MG also significantly reduced relative mRNA expression of transcription factor *Nrf2* (-16.7%, p<0,01) which controls antioxidant and lipogenic genes and increased relative mRNA expression of pro-inflammatory factor *Mcp-1*. Comparative transcriptomic analysis identified 61 differently expressed genes (FDR<0.05) in visceral adipose tissue after MG administration. Network analyses revealed these genes to be overrepresented in insulin signaling regulation (*Irs1, Igf2, Ide*), lipid metabolism (*Nr1d1, Lpin1, Lrpap1*) and apoptosis (*Bcl6, Irs1, Tp53inp1*).
Conclusion: In a rodent model of metabolic syndrome, methylglyoxal administration markedly impaired insulin sensitivity and fatty acid composition of white adipose tissue and increased inflammatory parameters on both transcriptomic and metabolic level suggesting a possible role of MG in the induction of the features of metabolic syndrome.

7-ketocholesterol regulates inflammation in mesangial cells: potential role in diabetic nephropathy

Y. Watanabe, T. Yamaguchi, N. Ishihara, S. Tanaka, R. Oka, A. Rikitake, H. Imamura, Y. Sato, N. Ban, H. Kawana, M. Ohira, N. Shimizu, A. Saiki, I. Tatsuno;
Toho University Medical Center Sakura Hospital, Chiba, Japan.

Background and aims: In type 2 diabetes, it is known that oxysterol is greatly involved in various organ disorders and also in diabetic nephropathy. The concentration of 7-ketocholesterol (7-KCHO), which is representative of oxysterols, is reported to increase in the blood of patients with type 2 diabetes, and it is also suggested that 7-KCHO is involved in the development of diabetic nephropathy. However, molecular mechanism of 7-KCHO for the development of diabetic nephropathy has not been sufficiently elucidated. Interestingly, lipoxygenase (LOX) and cyclooxygenase (COX), those are enzymes of arachidonic cascade, are also reported to be involved in the development of diabetic nephropathy. In order to clarify the roles of 7-KCHO in diabetic nephropathy, we studied the effects of 7-KCHO on cytotoxicity, inflammatory gene expression of IL-1β and Il-6, and arachidonic cascade gene expression of LOX and COX using human mesangial cells (MCs).
Materials and methods: Human MCs were purchased from Lonza (Basel, Switzerland). We used the cells between the three and eighth passages. Cell viability was determined by the WST-8 assay. Reverse transcription polymerase chain reaction was performed to examine the expression of each message. Detection of intracellular ROS production was evaluated by flow cytometry.
Results: Although 10 or 30μM of 7-KCHO did not affect cell proliferation of MCs at 24 and 48 hours, COX-2, 12-LOX and IL-6 mRNA expression were significantly stimulated by 30μM of 7-KCHO at 24h, and the increment of IL-1β mRNA expression was observed 48h after the treatment. Importantly, 5-LOX and 15-LOX mRNA expression were not detected with or without the treatment of 7-KCHO. Reactive oxygen species (ROS) in MCs was assessed by flow cytometry. 7-KCHO 30 or 50μM induced a dose-dependent increment of ROS. In contrast, addition of N-acetylcysteine (NAC) 5mM caused a decrease in ROS production to inhibit the mRNA expression of COX-2, 12-LO, IL-6, and IL-1β.
Conclusion: These data demonstrated that 7-KCHO induces the increment of inflammatory gene expression of IL-1β and Il-6, and arachidonic cascade gene expression of LOX and COX in a ROS-dependent manner in MCs suggesting that ROS, 12-LOX, and COX-2 are related to interactivity and may also be partly involved in the mechanism of development of nephropathy. These findings may lead to elucidation of the new etiology of diabetic nephropathy.

Treatment with 4-phenylbutyrate prevents pancreatic amyloid formation in obese mice overexpressing human islet amyloid polypeptide

S. de Pablo[1,2], J. Montane[1,2], C. Castaño[1,2], J. Rodríguez-Comas[1,2], G. Alcarraz-Vizán[1,2], J.-M. Servitja[1,2], A. Novials[1,2];
[1]Diabetes and Obesity Research Laboratory, Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), [2]Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders (CIBERDEM), Barcelona, Spain.

Background and aims: Loss of β-cell mass and function during Type 2 Diabetes (T2D) has been associated to several stressors suffered by the pancreatic β cell, including misfolding and aggregation of human islet amyloid polypeptide (hIAPP) that leads to amyloid deposits. It has been previously demonstrated that the administration of the chemical chaperone 4-phenylbutyrate (PBA) prevents amyloid formation in islets overexpressing hIAPP cultured at high glucose concentrations. Furthermore, PBA improves glucose metabolism abnormalities in a mouse model of obesity. The aim of the present work was to determine whether in vivo administration of PBA was able to prevent amyloid deposition and ameliorate glucose metabolism in obese mice overexpressing hIAPP, which present impaired fasting glucose and amyloid deposits, two hallmarks of T2D.
Materials and methods: Obese and insulin-resistant A^{vy} mice were crossed with mice overexpressing hIAPP. Mice were treated with PBA

dissolved in drinking water (1g/kg/day) during 12 weeks. Glucose and insulin tolerance tests were performed before and after treatment. Insulin plasma levels were determined by ELISA. After sacrificing mice, pancreas was removed, fixed and stained against amyloid deposits with Thioflavin S.

Results: PBA treatment started at 8 weeks of age, when A^{vy}-hIAPP transgenic mice presented impaired fasting glucose, and were glucose intolerant compared to wild-type, A^{vy} and hIAPP littermates. After 12 weeks of treatment, PBA decreased severe fasting hyperglycemia (320 ±20.6 mg/dL *vs*. 180±22.5 mg/dL, p<0.0001) and showed a tendency to decrease hyperinsulinemia (1.83±0.44 ng/mL *vs*. 0.68±0.23 ng/mL) in A^{vy}-hIAPP transgenic mice. Furthermore, both impaired glucose tolerance and insulin resistance observed in double transgenic mice were improved when mice were treated with the chemical chaperone. Finally, PBA administration also prevented amyloid accumulation (25.24±1.28 % *vs*. 9.00±0.88 %, p<0.0001) and prevalence (80.18±7.49 % *vs*. 52.42 ±4.06 %, p<0.05) in pancreatic islets of A^{vy}-hIAPP transgenic mice.

Conclusion: PBA treatment decreased fasting glucose, improved glucose tolerance and insulin sensitivity and prevented amyloid deposition in pancreatic β cells in obese mice overexpressing human IAPP. These results suggest that PBA could be considered as a therapeutic strategy to treat islet dysfunction in T2D.

Visceral adipose tissue of healthy male mice shows active de novo lipogenesis during both short-term and long-term high-sugar feeding

C. Marques[1], J. Silva[2], I. Viegas[1], F. Martins[2], M.P. Macedo[2,3], J. Jones[1,3];
[1]Metabolic Control, Center for Neurosciences and Cell Biology, Coimbra, [2]MEDIR- Metabolic Diseases Research Group, CEDOC, Chronic Diseases Research Center, Lisbon, [3]APDP, Lisbon, Portugal.

Background and aims: High sugar feeding promotes NAFLD through the stimulation of de novo lipogenesis (DNL). Visceral adipose tissue (VAT) is also implicated in promoting NAFLD by delivering high amounts of free-fatty acids (FFA) into the liver via the portal vein. To date, it has been assumed that the majority of DNL activity fuelling NAFLD is hepatic, with only minor contributions from adipose tissue. We hypothesized that VAT DNL is upregulated by high sugar feeding thereby contributing to increased FFA spillover into the liver. To determine if this occurs during short or long-term sugar feeding, we measured DNL in mice whose diet was supplemented with sugar for a single night (short-term, ST) or for 24 weeks (long-term, LT).

Materials and methods: Five adult male C57BL/6 mice fed on standard chow over a 12/12 hr light/dark cycle were injected intraperitoneally with 3g/100g body weight 99.9% ^2H_2O containing 0.9% NaCl w/w at the start of the dark period. The drinking water was supplemented with 17.5% fructose (w/v) and 17.5% glucose and the mice then fed naturally overnight. At the end of the dark period, mice were sacrificed, visceral and epididymal adipose tissues (EAT) and livers were freeze-clamped and triglyceride from each tissue extracted and purified. A second group of 5 mice that had been given the same amount of glucose/fructose in their drinking water for a period of 24 weeks prior, were likewise administered with ^2H_2O. Body water and FA methyl ^2H enrichments and were measured by ^2H NMR. Fractional rates of fatty acid synthesis (FA-FSR) were calculated from the ratio of FA methyl ^2H-enrichments to body water.

Results: For ST mice, the FSR of VAT was 7.4±2.9%, while that of EAT was 1.1±0.3%, both being significantly less than that of liver (33.0 ±3.6%). For LT mice, the FSR of VAT, EAT and liver were identical to that of ST (7.4±2.8%, 2.3±0.3% and 31.6±4.8%, respectively). While VAT and EAT FSR were not significantly different from each other within each group, when compared over both ST and LT groups, FSR values for VAT were significantly higher compared to EAT (p = 0.028).

Conclusion: Following ^2H_2O administration, triglyceride fatty acids of VAT, EAT and liver became enriched with ^2H. Enrichment of VAT was 2-3 fold higher than that of EAT following both short-term and long-term sugar feeding. These results suggest that compared to EAT, VAT has an inherently higher capacity for DNL from dietary sugar. Thus, an increase in visceral fat depots during obesity may represent a significant extrahepatic capacity for DNL from dietary sugar that may significantly contribute to NAFLD.

Effect of exercise training on insulin resistance and adipose tissue macrophages in elderly women

M. Stepan[1,2], E. Krauzova[1,2], K. Dadova[3], B. Svobodova[1], V. Stich[1,2], L. Rossmeislova[1], M. Siklova[1];
[1]Departent for The Study of Obesity and Diabetes, Charles University, Third Faculty of Medicine, [2]Second Department of Internal Medicine, University Hospital Kralovske Vinohrady, [3]Charles University, Faculty of Physical Education and Sports, Prague, Czech Republic.

Background and aims: Aging is associated with a progressive increase of fat mass (FM) to fat free mass (FFM) ratio as well as redistribution of adipose tissue (AT). Such changes contribute to the development of low grade systemic inflammation and increased risk of metabolic diseases such as diabetes mellitus type 2. The studies performed with elderly people suggest that the risk of metabolic diseases may be ameliorated by physical activity, however the effects of exercise training on AT remain largely unexplored. Therefore, we aimed to determine whether regular physical activity improves peripheral insulin sensitivity and inflammatory status of AT expressed as relative content and phenotype of adipose tissue macrophages in elderly women.

Materials and methods: Two groups of elderly women (mean age 68 years ± 3 years) differing in physical activity level, i.e. a group of trained women (n= 12) and a group of sedentary women (n= 12) were recruited for the study. Fitness status was assessed by senior fitness tests (chair stand, arm curl, sit and reach and back scratch test) and a bicycle ergometry with determination of VO_2 max. We compared anthropometric parameters, biochemical profile, and the degree of insulin sensitivity (using a hyperinsulinaemic euglycemic clamp (HEC). The samples of subcutaneous abdominal AT obtained by needle biopsy were used for isolation of stromal vascular fraction cells that were subjected to flow cytometry analysis.

Results: Compared to sedentary group, the group of trained women had higher physical performance expressed by VO_2max (29.7 vs. 18.2 ml/kg/min, p<0.001) and in senior fitness tests trained women scored more often significantly above normal average values for senior population. Trained women had lower BMI (23.4 vs. 27.5, p = 0.003), percentage of FM (33.9 vs. 39.9%, p = 0.001), and higher FFM percentage (66 vs. 60 % p = 0.001). In the biochemical analysis the only significant difference was higher total and LDL cholesterol in trained group (total 6.3 vs. 5.4 mmol/l, p= 0.038 and LDL 4.0 vs. 3.0 mmol/l, p= 0.005). Insulin sensitivity determined as Glucose Disposal during HEC was higher in trained group (6.7 vs 4.9 mg/kg/min, p=0.035).The monocyte/macrophage population defined as CD45+/14+ cells, and its subpopulations expressing either CD40+, TLR2 or TLR4 antigens did not differ among the investigated groups, while the content of CD45/14/206+ macrophages was higher in AT of the sedentary women (66 vs. 47%, p= 0.013).Negative correlation between FM and Glucose Disposal (r = -0.695, p<0.001) and VO_2max (r = -0.669, p = <0.001) was observed. Percentage of CD45/14/206+ macrophages showed trend to positively correlate with fat mass (r = 0.416, p=0.06) and negatively correlate with insulin sensitivity (r = -0.423, p=0.056).

Conclusion: The higher physical performance of trained elderly women was associated with higher insulin sensitivity and lower abundance of

FM. However, our findings suggest that inflammatory status of AT is not markedly influenced by exercise training in elderly and it is more dependent on the percentage of FM.

The influence of physical activity on risk of cardiovascular disease in metabolic healthy obese people

J. Yu[1], S. Moon[1], C.-M. Oh[2], M.-K. Choi[3], H. Yu[1];
[1]Hallym University College of Medicine, Seoul, [2]School of Medicine CHA University, Bundang, [3]Hallym University College of Medicine, Chuncheon, Republic of Korea.

Background and aims: The metabolic outcomes of metabolically healthy obesity (MHO) remain controversial. The aim of the present study was to determine the effect of physical activity on the cardiovascular disease (CVD) outcomes of MHO.
Materials and methods: The study included participants who were followed for 10 years and recruited from the Korean Health and Genome Study (KoGES), a population-based cohort study. Participants with previously recorded CVDs or cancer, or who had received steroids or anticoagulants at baseline were excluded.
Results: A total of 8144 participants (3,942 men and 4,202 women) fulfilled inclusion criteria. In a multivariate Cox regression model adjusted for age and sex, MHO participants were not at elevated risk of CVD compared with their metabolically healthy non-obese (MHNO) counterparts (HR, 1.28; 95% CI, 0.96- 1.71), although both the non-obese (HR, 1.50; 95% CI, 1.19-1.90) and obese (HR, 1.85; 95% CI, 1.48- 2.30) participants with metabolic abnormalities were at elevated risk. However, in the subgroup analysis by physical activity, physically inactive MHO participants had a significantly higher HR for CVD events compared to active MHNO participants (HR, 1.54; 95% CI, 1.03-2.30), while active MHO participants were not at elevated risk (HR, 1.15; 95% CI, 0.70-1.89)
Conclusion: In MHO participants, only physically inactive participants had a significantly increased risk of CVD compared to physically active MHNO participants.

Hazard ratios for CVD events according to obesity, metabolic health status and physical activity.

	Model1		Model2	
	HR (95% CI)	P	HR (95% CI)	P
MHNO with active PA	1 (Reference)		1 (Reference)	
MHNO with inactive PA	1.129 (0.794-1.607)	0.498	1.112 (0.781-1.582)	0.557
MHO with active PA	1.147 (0.697-1.886)	0.590	1.147 (0.697-1.888)	0.590
MHO with inactive PA	1.536 (1.026-2.298)	0.037	1.524 (1.018-2.281)	0.041

Cognitive behavioural group therapy to prevent weight regain in type 2 diabetes: a randomised controlled trial

K.A.C. Berk[1], H. Buijks[2], A.J.M. Verhoeven[1], M.T. Mulder[1], B. Ozcan[1], A. van t Spijker[2], R. Timman[2], J.J. van Busschbach[2], E.J.G. Sijbrands[1];
[1]Internal Medicine, Section of Pharmacology, Vascular and Metabolic Diseases, Erasmus Medical Center, [2]Psychiatry, Section of Medical Psychology and Psychotherapy, Erasmus Medical Center, Rotterdam, Netherlands.

Background and aims: Current weight loss programs for overweight and obese patients with type 2 diabetes are not effective in the long term due to regain of weight. The aim of this study was to determine the 2-years efficacy of cognitive behavioral group therapy (CBGT) in preventing long-term weight regain after a very low-calorie diet in patients with type 2 diabetes. The secondary objective was to determine the effect of CBGT on cardiovascular risk factors and psychological wellbeing.
Materials and methods: The Prevention Of Weight Regain (POWER) trial was a single center, parallel-group, randomized controlled trial, conducted from March 2010-May 2015. Participants were recruited from the outpatient diabetes clinic of a university hospital. Of the 276 eligible patients with type 2 diabetes and BMI ≥27 kg/m^2, 206 agreed to participate and started with the very low-calorie diet. The 158 participants who achieved ≥5% weight loss by 8 weeks of dieting were included in the trial. Subsequently, the participants were randomly assigned to the intervention or control group. Participants in the control group received usual care only, which consisted of regular scheduled visits to the treating internist and diabetes nurse. Participants in the intervention group received CBGT on top of usual care. The CBGT consisted of 17 group sessions led by a trained psychologist, aimed at restructuring dysfunctional cognitions on lifestyle, weight, body perception and relapse. The primary outcomes were the between-group differences in (1) body weight at two years and (2) weight regain from randomization to two years of follow-up. Secondary outcomes were the between-group differences in HbA1c, insulin dose, lipids, depression, anxiety, self-esteem, quality of life, fatigue, eating disorders and physical activity. Data were analyzed by linear mixed modeling (intention to treat as well as per-protocol).
Results: The between-group difference in body weight at two years was -1.2 [95%CI, -7.7 to 5.3] kg (p=0.717). The between-group difference in weight regain was -0.7 [95%CI, -3.1 to 1.6] kg (p=0.556). Similar results were found in the per-protocol analyses. None of the secondary outcomes differed between the two groups.
Conclusion: CBGT after diet-induced weight loss did not prevent weight regain or improve cardiovascular risk factors or psychological wellbeing better than usual care alone in obese patients with type 2 diabetes. Our results provide no scientific justification to offer CBGT on top of usual care to optimize the effect of weight loss dieting in obese patients with type 2 diabetes.

Beneficial effects of carotid sinus nerve resection on obesity co-morbidities

B.F. Melo, C.S. Prego, M.C. Correia, M.D. Cabral, J.F. Sacramento, S.V. Conde;
CEDOC, NOVA Medical School, Faculdade de Ciências Médicas da Universidade NOVA de Lisboa, Lisbon, Portugal.

Background and aims: Obesity is a major cause of cardiovascular and metabolic disturbances, contributing to significant morbidity and mortality worldwide. The therapeutic options to treat this pandemic are clearly scarce. Our group has recently proposed a new role for the carotid body (CB), a chemoreceptor organ classically defined as an O_2 sensor, in the pathogenesis of metabolic syndromes. We demonstrated that abolishment of CB activity, through the resection of its sensitive nerve, the carotid sinus nerve (CSN), prevents and reverses insulin resistance and glucose

intolerance in animal models of metabolic diseases. Herein, we investigated the effects of carotid sinus nerve resection on weight loss and the pathophysiological mechanisms that can contribute to these beneficial results.

Materials and methods: Experiments were performed in 9 weeks male *Wistar* rats. Animals were submitted to 10 weeks of high-fat diet (HF) (5.1Kcal/g) or to a standard diet (2.85Kcal/g). After 10 weeks of diet, animals were submitted to bilateral carotid sinus nerve (CSN) resection. A sham procedure was applied to control groups. CSN resection was confirmed by the absence of ventilatory responses to hypoxia by pletismography in conscious animals. After CSN resection, animals were kept under the respective diets and insulin sensitivity, glucose homeostasis, caloric intake and body weight were monitored. At a terminal experiment animals were anaesthetised with pentobarbital (60mg/kg i.p.) and white and brown adipose tissue were collected, weighted and store for analysis of proteins involved in adipose tissue metabolism.

Results: As expected, HF diet produced an increase in weight gain (weight controls=296.5±64.3 g, weight HF=365.8±87.2 g). CSN resection decreased weight gain by ≅13% in control animals and by ≅ 40% in HF animals, an effect that is not due to a decreased caloric intake (control sham=254.57±21.78 Kcal/day/Kg; control with CSN resection =262.50 ±62.11 Kcal/day/Kg; HF sham=301.74±49.12 Kcal/day/Kg; HF with CSN resection=287.20±84.65 Kcal/day/Kg). HF diet induced whole-body insulin resistance (K_{ITT} controls=4.52±1.18 %glucose/min; K_{ITT} HF=1.49±1.26 %glucose/min) and glucose intolerance (AUC glucose excursion curve controls=17059±1506 mg/dlxmin; AUC glucose excursion curve HF =22036±3206 mg/dlxmin). CSN resection restored insulin sensitivity (K_{ITT} before surgery=1.49±1.26 %glucose/min; K_{ITT} 3 weeks after CSN resection= 4.974±1.30%glucose/min) and glucose homeostasis (AUC HF before surgery=22036±3206 mg/dlxmin; AUC HF 3 weeks post-CSN resection =19423±1498 mg/dlxmin). Also, CSN resection in HF animals decreased the total fat amount of the animals by 38% and perinephric and subcutaneous adipose tissues by, 49 and 39%, respectively.

Conclusion: We can conclude that abolishment of CB activity through CSN resection positively impacts weight gain, an effect that was accompanied by a decrement in total, perinephric and subcutaneous adipose tissues and not attributable to alterations in caloric intake. We suggest that modulation of CB activity can be a therapeutic target for the treatment of obesity.*Both authors have contributed equally to this work.

The effect of transcranial direct current stimulation associated with hypocaloric diet in subjects with different degrees of glucose tolerance

C. de Araujo[1], R.C. Fitz[1], D.A. Nogara[2], J.P.U. Osorio[2], C. Rodrigues[3], P. Schestatsky[4], F. Gerchman[1];
[1]Endocrine Division, Hospital de Clínicas de Porto Alegre, Federal Univerity of Rio Grande do Sul, Porto Alegre, [2]Federal Univerity of Rio Grande do Sul, Porto Alegre, [3]Unilasalle University, Canoas, [4]Neurology Service, Hospital de Clínicas de Porto Alegre, Federal Univerity of Rio Grande do Sul, Porto Alegre, Brazil.

Background and aims: Non-adherence to lifestyle modifications is an important determinant of failure to treat obesity. The dorsolateral prefrontal cortex (DLPFC) plays an important role in appetite and food intake regulation and may be a target for electric brain stimulation, a new treatment modality that has been used in diseases such as depression and drug addiction. The aim of this study was to test the effect of active anodal tDCS (a-tDCS) over the right DLPFC (rDLPFC) associated with a hypocaloric diet on weight loss in overweight or obese adults with different degrees of glucose tolerance.

Materials and methods: In this randomized, placebo-controlled, double-blind pilot study, 9 overweight or obese adults with different degrees of glucose tolerance (NGT: normal glucose tolerance, IGM: impaired glucose metabolism, T2D: type 2 diabetes), aged 20-50 years, completed a 4-week (20 sessions) of fixed-dose tDCS (2mA, 20 min). Subjects were randomized in a 1:1 ratio to receive one of two types of intervention: (1) active a-tDCS + hypocaloric diet (*Active*), or (2) sham a-tDCS + hypocaloric diet (*Sham*), both delivered over the rDLPFC. To determine body mass index (BMI, in Kg/m²), body weight (BW, in kg) and height (m) was assessed at baseline (t_0), and BW at visits 5 (t_5), 10 (t_{10}), 15 (t_{15}), 20 (t_{20}), and at the last visit of the study (t_F); blood samples was collected for an 2-h OGTT, a standard 4-h meal tolerance test ([MTT], glucose and insulin measurements) and HbA_{1c} determination at t_0 and t_F. The self-reported Beck Depression Inventory ([BDI], score range 0-63, higher scores indicating worse mood) questionnaire was administered at t_0 and t_F. Changes in BMI and BW were analyzed with generalized estimating equations (GEE) and Bonferroni post-hoc testing for normally distributed continuous variables; descriptive statistics are reported as means±SD or %.

Results: 9 subjects completed the study on this interim analysis (female 66.7%, obese 66.7%, mean age 38.3±4.8 years, BMI 30.9±2.5 kg/m², IGM 11.1%, T2D 11.1%). Reduction of BW and BMI was respectively greater in the *Active* than in the *Sham* group (GEE, p=0.009 and p<0.001). Weight changes over the time (t_F-t_0; mean±SE) were -2.8±0.5 Kg for *Active* and -1.7±0.8 Kg for *Sham*. Changes over the time in BMI (t_F-t_0; mean±SE) were -1.0±0.2 kg/m² in the *Active* group and -0.6±0.3 kg/m² in the *Sham* group. Although there was a greater reduction in the AUC for glucose (GEE: p=0.091) and insulin (GEE: p=0.062) from t_0 to t_F in the *Active* vs *Sham* group during the MTT, these changes did not reach statistical differences.There was a greater reduction in *Active* compared to *Sham* in BDI scores over the 4-week intervention (mean±SE; *Active*: t_0=10.0±2.2; t_F=2.2±1.2 vs *Sham*: t_0=6.2±1.4; t_F=6.0±1.6, GEE, p=0.016).

Conclusion: This preliminary analysis suggests that repetitive active a-tDCS may be a promising non-invasive technique that could be used to increase weight reduction and improve BDI scores in overweight or obese individuals with different degrees of glucose tolerance on a low-calorie diet.

Effect of T cell specific PPARβ overexpression on diet-induced obesity and its associated inflammation and insulin resistance

G. Le Menn, B. Sibille, J. Murdaca, A.-S. Rousseau, R. Squillace, P. Grimaldi, I. Mothe-Satney, J.G. Neels;
Inserm U1065, C3M, Nice, France.

Background and aims: It is now recognized that obesity-induced chronic inflammation is central to the development of many obesity-associated pathologies such as type-2 diabetes. Obesity-induced T cell changes in adipose tissue (AT) has been linked to metabolic phenotypes of obese subjects. Interestingly, it has also been shown that T cell differentiation and responses may be altered by modulating their metabolism. Accordingly, we have recently shown that Peroxisome-Proliferator-Activated-Receptor beta (PPARβ) increases lipid metabolism in T cells, which changes T cell homeostasis. Our objectives were to study the consequences of changes in T cell populations induced by T cell-specific PPARβ overexpression on obesogen high fat diet (HFD)-induced AT inflammation and the subsequent development of insulin resistance (IR).
Materials and methods: We created transgenic mice that overexpress PPARβ specifically in T cells (Tg T-PPARβ mice) using the Cre-Lox system. 12-week old male mice (16 Tg T-PPARβ and 17 control Lck-Cre mice) were fed with HFD (60% of calories derived from fat) during 16 weeks. Insulin- and glucose-tolerance tests (ITT/GTT) were performed at week 11 and 13 of the diet, respectively. At the end of the 16-week diet, AT (subcutaneous and epididymal) stromal vascular cells were isolated for analysis of the presence of macrophage and T cell populations using flow cytometry. Liver steatosis was analyzed by histology and triglyceride measurements.
Results: HFD-induced weight gain was 8% less in Tg T-PPARβ compared to control mice (P<0.001). ITT/GTT data showed that Tg T-PPARβ mice develop less IR than control mice, even in weight-matched mice. Total AT macrophage numbers were decreased predominantly due to a decrease in pro-inflammatory M1 macrophages. Furthermore, AT T cells numbers were also decreased due to a decrease in αβ T cells, while γδ T cell numbers remained unchanged. Together, this led to an increase in the proportion of γδ T cells in AT. Liver weight and triglyceride content was decreased.
Conclusion: T cell-specific overexpression of PPARβ results in: 1) a partial protection against HFD-induced obesity, insulin resistance, and liver steatosis, 2) a reduction in AT inflammation, 3) an increase in the proportion of γδ T cells in AT. Our hypothesis is that the beneficial effects observed are the consequence of a decrease in αβ T cells (leading to an increase in γδ T cell prevalence) as the result of changes in T cell metabolism induced by PPARβ overexpression.

Loss of fractalkine-CX3CR1 signalling exacerbates obesity-induced inflammation and insulin resistance

M. Nagashimada, Y. Ni, K. Sawamoto, T. Ota;
Kanazawa University, Kanazawa, Japan.

Background and aims: Adipose tissue macrophage (ATM) accumulation via C-C chemokine receptor 2 (CCR2) and its ligand monocyte chemoattractant protein-1 (MCP-1) is pivotal for the development of insulin resistance. We previously reported that a different C-C chemokine receptor, CCR5, promotes obesity-associated adipose tissue inflammation and insulin resistance. Fractalkine (also known as CX3CL1) is a CX3C chemokine involved in cell adhesion, recruitment, and survival upon binding to its receptor, CX3CR1. Fractalkine-CX3CR1 is a chemokine system that exerts both negative and positive influences on disease pathogenesis and progression. However, it is unclear how the fractalkine-CX3CR1 axis impacts adipose inflammation and insulin resistance in the development of obesity. In the present study, we show that fractalkine-CX3CR1 signaling plays a crucial role in obesity-induced insulin resistance by suppressing ATM recruitment and adipose tissue inflammation.
Materials and methods: Comprehensive DNA microarray analyses of chemokines and their receptors in epididymal white adipose tissue (eWAT) of high-fat diet (HFD)-induced obese (DIO) mice or lean controls were performed. To determine whether fractalkine-CX3CR1 is required for obesity-induced ATM recruitment and insulin resistance *in vivo*, we examined the metabolic phenotype of *Cx3cr1*$^{-/-}$ mice. In addition, we performed bone marrow (BM) transplantation of *Cx3cr1*$^{-/-}$ and wild-type (WT) C57Bl/6J mouse donor cells into irradiated WT recipient mice to generate myeloid cell-specific chimeric mice.
Results: Fractalkine mRNA expression was persistently downregulated in eWAT of DIO mice compared to lean controls. Consistently, DNA microarray analyses of eWAT of DIO mice demonstrated decreased fractalkine gene expression despite increased expression of other chemokines systems, such as MCP-1-CCR2 and CCR5. Interestingly, downregulation of fractalkine preceded ATM recruitment in DIO mice. Furthermore, immunofluorescence analyses of eWAT in DIO mice revealed that both fractalkine and CX3CR1 were expressed by F4/80^{+} macrophages in crown-like structures. *Cx3cr1*$^{-/-}$ mice fed normal chow developed slightly worsened glucose tolerance. Compared to WT mice, *Cx3cr1*$^{-/-}$ mice fed an HFD exhibited increased macrophage infiltration and formation of crown-like structures in eWAT, despite similar body weight and adipocyte size. HFD-induced glucose intolerance, hyperinsulinemia (WT vs. *Cx3cr1*$^{-/-}$; 0.5 ± 0.1 ng/ml vs. 1.3 ± 0.2 ng/ml, $p < 0.05$), and insulin signaling were exacerbated in eWAT of *Cx3cr1*$^{-/-}$ mice. These findings were associated with increased plasma TNFα levels (WT vs. *Cx3cr1*$^{-/-}$; 47.9 ± 4.7 pg/ml vs. 73.2 ± 9.1 pg/ml, $p < 0.01$), JNK amplification, and NF-kB activation in eWAT, as well as progression of hepatic steatosis. Importantly, HFD-induced adipose inflammation and hyperinsulinemia were aggravated in chimeric mice lacking CX3CR1 in BM cells (BM transplantation of *Cx3cr1*$^{-/-}$ donor cells into WT mice), compared to BM transplantation of *Cx3cr1*$^{+/+}$ donor cells into WT mice.
Conclusion: Fractalkine gene expression is persistently decreased in WAT, and its downregulation precedes ATM recruitment in obese mice. Furthermore, loss of fractalkine-CX3CR1 signaling increases ATM recruitment, thereby exacerbating obesity-induced inflammation and insulin resistance. Thus, fractalkine-CX3CR1 signaling plays a critical role in obesity-induced insulin resistance by decreasing ATM recruitment and adipose tissue inflammation.

Background and aims: Obesity is associated with a low-grade inflammation, which could be promoted by intestinal barrier impairment as suggested by studies in fat-fed rodents. Intestinal permeability (IP) is poorly described in human obesity. We characterized IP in obese subjects and evaluated the impact of acute lipid supplies
Materials and methods: IP was evaluated ex vivo in Ussing chambers using FITC-labeled tracers at baseline and after exposure to lipid micelles, on jejunum samples of obese and non-obese subjects obtained from surgical waste of gastric bypass and surgeries performed in non-obese subjects. In vivo, IP was assessed by lactitol/mannitol urinary excretion ratio (L/M). Tight junction proteins were studied by immunofluorescence. LPS activity and zonulin levels were measured in serum. Effect of lipid micelles on epithelial permeability was studied in Caco-2/TC7 cells
Results: In fasting condition, P to 0.4 and 4 kDa tracers was not increased in obese as compared to non-obese subjects. Occludin and tricellulin labelling was reduced at tight junction. L/M ratio and seric LPS levels were comparable but increased zonulin serum levels were observed in obese subjects ($p=0.02$). In Caco-2/TC7 cells, lipid micelles increased paracellular permeability through a Src kinase-dependent mechanism. After lipid supply, higher values of ex-vivo IP were recorded for the jejunum of obese compared to non-obese subjects (+92%; $p<0.05$), with decreased tricellulin intensity. Ex vivo IP to 0.4 kDa tracer was positively correlated with systemic inflammation (Haptoglobin, CRP; $p<0.01$); IP to 4 kDa tracer was negatively correlated with insulin-resistance surrogate (adiponectin; $p<0.05$) and Fiber consumption ($p<0.01$). After lipid challenge, IP to 4kDa positively correlated with systemic (CRP), intestinal (calprotectin) inflammation ($p<0.01$) and negatively with Fruit and vegetable consumption ($p<0.05$)
Conclusion: Increase of jejunum permeability in obese subjects is exacerbated after an acute lipid supply and associated with tight junction impairments. Jejunum permeability is linked with systemic and local inflammation as well as dietary profile

Myeloid-specific deletion of SIRT1 aggravates hippocampal inflammation in a high-fat diet-fed mice

K. Kim, E. Jeong, J. Lee, C.-O. Yi, K.-A. Park, Z. Jin, G. Roh;
Department of Anatomy and Convergence Medical Science, Gyeongsang National University School of Medicine, Jinju, Republic of Korea.

Background and aims: Obesity-induced peripheral inflammation is associated with hippocampal inflammation. Sirtuin 1 (SIRT1) regulates cellular metabolism and inflammatory response. Nuclear factor kappa B (NF-κB)-mediated inflammation contributes to the development of insulin resistance and diabetes, however, the myeloid-specific SIRT1 function in the context of neuroinflammation is largely unknown.
Materials and methods: Myeloid-specific SIRT1 knockout (KO) mice were fed a high-fat diet (HFD) or normal diet (ND) for 40 weeks.
Results: HFD-fed SIRT1 KO mice had an increase in hepatic inflammation and macrophage infiltration of adipocytes compared to HFD-fed wild type (WT) mice. Hippocampal expression levels of acetylated NF-κB were increased in HFD-fed KO mice compared to HFD-fed WT mice. In particular, HFD-induced lipocalin-2 was increased in liver, adipose tissue, and hippocampus of WT mice. However, their expressions were decreased in KO mice compared to WT mice. SIRT1 deletion increased hippocampal iba1 and amyloid precursor protein expression in HFD-fed mice.
Conclusion: These results suggest that myeloid-specific SIRT1 deletion may contribute to the reduced secretion or production of LCN2 and lead to suppression of anti-inflammatory responses against HFD-induced obesity.

CXCL16: a novel regulator of insulin signalling in C2C12 myotubes

S. Bitsi[1], I. Ezeigbo[1], F. Karpe[2], M.E. Cleasby[1], C.P. Wheeler-Jones[1];
[1]Comparative Biomedical Sciences, Royal Veterinary College, London, [2]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, UK.

Background and aims: Insulin resistance often arises in the context of obesity and can lead to the development of type 2 diabetes. Chronic low-grade inflammation has emerged as a contributing factor to skeletal muscle insulin resistance, with several immune cells and cytokines being implicated. Macrophages infiltrate skeletal muscle in obesity and pro-inflammatory cytokines secreted locally impact insulin sensitivity. *In vitro*, the saturated fatty acid (FA) palmitate polarises macrophages towards a pro-inflammatory phenotype. However, the effects of secreted cytokines and chemokines on skeletal muscle, particularly those recently identified, such as CXCL16, have not been defined. In this study, we evaluated the secretion of cytokines and chemokines by palmitate-treated macrophages with the aim of identifying novel paracrine mechanisms impacting skeletal muscle insulin sensitivity.
Materials and methods: J774 macrophages were incubated with or without 500μM palmitate ± 500μM unsaturated FA (palmitoleate) for 8 hours, followed by incubation of cells with fresh media, which was collected after 16 hours. These conditioned media were analysed using a mouse cytokine array. The results of the array analysis were validated in separate experiments using specific ELISAs, including lipopolysaccharide (LPS) as a positive control. Differentiated C2C12 myotubes were treated with 750μM palmitate, murine recombinant soluble CXCL16 (sCXCL16), combined treatment, or control medium. The expression and activation state of insulin signalling pathway intermediates was determined by western blotting, while the overall response to insulin was assessed by measuring glycogen synthesis.
Results: Treatment of J774 macrophages with palmitate or palmitate plus palmitoleate led to secretion of a modified cytokine profile versus control. Of the 62 cytokines examined, 7 were significantly differentially expressed versus control. Intriguingly, secretion of CXCL16, a relatively recently described cytokine that has not been studied in the context of insulin resistance, was down-regulated by palmitate treatment (51.6 % decrease; $p<0.01$). Reduced CXCL16 secretion by palmitate-treated J774 macrophages was verified by ELISA (palmitate: 690 ± 147 pg/mL *vs* control: 1572 ± 258 pg/mL; $p<0.05$). Separate incubation with LPS also diminished CXCL16 secretion (836 ± 116 pg/mL; $p<0.05$ *vs* control). Short-term exposure (<1 hour) of C2C12 myotubes to sCXCL16 resulted in a concentration-dependent stimulatory effect of the cytokine on the phosphorylation state of Akt and ERK1/2. Treatment of C2C12 myotubes with 750μM palmitate (16 hours) led to the expected reduction of Akt phosphorylation upon insulin (100 nM) stimulation, which was attenuated by simultaneous treatment with 100ng/mL sCXCL16.
Conclusion: These data demonstrate that sCXCL16 modulates the insulin signalling pathway in murine skeletal muscle *in vitro* and ameliorates the negative effect exerted by palmitate. The attenuated secretion of CXCL16 by palmitate- or LPS-treated macrophages may contribute to diminished skeletal muscle insulin sensitivity, identifying CXCL16 as a putative novel mediator of skeletal muscle insulin signalling under conditions of chronic low-grade inflammation.

Exploring GPR120-mediated regulatory actions on lipid metabolism, inflammation and autophagy in islet beta cells: its potential as a therapeutic target for obesity and type 2 diabetes

D. Zhang, P.S. Leung;
School of Biomedical Sciences, The Chinese University of Hong Kong, Hong Kong, China.

Background and aims: The current therapies for obesity-related type 2 diabetes mellitus (T2DM) are suboptimal. In this regard, G protein-coupled receptor 120 (GPR120) is a novel potential therapeutic target for the prevention and treatment of T2DM. Recent studies have shown that GPR120 activation in pancreatic islet β cells promotes insulin secretion; however, there have been no report to further examine the modulatory roles of resident GPR120 in islet β-cell survival and function under lipotoxicity-induced diabetic conditions. In the present study, we therefore aimed to investigate into the potential roles of islet β-cell GPR120 in regulating lipid metabolism, inflammation and autophagy under lipotoxic conditions.
Materials and methods: Rat β-cell line INS-1E and isolated C57/BL6J mouse islets were used as in vitro and ex vivo models, respectively. GPR120 knockout (KO) mouse islets were used to validate the roles of GPR120. To induce lipotoxicity, β cells and islets were exposed to palmitic acid; GPR120 agonism was achieved by two agonists, namely docosahexenoic acid (DHA) and GSK137647 (GSK); the regulatory roles of GPR120 in β-cell/islet lipid metabolism and inflammation, as well as autophagy were then elucidated; the related signaling pathways involved in the GPR120-mediated protective actions were further examined.
Results: GPR120 agonists DHA and GSK inhibited the mRNA expression of the lipid uptake/synthesis-related genes, such as SREBP-1c (1.69 ±0.11 vs 0.71±0.10, p<0.001; 1.69±0.11 vs 1.19±0.08, p<0.01), in mouse islets and INS-1E cells under lipotoxic conditions. In addition, DHA reversed the lipotoxicity-induced mRNA expression of pro-inflammatory genes in both mouse islets and INS-1E cells, of which these inhibitory effects were abrogated in mouse islets with GPR120 KO (18.42±3.97 vs 5.34±1.29, p<0.05; 40.81±8.18 vs 45.57±13.80, p>0.05). Moreover, the GPR120 KO mouse islets exhibited alterations in the expression of autophagy-related genes (1.01±0.03 vs 0.80±0.04, p<0.05; 1.01±0.07 vs 1.3±0.06, p<0.05). On the other hand, INS-1E cells with GPR120 knockdown exhibited reductions in insulin expression and intracellular insulin content; consistently, GPR120 KO mice were characterized with higher fasting blood glucose levels (7.34±0.36 vs 10.56 ±0.59, p<0.01). Our mechanistic studies further showed that the gene expression related to β-cell proliferation, function and insulin synthesis were reduced in GPR120-knocked-down INS-1E cells. In corroboration, the stimulatory effects of DHA on protein kinase B (also known as Akt) and extracellular signal-regulated kinases (ERK) phosphorylation were abolished in GPR120 KO mouse islets (1.00±0.01 vs 2.11±0.28, p<0.05; 1.00±0.01 vs 1.04±0.27, p>0.05; 1.08±0.08 vs 1.35±0.05, p<0.05; 1.00 ±0.04 vs 1.12±0.07, p>0.05).
Conclusion: These data indicate that GRP120 agonism in β cells/islets may have therapeutic potential in regulating lipid accumulation, lipotoxicity-induced inflammation, and autophagy, as well as being associated with β-cell proliferation and insulin synthesis, probably via the mediation of Akt/ERK signaling pathway.

Fetuin A disrupts energy homeostasis through cleavage of SIRT1 in lipid induced inflamed adipocyte

M. Chattopadhyay[1], S. Mukherjee[1], S. Das[1], D. Chattopadhyay[1], S. Chatterjee[1], S. Mukherjee[1], S. Mukhopadhyay[2], S. Bhattacharya[1];
[1]Department of Zoology, Visva Bharati University, Santiniketan, [2]Department of Endocrinology and Metabolism, Institute of Post Graduate Medical Education and Research, Kolkata, India.

Background and aims: Lipid is associated with two critical metabolic diseases, type 2 diabetes and cardiovascular disease, together called as metabolic syndrome which is posing a major threat to global human health. Adipose tissue inflammation is in the centre stage of this disease. Morphology and functional status of adipocyte dramatically changes during obesity induced insulin resistance, it becomes an inflamed tissue with increase in number of hypertrophied adipocytes that stores excess amount of lipid and produces proinflammatory cytokines. Result is more of energy stored than expenditure; this misbalance could be sensed by energy sensor, SIRT1 which act as gatekeeper of the master regulator of mitochondria, PGC1α. SIRT1 activate PGC1α through deacetylation and this enhances the expression of plethora of genes which regulates lipid mobilization for energy yield and that effects insulin sensitization. In hypertrophied adipocytes, this pathway is disrupted and that produces insulin resistance. However, underline mechanism of excess lipid induced negative signals that disrupts energy homeostasis is still incompletely understood. Whether excess lipid is directly involved in producing these metabolic defects or there are some other mediators which are/is involved here is not yet clear.
Materials and methods: Abdominal adipose tissue and serum were collected from standard diet (SD), high fat diet (HFD), FetA gene knocked down HFD mice ($FetA^{KD}$HFD) and FetA reinforced $FetA^{KD}$HFD mice and OGTT, ITT, FetA, pro-inflammatory cytokines, inflammasome markers, SIRT1 and its downstream targets were investigated. In vitro effects of FetA on SIRT1 were assessed in 3T3L1 adipocytes and TNFα knocked down (TNFα siRNA) 3T3L1 adipocytes. Further, mitochondria were isolated from mice as well as 3T3L1 adipocytes and mitochondrial bioenergetics and biogenesis parameters were investigated.
Results: In the present study we have observed that inactivation of SIRT1 through its cleavage and subsequent decrease of acetylated PGC1α (p<0.05), mitochondrial mass (p<0.01) and ATP synthesis (p<0.05) coincided with the higher Fetuin A (FetA) level in high fat diet (HFD) induced obese diabetic mice. Knock down of FetA gene ($FetA^{KD}$) markedly recovered SIRT1 and its downstream targets in HFD mice, while reinforcement of FetA into $FetA^{KD}$HFD mice reduced SIRT1 activity significantly (P<0.01). Interestingly, there was concurrent increase in TNFα expression (p<0.05) and caspase1 activity (p<0.01) in HFD mice adipocytes when FetA level was high. Overexpression of TNF α by FetA augmented inflammasome formation (increased levels of NLRP3, ASC) and caspase1 release (p<0.01). FetA failed to increase caspase1 and cleave SIRT1 when TNFα gene was silenced in 3T3L1 adipocytes. These results suggest that FetA mediate its inhibitory effect on SIRT1 through TNFα-caspase1 pathway.
Conclusion: Our results indicate that FetA is obligatory for defects in SIRT1 and PGC1α pathway that cause impairments in mitochondrial biogenesis, bioenergetics, which in turn adversely affect insulin sensitivity.

cd36 acts as an important mediator of FFA, FetA and TLR4 induced adipose tissue inflammation

S. Mukherjee[1], S. Mondal[2], S. Mukhopadhyay[2], S. Bhattacharya[1];
[1]Zoology, Visva-Bharati (a Central University), Santiniketan, [2]Department of Endocrinology and Metabolism, Institute of Post-Graduate Medical Education and Research-Seth Sukhlal Karnani Memorial (IPGME&R−SSKM) Hospital, Kolkata, India.

Background and aims: Type 2 diabetes (T2DM) currently affects more than 382 million people worldwide and by 2035 the prevalence may go

up to 592 million (Diabetes Atlas, 2015). Lipid induced insulin resistance (IR) plays an important role in the pathogenesis of T2DM and 'Diabetes Lipidius" is believed to precede 'Diabetes Mellitus'. Elevated plasma levels of free fatty acids (FFAs) induce production of proinflammatory cytokines from liver and adipose tissue. We recently reported that FetuinA (FetA), a hepato-adipokine, acts as an adaptor protein between FFA and TLR4 to initiate adipose tissue inflammation. However, how FFA-FetA-TLR4 complex trigger adipose tissue inflammation is yet unclear. Available reports suggest that cd36, a scavenger receptor, binds with TLR4 and TLR6 to activate NLRP3-inflammasome formation and participates in LPS- TLR4 mediated inflammatory signals. As TLR4 mediated inflammatory response also requires FetA, we went on to see if FetA also operates through cd36 to trigger adipose tissue inflammation.
Materials and methods: We preincubated 3T3L1 cell line and adipocytes from Balb/c mice with cd36 recombinant protein at increasing concentration along with either FFA or FFA+FetA for 4 h followed by ELISA and immunoblot analysis of proinflammatory cytokines (TNFα, IL6 and IL1β). Insulin sensitivity was estimated by ^{14}C-2DOG uptake and immunoblot of pGLUT4, pAKT and pIR from both the cell line and primary adipocyte culture. To investigate whether cd36 induced activation of inflammation requires direct binding of FetA, we generated high fat diet (HFD)-diabetic mice and performed co-immunoprecipetation experiment from the adipocyte cell lysates of standard diet (SD) and HFD mice. We also immunodepleted FetA and TLR4 and then immunobloted the adipocyte lysates with cd36 antibody to confirm cd36 interaction with FetA.
Results: On ELISA and immunoblot analysis of cd36 immunodepleted adipocytes, FFA+FetA+TLR4 trimer failed to elicit a proinflammatory cytokine response (TNFα,IL6 and IL1β). Cells treated with FFA alone, FetA alone or FFA +FetA showed significant increase in the proinflammatory cytokines (2-4 folds; n=5). No notable stimulation in mRNA expression and activation of NFkB was noted in cd36 immunodepleted cells. Adipose tissue inflammation induced by FFA-FetA-TLR4 trimer impaired insulin sensitivity as observed by underexpression of insulin sensitive molecules (pIR, pAKT,pGlut4)and reduced ^{14}C-2DOG uptake, while suppression of cd36 in these cells abrogated these defects. Co-immunoprecipetation experiment involving adipocytes from SD and HFD mice confirmed cd36 binding to FetA.
Conclusion: The present investigation establishes cd36 is an important mediator of FFA-FetA-TLR4 trimer induced adipose tissue inflammation that impairs insulin sensitivity. Since targeting TLR4 in T2DM patients may leads to unwanted inhibition of immune function, cd36 could be a potentially useful drug target to treat T2DM.

Alpha1-antitrypsin prevents cytokine-induced beta cell death in mouse islets and improves glucose homeostasis in human islet amyloid polypeptide transgenic mice

J. Rodríguez-Comas[1,2], M. Obach[1,2], R. Horrillo[3], C. Castaño[1,2], J. Moreno-Vedia[1], M. Costa[3], A. Novials[1,2], J.-M. Servitja[1,2];
[1]Diabetes and Obesity Research Laboratory, IDIBAPS, Barcelona, [2]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Madrid, [3]Research & Development Area, Grifols Bioscience Industrial Group, Parets del Vallès, Spain.

Background and aims: Islet inflammation has emerged as a key factor for the loss of functional β-cell mass in both type 1 (T1D) and type 2 diabetes (T2D). Alpha1-antitrypsin (AAT) is a circulating serine protease inhibitor that exerts anti-inflammatory effects, and AAT therapy offers great promise in protecting islets from inflammation. Human islet amyloid polypeptide (hIAPP) aggregation is associated with β-cell death in type 2 diabetes (T2D) and induces islet inflammation and β-cell dysfunction in transgenic mice overexpressing hIAPP. The aim of this study was to determine the protective effects of human AAT on β cells from cytokine-induced death in mouse islets and in transgenic mice overexpressing hIAPP.
Materials and methods: Isolated mouse islets were treated with cytokines (50U/mL Il1β, 1000U/mL TNFα, 1000U/mL IFNγ) and AAT (0.5mg/mL). Apoptosis and cell death was determined by *in toto* staining of cleaved caspase-3 and propidium iodide, respectively. Clodronate liposomes (1mg/ml) were used to deplete islet macrophages. Global gene expression analysis of isolated islets was performed and selected genes were validated by qPCR. 8 week-old wild-type and hIAPP transgenic mice were treated with intraperitoneal injections of AAT (2-6 mg/mouse) for 4 weeks. Glucose tolerance tests were performed before and at the end of the treatment.
Results: Low doses of pro-inflammatory cytokines induced the activation of a transcriptional inflammatory program and β-cell death in mouse islets. AAT abolished 90±5% of islet cell death and 83±9% of β-cell apoptosis induced by exogenous cytokines. Clodronate liposome-mediated depletion of islet macrophages blocked cytokine-induced β-cell apoptosis, indicating that resident macrophages are required for the cytotoxic action of cytokines in islets. A global transcriptomics analysis revealed that AAT treatment did not globally block the inflammatory program induced by cytokines, but interestingly decreased the expression of pro-inflammatory genes, including *Ccl2*, and increased by two-fold the expression of *Hspa1*, a stress-induced gene known to protect β cells. Finally, we also explored the effect of AAT *in vivo* in hIAPP transgenic mice. AAT treatment was started at 8 weeks of age, when these mice were already glucose intolerant. After 4 weeks, non-treated animals presented a more exacerbated phenotype. Remarkably, AAT treatment prevented the impairment of glucose intolerance and normalized glucose homeostasis in hIAPP transgenic mice.
Conclusion: Our results demonstrate that AAT prevents macrophage-mediated β-cell death induced by cytokines and normalizes glucose homeostasis in a mouse model of islet inflammation and dysfunction, highlighting the potential of AAT treatment as a therapeutic strategy for the treatment of T1D and T2D.

Circulating lipopolysaccharide and gut permeability in obese subjects with type 2 diabetes: the influence of surgical and endoscopic interventions

A. Cinkajzlova[1,2], Z. Lacinova[1,2], J. Klouckova[1,2], P. Kavalkova[2], H. Kratochvilova[1,2], J. Krizova[3], K. Dolezalova[4], M. Fried[4], M. Benes[5], Z. Vlasakova[6], T. Pelikanova[6], M. Mraz[6,2], M. Haluzik[1,2];
[1]Centre for Experimental Medicine, Institute for Clinical and Experimental Medicine, [2]Institute for Medical Biochemistry and Laboratory Diagnostics, General University Hospital and Charles University in Prague 1st Faculty of Medicine, [3]3rd Department of Medicine, General University Hospital and Charles University in Prague 1st Faculty of Medicine, [4]Department of Surgery, OB Clinic, [5]Hepatogastroenterology Department, Institute for Clinical and Experimental Medicine, [6]Diabetes Centre, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Background and aims: Low-grade inflammation is considered one of the key mechanisms linking obesity to type 2 diabetes mellitus (T2DM) with translocation of gut microbiota being suggested as its potential initiator. The aim of our study was to assess the effect of selected interventions on parameters of intestinal leakage along with systemic and adipose tissue inflammation in obese subjects with T2DM.
Materials and methods: Thirty obese T2DM subjects (15 undergoing gastric plication (GP) and 15 endoscopic duodenal-jejunal by-pass liner implantation (DJBL)) and 10 healthy lean controls (C) were examined at baseline, 1 month and 6 (GP) and 10 months (DJBL) after intervention. Lipopolysaccharide binding protein (LBP) was used as a marker of circulating lipopolysaccharide levels and fatty acid binding protein 2 (FABP-2) as an indicator of intestinal leakage. Subcutaneous adipose tissue macrophages (ATMs) were quantified using flow cytometry.
Results: At baseline, both GP and DJBL groups had increased hsCRP (3.3±1.1 and 3.5±0.8 vs. 0.7±0.3 mg/l for GP and DJBL vs. C, p=0.002) and LBP (15.4±1.1 and 14.0±1.5 vs. 9.8±0.7 μg/ml, p=0.002) which positively correlated with ATMs percentage (R=0.463, p=0.035). Baseline FABP-2 did not differ between groups (1.81±0.29 and 1.65 ±0.25 vs. 1.24±0.97 ng/ml for GP and DJBL vs. C, p=0.478). Postprocedurally, except of reduced body weight (BMI 42.4±1.3 vs. 36.0±1.3 kg/m^2, p<0.001 for GP and 42.5±1.0 vs. 38.7±1.2 kg/m^2, p<0.001 for DJBL), HbA_{1C} (60.1±4.5 vs. 43.9±2.0 mmol/mol, p<0.001 for GP and 72.1±5.0 vs. 52.6±3.8 mmol/mol, p<0.001 for DJBL) and hsCRP (3.3±1.1 vs. 1.3±0.3 mg/l, p=0.040 for GP and 3.5±0.8 vs. 2.0 ±0.3 mg/l, p=0.069 for DJBL) both groups showed decreased amount of ATMs (26.8±2.7 vs. 15.4±2.0 %, p=0.008 for GP and 21.0±2.1 vs. 13.3 ±1.9 %, p=0.027 for DJBL), while no effect was seen on LBP (15.4±1.1 vs. 13.3±0.8 μg/ml, p=0.059 for GP and 14.0±1.5 vs. 12.7±1.3 μg/ml, p=0.104 for DJBL) and FABP-2 levels (1.81±0.29 vs. 1.91±0.47 ng/ml, p=0.109 for GP and 1.65±0.25 vs. 2.15±0.32 ng/ml, p=0.161 for DJBL).
Conclusion: Both interventions were associated with the reduction of systemic as well as subcutaneous adipose tissue inflammation. Modification of circulating lipopolysaccharide levels or gut leakage do not seem to be involved in these effects although circulating lipopolysaccharide might play a role in the increased ATM content in obese T2DM subjects.

Early remission and later progression of type 2 diabetes after gastric bypass are related to changes in intestinal glucose transport

F. Pattou[1], V. Raverdy[1], A. Duhamel[2], M. Pigeyre[1], H. Verkindt[3], R. Caiazzo[1], P. Fontaine[4];
[1]Translational Research in Diabetes, EGID, Univ Lille, INSERM, CHRU Lille, Lille, [2]Statistics, Univ Lille, CHRU Lille, Lille, [3]Translational Research in Diabetes, EGID, Univ Lille, INSERM, CHRU Lille, Pérenchies, [4]Diabetology, Univ Lille, CHRU Lille, Lille, France.

Background and aims: Understanding the intestinal mechanisms responsible for the metabolic benefit of Roux-en-Y gastric bypass (RYGB) may open novel strategies to treat type 2 diabetes. We recently showed in minipigs that RYGB modulates postprandial glycemic response by reducing intestinal sodium-glucose cotransport. The aim of this study was to confirm the clinical relevance of this mechanism in patients with type 2 diabetes submitted to RYGB.
Materials and methods: In this longitudinal study, we studied during 5 years obese patients with type 2 diabetes submitted to RYGB (n=26) or calorie restriction alone with adjustable gastric banding (n=20). Postprandial glycemic response, insulin and glucagon-like peptide 1 secretion as well as intestinal D-xylose absorption were evaluated during 180 min after a standardized mixed meal prior to surgery, and again during 3 postoperative visits: after the loss of 10 percent of initial body weight, after one year, and after five year.
Results: The postprandial glycemic response decreased significantly after RYGB independent of weight loss while it remained unchanged after adjustable gastric banding. This decrease in postprandial glycemic response after RYGB coincided with a reduction of intestinal D-xylose absorption and an increase in beta cell function and GLP1 postprandial response. In patients experiencing diabetes remission one year after RYGB (N=19), later disease progression and diabetes relapse at 5 years (N=8) were associated with higher D-xylose absorption (but not with lower BMI, beta cell function, nor GLP1 postprandial response
Conclusion: Conclusion: The decrease in intestinal glucose transport plays a central role in the metabolic benefit of Roux-en-Y gastric bypass in type 2 diabetes.

Roux-en-Y gastric bypass results in rapid postprandial mixing of bile and foods and augmented enterohepatic bile acid retention

A. Eiken[1], S. Fuglsang[2], M. Eiken[1], M.S. Svane[1], J.J. Holst[3], K.N. Bojsen-Møller[1], S. Madsbad[1], J.L. Madsen[2], C. Dirksen[1];
[1]Dept. of Endocrinology, Hvidovre Hospital, [2]Dept. of Clinical Physiology and Nuclear Medicine, Hvidovre Hospital, Hvidovre, [3]Dept. of Biomedical Sciences, University of Copenhagen, Copenhagen, Denmark.

Background and aims: Bile acids are major metabolic regulators with important effects on glucose homeostasis. After Roux-en-Y gastric bypass (RYGB) plasma concentrations of bile acids are increased, which could explain some of the metabolic improvements observed after surgery. To elucidate the mechanisms responsible for this increase, we assessed flow of bile and foods using direct scintigraphic techniques in RYGB operated patients and non-surgical matched controls.
Materials and methods: 15 RYGB patients (P) (age 46.5±10.8 yrs [mean ±sd], BMI 29.4±3.0 kg/m^2, time from surgery 3.8±1.2 yrs) and 15 non-surgical controls (C) (46.8±10.0 yrs, BMI 29.4±3.6 kg/m^2) underwent cholescintigraphy using an intravenous radiolabelled bile marker (^{99m}Tc-mebrofenin) combined with a standardized test-meal also containing a radiolabelled marker (^{111}In-DTPA). This method allowed concomitant visualization of foods and bile in the gastrointestinal tract, including assessment of the timing and extent of the mixing phase. Bile acid retention was estimated using a standard ^{75}Se-HCAT method (a radiolabelled taurine conjugated bile acid analog), which measures the fraction of ^{75}Se-HCAT retained in the enterohepatic bile circulation 7 days after oral ingestion.
Results: Prior to the meal, peak gallbladder filling was decreased in RYGB patients (25.0±3.9 vs 37.9±4.2%, p=0.029) and more bile marker had passively passed into the small intestine (median 58.1% [IQR 32.9;65.0] vs 17.4% [5.2;26.4], p=0.005). Gallbladder emptying in response to the meal was seen in both groups, but the total content of bile marker in the small intestine remained elevated over time in RYGB patients (at 30 min 86.7±10.8 vs 68.9±13.8%, p<0.001). By the end of the meal, pouch retention of the meal marker in RYGB patients was negligible compared to gastric retention in controls (9.5% [7.3;16.4] vs 94.7% [89.5;100], p<0.001). Consequently, almost complete mixing of foods with bile was seen immediately after the end of meal in RYGB patients, compared to a slow and gradual mixing in controls (percent of foods mixed with bile by end of meal: 80.0% [66.9; 89.7] vs 5.7% [0.0;9.6], p<0.001). After 7 days, retention of ^{75}Se-HCAT was increased in RYGB patients compared to controls (54.0±24.6 vs 31.7±21.1%, p=0.016). Further, in RYGB patients, bile acid retention was positively correlated with the amount of bile marker in the small intestine prior to meal intake during the cholescintigraphy (r=0.57, p=0.034).
Conclusion: RYGB patients are characterized by reduced gallbladder filling, increased bile flow from the liver into the small intestine in the fasting state, and augmented enterohepatic retention of bile acids. Combined with a negligible meal retention in the gastric pouch in these patients, rapid mixing of foods and bile is seen after RYGB. These alterations in bile circulation after RYGB likely affect plasma bile acid concentrations and nutrient absorption, in particular fat, and might thereby contribute to the postoperative metabolic improvements seen after RYGB surgery.

Metabolic control and bone turnover after Roux-en-Y gastric bypass in response to weight loss and weight stabilisation

K.N. Bojsen-Møller[1,2], M.S. Svane[1,2], C. Dirksen[1,2], N.B. Jørgensen[1,2], I.H. Thorius[1,2], V.B. Kristiansen[3], B. Hartmann[4,2], J.J. Holst[4,2], N.R. Jørgensen[5], J.-E.B. Jensen[1], S. Madsbad[1,2];
[1]Department of Endocrinology, Hvidovre Hospital, Hvidovre, [2]NNF Centre for Basic Metabolic Research, Copenhagen, [3]Department of Surgical Gastroenterology, Hvidovre Hospital, Hvidovre, [4]Department of Biomedical Sciences, Copenhagen, [5]Department of Biochemistry, Rigshospitalet, Glostrup, Denmark.

Background and aims: Metabolic improvements after Roux-en-Y gastric bypass (RYGB) are attributed to altered nutrient absorption and gut-islet cell cross talk in addition to major weight loss. Bone mineral density (BMD) is decreased, but whether RYGB induces changes in bone turnover beyond adaptation to major weight loss is not known. We investigated metabolic control and bone turnover during weight loss and after weight stabilization from 1 week (wk) post-RYGB and throughout the first 4 years (y).
Materials and methods: Ten subjects with preoperative type 2 diabetes (T2D) and ten with normal glucose tolerance (NGT) were investigated before (pre), 1 wk, 3 months (mo) and 1 y after RYGB with 16 subjects returning after 4 y. Plasma markers of metabolic control and bone turnover were obtained at fasting at all visits, during oral glucose tolerance tests (OGTTs) at all but 1 wk and DXAs (lumbar spine, hip and forearm) before, at 1 y and 4 y.
Results: Weight loss was maximal at 1 y post-RYGB with weight stabilization until 4 y (BMI pre: 39.1±4.2 kg/m^2 [mean ±SD], 1 year: 29.6 ±5.4, 4 year: 30.9±5.6, all p<0.01 vs pre). Good glycemic control was obtained early and maintained for 4 y despite cessation of antidiabetic agents in 9/10 T2D subjects (HbA1c pre: 7.0±1.0 %, 3 mo: 5.9±0.6, 4 y: 5.9±0.5, all p<0.01 vs pre). In both groups, insulin sensitivity (OGIS index from OGTT) increased during weight loss and remained stable from 1 y to 4 y. Early insulin secretion (IGI) increased in T2D only. Low glucose (<3.9 mmol/L) was observed in 7/16 (6 NGT) post-OGTT at 4 y contrasting 0/20 pre-RYGB, but neuro-glycopenic symptoms occurred only in 1 NGT. Fasting CTX, P1NP and osteocalcin were similar in T2D and NGT; unchanged at 1 wk, but increased by 60-100% at 3 mo, 110-150% at 1 y and remained 40-100% elevated at 4 y. CTX suppression during OGTT increased in both groups ($iAUC_{0\text{-}120}$ pre: −8±5 mg · min/mL, 3 mo: −32±11, 1 y:−29±14, 4y:−23±11, all p<0.01 vs pre), while suppression of P1NP and osteocalcin was largely unchanged post-RYGB. Changes in BMD were similar between groups with 6-8% decreases in hip and lumbar BMD during weight loss (pre - 1y) and 3-5% after weight stabilization (1y - 4y). In contrast, the largest decrease in forearm BMD was observed during weight stabilization, particularly in trabecular (pre-1y: −4% [95CI:−6, −2]; 1-4y:−11% [−14, −8]) but also in cortical bone (pre-1y: −0.6% [−3, +2]; 1-4y:−4% [−7, −1]).
Conclusion: Metabolic control in T2D is obtained early after RYGB and maintained for 4 years, whereas bone turnover is increased both during and after weight loss. Continued BMD loss is observed after weight stabilization, especially in non-weight bearing bone suggesting effects beyond adaptation to decreased mechanical load. Benefits in terms of long term stable glycemic control vs risks of accelerated bone loss must be considered when referring patients with type 2 diabetes to RYGB. Additionally, glucose tolerant patients are at particular risk of developing postprandial hypoglycemia after RYGB.

Soluble urokinase plasminogen activator receptor (suPAR) and high-sensitivity C-reactive protein (hsCRP) levels after bariatric surgery

C. Liaskos[1], K. Alexiadou[1], I. Papassotiriou[2], A. Margeli[2], G. Argyrakopoulou[1], D. Perrea[3], A. Alexandrou[4], N. Katsilambros[1], T. Diamantis[4], A. Kokkinos[1], N. Tentolouris[1];
[1]First Department of Propaedeutic and Internal Medicine, Athens University Medical School, Laiko General Hospital, [2]Department of

Clinical Biochemistry, "Aghia Sophia" Children's Hospital, [3]Laboratory of Experimental Surgery and Surgical Research "NS Christeas", Athens University Medical School, [4]First Department of Surgery, Athens University Medical School, Laiko General Hospital, Athens, Greece.

Background and aims: Low-grade inflammation in obesity can contribute to the development of cardiovascular disease, type-2 diabetes mellitus, cancer and mortality. The urokinase-mediated plasminogen activation system, including the urokinase-type plasminogen activator and its cellular receptor (uPAR) is connected to fibrinolysis, as it converts plasminogen to plasmin, angiogenesis, and shows promitogenic and proinflammatory qualities. uPAR's soluble form (suPAR) shed from the cellular surface and presents analogous levels in plasma to the anchored receptor. Although several studies have been conducted regarding biomarkers in severely obese patients, and the possibly favorable effects of weight reduction, to our knowledge only few series have examined the uPA/uPAR system with regard to inflammation following obesity. In this study we examined changes in plasma concentrations of suPAR amid other measurements, among a small cohort of severely obese subjects, undergoing two different types of bariatric surgery.
Materials and methods: Sixteen non-obese healthy subjects and 32 severely/morbidly obese patients who had already settled upon bariatric surgery [either Roux-en-Y gastric by-pass (RYGB) or sleeve gastrectomy (SG)] were included in the study. Non-obese patients were examined once, at study baseline; obese patients were examined pre-operatively and at 3, 6 and 12 months postoperatively. Fasting (FBG) and 2-h postprandial (PPG) serum glucose, triglycerides (TG), total cholesterol (Tchol), high-density lipoproitein cholesterol, fasting insulin, high-sensitivity C-reactive protein (hsCRP) and suPAR (using ELISA) levels were measured.
Results: Plasma suPAR concentrations at baseline were higher in obese than in lean participants (2.68 ± 0.85 vs. 1.85 ± 0.34 ng/ml, p=0.001). However, plasma levels of suPAR following bariatric surgery did not change and no differences were found between those undergoing SG and RYGB. Overall differences in levels between surgical arms were noted for FBG (p=0.013), PPG (p=0.008), Tchol (p=0.004) and LDLc (p=0.010), with SG patients presenting higher mean levels than RYGB patiens. Tchol (r=- 0.006, p=0.01) and LDLc levels (r= -0.008, p=0.007) were negatively, while log-transformed hsCRP (r=0.345, p=0.032) were positively associated with suPAR levels. One-year change in BMI was negatively associated with suPAR levels (r= -0.106 p=0.046).
Conclusion: Our findings strongly support association of obesity with inflammatory biomarkers and significant post-operational effects on levels of such biomarkers; however, a differential pattern of change was noted between suPAR and hsCRP levels.

Reductions in circulating Fetuin B and TGFβ1 contribute to higher hepatic insulin sensitivity after gastric bypass surgery compared to sleeve gastrectomy

S. Gancheva[1,2], C. Koliaki[1,3], J. Szendroedi[1,4], C. Herder[1,2], T. Jelenik[1,2], K. Strassburger[5,2], O. Kuss[5,2], D. Markgraf[1,2], M. Schlensak[6], M. Roden[1,4];
[1]Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, [2]German Center for Diabetes Research (DZD e.V.), Munich-Herberg, Germany, [3]First Propaedeutic Department of Internal Medicine, Laiko University Hospital, Athens, Greece, [4]Medical Faculty, Heinrich Heine University, Department of Endocrinology and Diabetology, Düsseldorf, [5]Institute for Biometry and Epidemiology, German Diabetes Center, Düsseldorf, [6]General Surgery Department, St. Martinus Hospital, Düsseldorf, Germany.

Background and aims: Duodenum exclusion via gastric bypass surgery has been suggested to contribute to higher type 2 diabetes remission rates compared to sleeve gastrectomy. Whether improvements in hepatokine and adipokine profiles as well as in hepatic and adipose tissue insulin sensitivity differ between surgery types remains unclear.
Materials and methods: Obese patients (OBE, n=36, age 40±11 yrs, BMI 51±7 kg/m^2) underwent hyperinsulinemic-euglycemic clamps with [6,6-$^2H_2$]glucose to assess hepatic and adipose tissue insulin sensitivity measured from insulin-mediated EGPsuppr (endogenous glucose production suppression) and AUC_{FFA} (free fatty acid area under the curve) during clamp, respectively. Measurements were performed before, 2, 12, 24 and 52 weeks after gastric sleeve (GS) or gastric bypass (GB) surgery. Covariance pattern models were used for statistical analysis. Normal-weight humans were studied at baseline (CON; n=7, age 38±4 yrs, BMI 24.9±1.1 kg/m^2).
Results: OBE had higher AUC_{FFA} at baseline (733±245 vs 358±28 AU in CON, p<0.05), which increased ca. 2-fold at 2 weeks, but was improved at 24 and 52 weeks after both surgical procedures. Impaired suppression of lipolysis at 2 weeks related positively to increases in fibroblast growth factor 21 (FGF21), cytokeratin 18 and interleukin-1 receptor antagonist (IL-1ra) by 112%, 12% and 286%, respectively, while improved AUC_{FFA} at 52 weeks associated with decreases in FGF21 and transforming growth factor β 1 (TFGβ1) and increase in adiponectin. Hepatic insulin sensitivity was comparable between CON and OBE at baseline (90±24 vs 89±9 % in CON, p>0.05). Only bypass surgery resulted in continuous improvements of EGPsuppr from 24 to 52 weeks in OBE. Of note, gastric bypass surgery, but not sleeve gastrectomy, improved both fetuin B (2.2±0.3 vs 2.6±0.6 μg/ml at baseline, p=0.03) and TGFβ1 levels (26.9±6.5 vs 30.8±5.5 ng/ml at baseline, p<0.05) 52 weeks after surgery.
Conclusion: The unrestrained adipose tissue lipolysis occurring after bariatric surgery is linked to altered hepatokine and cytokine release. Reduction in fetuin B and TGFβ1 likely contribute to the better metabolic outcomes after gastric bypass compared to gastric sleeve surgery.

Increased albuminuria and its determinants in non-diabetic and diabetic patients with morbid obesity and the effect of weight loss following bariatric surgery

J.M. Brix[1,2], C.T. Herz[3], H.P. Kopp[1,2], A. Feder[1,2], G.H. Schernthaner[4], G. Schernthaner[1], B. Ludvik[1,2];
[1]Department of Medicine I, Rudolfstiftung Hospital, [2]Karl Landsteiner Institute for Obesity and Metabolism, [3]Department of Medicine III, Medical University of Vienna, [4]Department of Medicine II, Division of Angiology, Medical University of Vienna, Vienna, Austria.

Background and aims: Patients with morbid obesity carry a high cardiovascular risk, which can only be partially explained by classic cardiovascular risk factors. In this study we wanted to evaluate (a) the prevalence of microalbuminuria and its determinants in non-diabetic and diabetic patients and (b) the effect of weight loss following bariatric surgery.
Materials and methods: We included 1307 patients (77% women, mean age: 40 ±12 years, mean BMI: 45.6 ± 6.6kg/m²) in a cross-sectional study. A subgroup of these patients (n=318) was followed up for two years after bariatric surgery. Apart from weight and cardiovascular risk-markers (blood pressure, lipids), a glucose tolerance test (75g oGTT), renal and inflammation parameters were assessed. HOMA-IR was calculated. Albuminuria was assessed by collecting 24h urine on three consecutive days.
Results: In the cross sectional study, prevalence of microalbuminuria was 16.0% (n=209), and of macroalbuminuria 3.1% (n=41). The Chi square for the association of albuminuria and diabetes was 31.937; p-value <0.001. However, of all patients with albuminuria 42.3% had a normal glucose tolerance. In a multivariate linear stepwise backward regression analysis, systolic blood pressure (beta= 0.236; p<0.001), log fasting

insulin (beta= 0.309; p<0.001) and log 2hour postprandial insulin (beta= -0.173; p=0.033) remained the most predicting parameters for albuminuria. In the longitudinal study, we found a significant decrease of albuminuria: 11.1 mg/24h (6.4, 18.4 mg/24h) to 7.8 mg/24h (4.9, 13.0 mg/24h; p< 0,001) in the whole group (n=318). In the group with albuminuria preoperatively, albuminuria decreased from 65.7 mg/24h (38.2, 147.08 mg/24h) to 13.5mg/24h (8.4, 36.8 mg/24h; p<0.001). After adjusting for age, sex and baseline albuminuria, patients with a lower creatinine clearance showed a smaller decrease of albuminuria (beta= 0.177; p= 0.021).
Conclusion: A substantial portion of patients with morbid obesity exhibits microalbuminuria, nearly half of those present with normal glucose tolerance. After significant weight loss induced by bariatric surgery we found a significant decrease of albuminuria, potentially indicating or even contributing to the known reduction of cardiovascular mortality after bariatric surgery.

A comparison of the effects of Roux-en-Y gastric bypass on glucose tolerance in Zucker diabetic fatty rats

L. Shakerdi[1], M. Nair[2], J. Elliott[2], N. Fearon[2], N. Kapoor[2], M. Abdelaal[2], N. Docherty[2], C. Le Roux[2];
[1]University College Dublin, [2]Conway Institute, University College Dublin, Dublin, Ireland.

Background and aims: Roux-en-Y gastric bypass (RYGB) is the most efficacious intervention for the treatment of obesity and type 2 diabetes. Improvements in glycaemic control begin prior to significant weight loss and are characterised by improved hepatic insulin sensitivity and oral glucose tolerance (OGTT), the latter occurring secondary to enhanced incretin responses. We previously showed that in Zucker Diabetic Fatty rats (ZDF), RYGB equivalent weight loss achieved through food restriction could not in isolation recapitulate the glycaemic improvements seen after RYGB. The aim of the current study was to compare intravenous and oral glucose tolerance between Zucker Diabetic Fatty rats 7 weeks after either RYGB or a multimodal diet and pharmacotherapy protocol aimed at mimicking RYGB induced weight loss and improvements in fasting glycaemia.
Materials and methods: At 12 weeks of age, ZDF *fa/fa* rats underwent RYGB (n=15) or Sham surgery (laparotomy, n=25). Sham operated rats were assigned to a control untreated group (8) or "medical bypass" group (MB) (17). The MB group was calorie restricted to mimic weight loss in the RYGB group and received medication including GLP-1 analogue to control hyperglycaemia, hyperlipidemia and blood pressure. Intraperitoneal and oral glucose tolerance tests (IPGTT and OGTT) were carried out at 19 weeks in all groups and values obtained compared against non-diabetic, non-obese *fa/+* control rats. For the OGTT, half of the medical bypass group were withdrawn from GLP-1 analogue therapy for 24 hours.
Results: RYGB resulted in 20-30% weight loss and normalized fasting glycemia. The MB protocol successfully matched both the weight loss and improvement in fasting glycaemia of the RYGB group without the requirement for ongoing insulin administration. Glucose tolerance as assessed by IPGTT and OGTT was improved versus Sham by both RYGB and MB, but reductions in 2-hour area under the curve (AUC) for plasma glucose IPGTT were greater after MB (RYGB 1669 ± 353 v MB 1335 ± 269, p=0.02). Elevations in AUC for plasma glucose relative to control rats only persisted following OGTT after RYGB (*fa/fa* 1145 ± 142 v *fa/+* 721 ± 142 p=0.03).
Conclusion: In the ZDF rat, multimodal diet and pharmacotherapy resulting in RYGB matched weight loss and reductions in fasting glycaemia, improved both intravenous and oral glucose tolerance to extent to a greater degree than observed in RYGB operated rats, even when GLP-1 analogue was omitted from RYGB. Thus, despite the increased clinical efficacy of RYGB, enhanced improvements in glycaemic control can be obtained non-surgically when equivalent weight loss is paired with comprehensive metabolic control measures. Future studies may identify a lesser threshold of weight-loss feasibly achievable in the clinic which when accompanied by comprehensive medical control of the metabolic milieu may prove as effective as RYGB in the treatment of obesity and type 2 diabetes

PS 042 Brown adipose tissue functioning and dysfunctioning

626

Inhibitory action of secretin on food intake depends on UCP1-mediated thermogenesis in brown adipose tissue

K. Braun, Y. Li, F. Bolze, S.-M. Gabler, A. Bast, M. Klingenspor;
Technical University Munich, Chair of Molecular Nutritional Medicine, Freising, Germany.

Background and aims: Secretin was discovered as the endocrine stimulus of pancreatic fluid production more than 100 years ago, but since then was also reported to have other effects including the inhibition of food intake. Like many other gut hormones, secretin levels in the circulation rise after a meal. We found that the secretin receptor is highly expressed in brown fat, which harbors a remarkable capacity to evoke energy expenditure through uncoupling protein 1 (UCP1) dependent thermogenesis in brown adipocyte mitochondria. A role of brown fat for meal-induced thermogenesis, defined as the increase of energy expenditure induced by meal ingestion, was suggested in the past. According to the thermostatic theory, meal-induced thermogenesis may serve as a feedback signal for satiation thereby controlling meal size. Therefore, the aim of this study was to investigate the effect of the gut hormone secretin on brown fat thermogenesis and food intake.
Materials and methods: Microplate respirometry of murine primary brown adipocytes was applied to investigate oxygen consumption, which is a key readout for thermogenic UCP1 activity. Reverse transfection with siRNAs was applied to knock down the secretin receptor. *In vivo*, oxygen consumption of mice was measured via indirect calorimetry after i.p. injection of either secretin or vehicle (PBS). Furthermore, the impact of exogenous secretin on food intake was investigated in both UCP1 wildtype and knockout mice after i.p. injection following ad libitum refeeding after an 18h fasting period.
Results: Stimulation of primary brown adipocytes with secretin acutely increased cell respiration comparable to isoproterenol, a β-adrenergic receptor (AR) agonist known to activate uncoupled respiration mediated by UCP1 (3.8±0.1 vs. 4.1±0.7-fold above basal proton leak, p=0.89, n=5). The β-AR antagonist propranolol abolished the effect of isoproterenol, but not the thermogenic effect of secretin. Secretin induced respiration was abolished knockdown of the secretin receptor. Mice injected with secretin showed a larger increase in oxygen consumption compared to vehicle injected controls (4376 ±661 vs. 3691±354 ml O_2/h, p=0.011, n=8-9). Furthermore, exogenous secretin injection reduced food intake in fasted mice compared to vehicle injection (0.56±0.30 vs. 0.89±0.19 g/h, p=0.0008, n=6-7). Notably, these effects of secretin on thermogenesis and food intake were attenuated in UCP1 knockout mice.
Conclusion: Our results reveal secretin as a novel non-adrenergic activator of brown fat that potentially stimulates meal-induced thermogenesis. The inhibitory action of secretin on food intake depends on UCP1-mediated thermogenesis in brown fat. In line with the thermostatic theory of feeding, we suggest that meal-induced thermogenesis is triggered by a post-prandial rise in circulating secretin and activation of thermogenesis in brown fat, which promotes meal termination. This proposed mechanism does not necessarily require central action of secretin in the brain, as secretin directly stimulated thermogenesis in cultured brown adipocytes. Notably, brown fat activity is negatively associated with BMI and age, and largely attenuated in obese and diabetic patients. Thus, secretin might hold promise for developing novel obesity therapies as the activation of brown fat exhibits negative impact on energy balance through both, increasing energy expenditure and decreasing energy intake.

Ambient air pollution exposure promotes insulin resistance via changes in white and brown adipose tissues in mice

Q. Sun;
College of Public Health, The Ohio State University, Columbus, USA.

Background and aims: Increasing evidence implicates ambient fine particulate matter (less than 2.5 mm in aerodynamic diameter, PM2.5) air pollution as a risk factor that are associated with systemic diseases globally, especially with cardiovascular morbidity and mortality, such as atherosclerosis and obesity. Adipose tissues, which includes mainly white and brown adipose tissues, endure important endocrine and metabolic functions, especially with recent demonstration of considerable amounts of metabolically active brown adipose tissue in adult humans. We therefore hypothesized that exposure to ambient PM2.5 exposure would induce inflammation and oxidative stress with adipocyte-specific gene changes in adipose tissues, which result in mitochondrial dysfunction and insulin resistance, and promote type 2 diabetes and metabolic disorders.
Materials and methods: To demonstrate the impact of PM2.5 exposure on insulin resistance and metabolic disorder via adipose tissues, mice were exposed to concentrated ambient PM2.5 or filtered air (FA) (6 hours/day, 5 days/week) for up to 10 months in Columbus, OH. Major examinations were performed, which primarily include energy-dispersive X-ray fluorescence (ED-XRF) for elemental analysis on the filters collected, intraperitoneal glucose tolerance test before and after the exposure, blood samples for the measurement of circulating inflammatory biomarkers, ultrastructure of adipose tissues by transmission electron microscopic (TEM), Dihydroethidium (DHE) staining to detect superoxide, immunohistochemical staining and Western blot for protein examination in the adipose tissues, and quantitative real-time PCR for adipose tissue gene analysis.
Results: Exposure to PM2.5 increased reactive oxygen species (ROS) production, decreased mitochondrial size in brown adipose tissue while mitochondrial number was significantly reduced in both white and brown adipose tissues. PM2.5 exposure also down-regulated brown adipocyte-specific genes while white adipocyte-specific genes up-regulated. In addition, PM2.5 exposure induced insulin resistance and decreased glucose tolerance compared with the FA exposure. Circulating adiponectin and leptin were significantly decreased in PM2.5-exposed group although there were no significant differences in circulating cytokines between PM2.5- and FA-exposed groups. Additionally, PM2.5 exposure decreased mitochondrial count in visceral adipose and mitochondrial size in interscapular adipose tissue, which were associated with reduction of uncoupling protein 1 (UCP1) expression and downregulation of brown adipocyte-specific gene profiles.
Conclusion: These findings suggest that ambient PM2.5 exposure triggers oxidative stress that results in mitochondrial gene expression and mitochondrial alterations in brown adipose tissue, which causes imbalance between white and brown adipose tissue functionality, impaired glucose tolerance and insulin resistance and thereby predispose to metabolic dysfunction and a risk factor for the development of type 2 diabetes.

Zbtb16 affects impact of maternal high-sucrose feeding on the metabolic and transcriptomic profiles of the offspring

O. Seda, E. Skolnikova, L. Sedova, D. Krenova, V. Kren;
Institute of Biology and Medical Genetics, First Faculty of Medicine, Prague, Czech Republic.

Background and aims: Over-nutrition in pregnancy and lactation affects fetal and early postnatal development, which can result in metabolic disorders in adulthood. Previous studies have shown the effects of improper

maternal diet and associated them with altered fetal development, however, little is known about involvement of genetic factors in this process. We suggested that a significant energy metabolism regulator, Zbtb16 gene, could be important for pathogenesis of metabolic syndrome and tested a hypothesis that variation of Zbtb16 gene modulates the programming effect of high-sucrose diet (HSD) on metabolic and transcriptomic profiles of the offspring.

Materials and methods: We established a new minimal congenic rat strain containing only a single gene, Zbtb16, from a metabolic syndrome model, the polydactylous rat (PD/Cub) strain, within the spontaneously hypertensive rat (SHR) strain genomic background. 16-week-old SHR and SHR-Zbtb16 rat dams were fed either standard diet during pregnancy and 4 weeks of lactation (control groups) or a high-sucrose diet (HSD, 70% calories as sucrose) during the same period. We assessed comprehensively the metabolic profiles of the four groups of dams as well as their adult offspring fed standard diet including glucose tolerance tests, levels of insulin, cytokines and hormones as well as concentrations of triglycerides and cholesterol in 20 lipoprotein fractions. Furthermore, we have assessed the transcriptome (GeneChip Rat Gene 2.1 ST Array Strip) in liver, brown and white adipose tissue. Two-way ANOVA with STRAIN and MatDIET as major factors was used for metabolic profile, transcriptomic data were processed in Partek Genomics Suite and resulting differentially expressed transcripts (FDR < 0.05) were analyzed by Ingenuity Pathway Analysis.

Results: In dams of both strains we observed an increase of cholesterol and triglyceride concentrations in large particles (chylomicrons, VLDL) and decrease of cholesterol and triglyceride concentrations in medium to very small LDL particles when fed HSD. We identified significant STRAIN*MatDIET interactions for levels of VEGF (p=0.01), PYY (p=0.03) and area under te glycemic curve (p=0.02). In offspring, exposure to maternal HSD substantially increased brown fat weight in both strains (MatDIET p = 1.52E-10), decreased triglycerides in most fractions of LDL particles (16.7-25.5 nm, MatDIET p = 0.003) and impaired glucose tolerance exclusively in SHR offspring. The transcriptome assessment in offspring revealed networks of transcripts reflecting the shifts induced by maternal HSD with major nodes including mir-126, Hsd11b1 in the brown adipose tissue ; Pcsk9, Nr0b2 in liver and Hsd11b1, Slc2a4 in white adipose tissue.

Conclusion: Our results show that Zbtb16 gene substantially modulates the effect of HSD-induced programming on metabolic and transcriptomic profiles of the offspring.

NFIA controls the brown fat gene programme by co-localising with PPARgamma at cell type-specific enhancers

T. Yamauchi, Y. Hiraike, H. Waki, T. Kadowaki;
Department of Metabolic Diseases, University of Tokyo, Tokyo, Japan.

Background and aims: Brown fat dissipates energy in the form of heat by means of the uncoupling protein-1 (UCP1) on the mitochondrial inner membrane. In humans, brown fat activity is inversely correlated with body mass index. Therefore, stimulating development and/or function of brown fat would be a novel strategy for the treatment of obesity and its complications. However, global landscape of brown fat development is not entirely understood.

Materials and methods: To profile the tissue-specific accessible chromatin landscape, we performed FAIRE-seq analyses of murine interscapular brown fat and white fat using 8-week-old male C57BL/6J mice. We next performed motif analyses of depot-specific open chromatin regions to seek a novel transcriptional regulator. To examine whether NFIA can induce adipocyte differentiation from myoblasts, we introduced NFIA into C2C12 myoblast cell lines using retroviral vectors. To evaluate the physiological relevance of NFIA in BAT in vivo, we analyzed BAT in wild-type and NFIA-KO mice.

Results: Here, we identified nuclear factor I-A (NFIA) as a novel transcriptional regulator of brown fat. The binding motif for Nuclear factor I (NFI) transcription factor is enriched within brown-fat-specific open chromatin regions. Of the four isoforms of NFI family, NFIA is highly expressed in brown fat compared to white fat or muscle. Introduction of NFIA into myoblasts results in lipid accumulation, activation of the brown-fat-specific gene program and suppression of muscle genes. Conversely, the brown fat of NFIA knockout mice displays impaired expression of the brown-fat-specific genes and reciprocal elevation of muscle genes. Mechanistically, NFIA selectively co-localize with PPARgamma at the brown-fat-specific enhancers, and co-localization of NFIA facilitates the binding of PPARgamma, leading to increased chromatin accessibility and active transcription.

Conclusion: Collectively, these results indicate that NFIA is a novel key transcription factor that co-localizes with PPARgamma and activates the brown-fat-specific gene program.

The pivotal role of O-GlcNAcylation in cold-induced thermogenesis by brown adipose tissue

N. Ohashi[1], K. Morino[1], S. Ida[1], O. Sekine[1], M. Lemecha[1], S. Kume[1], S.-Y. Park[2], C.S. Choi[2,3], S. Ugi[1], H. Maegawa[1];
[1]Department of Medicine, Shiga University of Medical Science, Otsu, Japan, [2]Korea Mouse Metabolic Phenotyping Center, Gachon University, Incheon, [3]Department of Internal Medicine, Gachon University, Incheon, Republic of Korea.

Background and aims: Brown adipose tissue (BAT) is important for non-shivering thermogenesis under cold conditions in rodents and also plays significant roles in glucose and lipid metabolisms. During cold exposure, glucose and fatty acid oxidations increase in order to maintain core temperature by stimulating heat production in BAT.O-GlcNAcylation is the post-translational modification that is characterized by the addition of N-acetylglucosamine to various proteins by O-GlcNAc transferase (Ogt). Since O-GlcNAcylation is considered as a "nutrient sensor" for glucose and fatty acids, it could influence BAT function. However, little is known about the role of O-GlcNAcylation in BAT. Therefore, we investigated the physiological role of O-GlcNAcylation in BAT.

Materials and methods: BAT-specific Ogt knockout (Ogt-BKO) mice were generated using the Cre-LoxP system. We crossbred Ogt-flox ($Ogt^{f/f}$) female mice with uncoupling protein 1 (UCP1) promotor Cre mice. We have confirmed that Ogt protein expressions and subsequent O-GlcNAcylations were decreased only in BAT in Ogt-BKO mice.

Results: Ogt-BKO mice led to hypertrophy and displayed an accumulation of enlarged lipid droplets in BAT cells, although there were no differences in body weights compared to control mice. During cold exposure, Ogt-BKO mice showed severe cold intolerance, and BAT UCP1 protein expression was severely diminished. In addition, a significant reduction in protein expression of peroxisome proliferator-activated receptor gamma coactivator 1-α (PGC-1α), a key regulator of thermogenesis, was observed. Also, mitochondrial related proteins were significantly decreased, accompanied by decreased PGC-1α expression. Blood glucose levels in Ogt-BKO mice during an intraperitoneal glucose tolerance tests under cold condition were lower than those in control mice, although there were no significant differences at room temperature. Moreover, the impaired cold-induced thermogenesis in Ogt-BKO mice was recovered

by following glucose injection or oral intake of a normal diet, but not by following olive-oil injection or oral fat load.
Conclusion: O-GlcNAcylation in BAT is essential for cold-induced thermogenesis and mitochondrial biogenesis by modulating PGC-1α. Ogt deletion in BAT preferentially utilize glucose, and defective fat utilization. Our findings suggest that O-GlcNAcylation plays a crucial role in glucose and lipid homeostasis in cold environments and may act as a "metabolic switch" in BAT.

IL-10/JAK1/STAT3 signalling loss links changes in mitochondria cristae architecture and nonshivering thermogenesis in brown adipose tissue

J. de Lima-Júnior, G.F.P. de Souza, A.M. Assis, D.L. Ferrucci, L.A. Velloso;
State University of Campinas - UNICAMP, Campinas, Brazil.

Background and aims: Several studies has shown that obesity is linked to chronic low-grade inflammation. The anti-inflammatory cytokine interleukin-10 (IL-10) has a key role as a regulator of obesity-induced inflammation. Since non-shivering thermogenesis in brown adipose tissue (BAT) is important to whole body energy balance, disruption on BAT thermogenesis may lead to obesity. Given that IL-10 activates JAK1/STAT3 pathway and activated STAT3 contributes to regulation of brown adipose tissue differentiation, here we addressed whether IL-10 signaling regulates brown fat function.
Materials and methods: We analyzed protein levels in BAT using immunoblotting. In vivo role of IL-10 signaling in nonshivering thermogenesis was evaluated with ^{18}fluorodeoxyglucose uptake by BAT (measured using PET/CT) during mild cold exposure and interscapular temperature using infrared thermography (FLIR® instruments) in IL-10 deficiency mice. Metabolic activity of BAT was measured using fluorescence lifetime imaging microscopy (FLIM) of NADH and FAD and isolated brown-fat mitochondria respiration using Oxygraph-2k respirometer. Morphological examination of mitochondria was performed with transmission electron microscope (TEM).
Results: IL-10 KO mice upon to high-fat feeding (HF) displayed a higher weight gain compared to wild-type mice. Since no difference on caloric ingestion or activity was detected between IL10d and wild type mice, we observed that IL-10 KO mice consumed less oxygen than control mice. HE staining revealed the presence of larger adipocytes in interscapular BAT depot in IL-10 KO mice. Consistent with this, IL-10 KO developed impaired glucose tolerance in ipGTT. To evaluate in vivo role of IL-10 signaling in adaptive thermogenesis, we challenged the IL-10 KO mice with cold exposure (16°) for 1 hour. After that, the IL-10 KO showed decreased ^{18}fluorodeoxyglucose uptake by BAT using PET/CT and decreased interscapular temperature (using infrared thermography). As assessed by UCP1 expression, IL-10 KO exhibited impaired UCP1 increment after HF feeding in relation to WT mice. Nevertheless, IL-10 KO showed similar oxygen consumption and interscapular temperature change after β3-agonist (CL-316,243) stimulation. In vitro, we measured the oxygen consumption of isolated BAT mitochondria, and the IL-10 KO mitochondria showed a significantly lower consumption when compared to wild type, mainly due a decrease in UCP-1 related consumption. Indeed, UCP-1 protein levels were decreased in IL-10 KO BAT. In addition, in vivo FLIM of NADH and FAD, the mean lifetime of FAD was longer than the mean lifetime of NADH in the IL-10 KO mice in relation to WT mice, as well as the IL-10 KO mice showed increased cellular redox ratio and consequent decreased cellular metabolic activity. Besides, we performed TEM on BAT mitochondria of the two groups and revealed that IL-10 signaling loss is accompanied by decreased cristae density and mitochondria fragmentation. The treatment with TNF-alfa antibody and gain-of-function experiment reverted these structural abnormalities, pointing out that this anti-inflammatory cytokine signaling is involved in the mitochondria disruption.
Conclusion: Thus, in the absence of IL10 there is an impairment of thermogenesis leading to increased body mass gain and mitochondria fragmentation.

The reduced adipocyte mitochondrial oxidative phosphorylation are linked to impaired beta 3-adrenergic receptor signalling in obese adults

X. Yin[1], S. Pang[1], Y. Lu[1], L. Wang[1], W. Cao[2];
[1]Shandong University affiliated Jinan Central Hospital, [2]Shandong University, Jinan, China.

Background and aims: Obesity is increasing in an epidemic manner in most countries and constitutes a public health problem by enhancing the risk for cardiovascular disease and metabolic disorders such as type 2 diabetes. Early indications suggest that brown adipose tissue (BAT) metabolism is defective in obesity and type 2 diabetes mellitus, which may have important pathological and therapeutic implications. The beta3-adrenergic receptor (β3-AR) pathway is a dominant signaling pathway to activate BAT thermogenesis in humans, selective β3-AR agonist had been proved to stimulated glucose uptake in the BAT depots and increase resting metabolic rate in healthy adult humans, but minimal efficacy on BAT activity was observed in obese subjects after administration of adrenergic agonist. The lack of efficacy of β-AR agonists in obese subjects appears to be due to an impaired β-AR signaling in adipose tissues. The underlying mechanisms for the β-AR resistance remain poorly understood. Our objective was to determine whether the reduced adipocyte mitochondrial oxidative phosphorylation level in obesity is associated with β3-AR expression in non-diabetes adults.
Materials and methods: Omental and/or abdominal subcutaneous adipose samples were collected from 86 age-matched non-diabetic men and women undergoing elective abdominal surgery, mature adipocytes were separated from adipose tissue by collagenase digestion. Mitochondria oxygen consumption rate (OCR), the abundance of mtDNA-encoded NADH dehydrogenase 1 genes (ND1/28S), Citrate synthase (CS) activity, expression levels of β3-AR, HSL and CPT-1 of mature adipocytes were measured using a real-time quantitative PCR system, Clark-type oxygen electrode, spectrophotometric method and western-blot.
Results: The β3-AR mRNA expression of mature adipocyte in obese group was lower (1.8±0.92 vs. 5.6±2.21, P=0.01) compared to non-obese group. Mitochondria OCR (125.01±60.76 vs. 64.52±29.6 pmol/(s*ml)/mg protein, P=0.007) and CS activity levels (1.4 ± 0.18 vs. 0.76 ± 0.06 μmole/min/mg protein, respectively, P = 0.006) were higher in non-obese group than obese ones. A positive correlation between adipocytes mitochondrial OCR and β3-AR mRNA expression level was reported(r=0.6, P<0.05). There were no significant difference between obese and non-obese groups in the abundance of ND1/28S (P>0.05), which showed the different oxidative phosphorylation level between two groups suffered from the difference in the adipocyte mitochondrial capacity, not in the mitochondrial content. The HSL enzyme activity (1.6 folds, P=0.01), CPT-1 enzyme activity (1.8 folds, P=0.008) and CPT-1 mRNA expression levels (2.1 folds, P=0.006) in non-obese group was higher compared to obese group.
Conclusion: Obese individuals suffered from impaired mitochondrial oxidative capacity, followed by lipid metabolism disorders and increased oxidative stress. Promoting BAT recruitment is an important aspect to be considered for obesity who do not possess sufficient amounts of active BAT. The lack of efficacy of cold and β3-AR agonist in recruiting BAT was partly due to impaired β3-AR pathway in obese individuals. The

underlying mechanisms for the β3-AR pathway dysfunction remain poorly understood and should be further investigated.

Adenosine and A_{2A} receptors in human brown adipose tissue

M. Lahesmaa[1], V. Oikonen[1], S. Helin[1], P. Luoto[1], T. Gnad[2], A. Pfeifer[2], T. Niemi[3], M. Taittonen[3], P. Nuutila[1], K.A. Virtanen[1];
[1]Turku PET Centre, Turku, Finland, [2]University of Bonn, Bonn, Germany, [3]Turku University Hospital, Turku, Finland.

Background and aims: Brown adipose tissue (BAT) has emerged as a potential target to combat obesity and diabetes in humans. Novel strategies to activate BAT and improve metabolism are needed. Adenosine is a purine nucleoside released locally in BAT when noradrenaline and ATP are released from sympathetic nerves. Recently it was found that adenosine activates murine and human brown adipocytes, and recruits beiging of white fat via adenosine A_{2A} receptors (A2AR). Furthermore, studies with mice have shown improvements in glucose homeostasis after administration of A2AR agonists. In this study we aimed to investigate the significance of adenosine and A_{2A} receptors in human BAT in vivo. Using PET imaging we measured perfusion and A2AR in supraclavicular BAT and other tissues in healthy men.
Materials and methods: We studied healthy male subjects using PET imaging (n=10, age 25 ± 6 years, BMI 24.5 ± 1.7 kg/m^2). Perfusion of BAT, white adipose tissue (WAT) and muscle were measured with [^{15}O]H_2O PET/CT in basal conditions, during cold exposure and during intravenous infusion of adenosine (0.14 mg/kg/min). To investigate adenosine A_{2A} receptors in BAT, PET imaging with A2AR PET radioligand [^{11}C]TMSX was done once in basal conditions and once during controlled cold exposure (average 16.2 ± 1.6 Celsius degrees, cooling blanket Blanketrol III, Cincinnati Sub-Zero). Before all PET scans the study subjects fasted overnight and avoided caffeine and strenuous exercise for minimum of 24 hours. Distribution volume (DV), i.e. the ratio of the radioligand concentration in tissue to that in plasma at equilibrium, was quantified using Logan plot. BAT and WAT biopsies were obtained from 3 study subjects and are currently being analyzed.
Results: Intravenous adenosine infusion caused a maximal perfusion effect in supraclavicular BAT. As expected, cold exposure doubled the perfusion of BAT compared to basal conditions (basal 8.5 ± 4.5 vs. cold 19.6 ± 8.6, P=0.004) and interestingly adenosine further increased perfusion by nearly 50% (cold 19.6 ± 8.6 vs. adenosine 28.6 ± 7.9, P=0.03). In line with previous studies, i.v. adenosine also increased muscle perfusion 9-fold (P=0.03) and WAT perfusion 5-fold (P=0.004). DV of the A2AR radioligand [^{11}C]TMSX in BAT was significantly lower in cold conditions when BAT was activated compared to baseline conditions (0.89 ± 0.1 vs. 1.36 ± 0.5, P=0.038). DV of [^{11}C]TMSX in muscle was similar as reported in earlier studies and cold exposure caused no significant change.
Conclusion: Exogenous adenosine increased BAT blood flow even more than cold exposure. Adenosine A_{2A} receptor density can be quantified in human BAT using [^{11}C]TMSX PET/CT. Cold exposure decreased the density of A_{2A} receptors available for radioligand binding in human BAT. This may be due to an increase in locally released endogenous adenosine during cold activation of BAT. These results support that adenosine and A2AR are significant in human BAT physiology.

Secretin increases glucose uptake in human brown adipose tissue

S. Laurila[1,2], M. Lahesmaa[1,2], K. Braun[3,4], K. Virtanen[1,2], M. Klingenspor[3,4], P. Nuutila[1,2];
[1]Turku PET Centre, University of Turku, Turku, [2]Department of Endocrinology, Turku University Hospital, Turku, Finland, [3]ZIEL - Institute for Food and Health, Technical University Munich, Freising, [4]Chair for Molecular Nutritional Medicine, EKFZ - Else Kröner-Fresenius Center, Technical University Munich, Freising, Germany.

Background and aims: GI peptides have a role in energy metabolism and in the development of diabetes and obesity. Obesity and type 2 diabetes are associated with impaired cold-induced brown adipose tissue (BAT) function. Recent preclinical findings suggest that secretin activates BAT in mice. The aim of our study was to investigate whether secretin activates BAT in humans.
Materials and methods: Fifteen healthy, normal-weight males were recruited. Data is presented on the subjects (n=7, mean age 46.6 ± 11.9 years, mean BMI 23.7 ± 2.0) who have completed all studies, while studies for the rest of the subjects will be finalized by August 2017. Supraclavicular BAT glucose uptake (GU) and blood flow were measured with [^{18}F]-FDG- and [^{15}O]-H_2O-PET-CT. The protocol included three separate study days: one during cold exposure and after placebo (saline) or secretin (2 IU/kg of secretinpentahydrochloride) injections. Administration of secretin and placebo were randomized and blinded. Graphical image analysis was blinded. Plasma secretin concentration was measured at baseline and at specific time points during all scans.
Results: Plasma secretin concentration increased after i.v. injection of secretin to a postprandial level for 30 minutes. Compared to saline, secretin administration stimulated an increase in BAT glucose uptake (GU 1.5 ± 0.8 vs GU 0.8 ± 0.4 μmol/100g•min, secretin vs. placebo p=0.04, N=7). Secretin did not increase BAT flow compared to placebo (4.0 ± 2.0 vs 5.6 ± 2.0 ml/100g•min, p=0.12, N=7). In the whole group, cooling tended to increase BAT GU (4.0 ± 4.3 vs. 0.8 ± 0.4 μmol/100g•min, cold vs. placebo, p=0.08, N=7), with three out of seven subjects having metabolically active BAT.
Conclusion: Secretin increases supraclavicular BAT glucose uptake compared to placebo in humans independently of perfusion. These results indicate a potential role of secretin in postprandial thermogenesis and merit further human studies addressing the pharmacological potential of secretin in BAT activation.

Association of glycaemic control with the depletion of mucosal-associated invariant T (MAIT) cells in cardiometabolic diseases

K.E. Assmann[1], S. Touch[1], J. Aron-Wisnewsky[1], F. Marquet[1], C. Rouault[1], M. Fradet[1], H. Mosbah[1], A. Lehuen[2], C. Poitou[1], K. Clément[1], S. André[1], MetaCardis Consortium;
[1]Institut of Cardiometabolism and Nutrition (ICAN); INSERM, UMR_S U1166, Nutriomics team; Assistance Publique-Hôpitaux de Paris AP-HP, Pitié-Salpêtrière Hospital; Sorbonne Universités, UPMC University Paris 6, [2]INSERM U1016, Institut Cochin, and Laboratoire d'Excellence INFLAMEX, Université Paris Descartes, Université Sorbonne Paris Cité, Paris, France.

Background and aims: Cardiometabolic diseases (CMDs) represent a considerable burden for health care systems. Systemic low-grade inflammation is an important and common mediator of CMDs. We recently reported that a subset of T cells, circulating mucosal-associated invariant T (MAIT) cells, not only decrease in frequency in obesity and type-2 diabetes (T2D), but are also strongly proinflammatory. It is unknown if MAIT cell reduction and modified phenotype worsens with CMD severity. Here, we assessed circulating MAIT cell characteristics in 439 subjects from the EU-Metarcardis cohort and examined potential mechanisms underlying MAIT cell loss from the bloodstream.
Materials and methods: The frequency of MAIT cells identified as $CD3^{+}CD161^{hi}V\alpha7.2\ TCR^{+}$ cells by flow cytometry of blood samples was examined in 66 healthy subjects and 373 patients with different stages of CMD severity. These patients were stratified in 5 groups of CMDs as follows: metabolic syndrome, obesity, T2D, coronary artery disease with or without heart failure. We examined the relationships between MAIT cell characteristics and CMD clinical phenotypes.
Results: Compared to healthy controls, blood MAIT cell frequency was significantly decreased in CMD groups (median values: 3.5% among controls vs. 0.4% - 1.6% in the different CMD groups, all p from age-adjusted ANCOVA < 0.05). The most substantial decrease was observed in patients with coronary artery disease and heart failure (0.4%). Moreover, absolute MAIT cell numbers were decreased among CMD patients despite an increase of overall circulating leukocytes. MAIT cell abundance was associated with metabolic and inflammation variables such a glycated hemoglobin ($r=-0.28$, $p<0.0001$), hs-CRP ($r=-0.24$, $p<0.0001$) and IP-10 ($r=-0.22$, $p<0.0001$). In vitro exposition of immune cells to increasing doses of glucose promoted MAIT cells apoptosis while conventional T cells were not altered.
Conclusion: A reduced proportion of circulating MAIT cells is a common cellular signature observed in CMD patients, and is related to markers of glycemic control and of chronic inflammation. Thus, MAIT cell loss may in part be related to inflammatory and metabolic stress, notably hyperglycemia, in these patients.

Perilipin family determines lipid droplet storage in macrophages and alters their inflammatory character

K. Cho, H. Miyoshi, K. Yamamoto, A. Nakamura, T. Atsumi;
Division of Rheumatology, Endocrinology and Nephrology, Hokkaido university Graduate School of Medicine, Sapporo, Japan.

Background and aims: Macrophages play a role in the growth and vulnerability of atherosclerotic plaques. Macrophage polarity (the balance between pro-inflammatory macrophages (M1) and anti-inflammatory macrophages (M2)) is associated with an increased incidence of stroke. Macrophages store lipids in cytosolic lipid droplet (LD), surrounded mainly by the perilipin (PLIN) family. In adipose tissue, immature small LDs are surrounded by PLIN2 being replaced by PLIN1 to large LDs. PLIN1 coordinates multiple related proteins for the maturation of LDs and the lipolysis stimulated by promoted PKA. However, there have been few reports on the roles of PLIN1 in macrophage development and the inflammatory polarity. The aim of this study was to investigate the relationship between LD proteins and the inflammatory character of macrophages.
Materials and methods: The experiments used tissues from human arteries in 65 patients who had undergone a carotid endarterectomy, and cultured macrophages were generated from healthy human peripheral blood mononuclear cells. Tissue plaques were evaluated using immunostaining, real-time PCR, and western blotting. Monocytes were harvested and differentiated into macrophages. M1 macrophages were differentiated with TNF-α, and M2 macrophages with human IL-4. Macrophages were incubated in the presence of cholesterol (oxidized LDL or VLDL) for 24 hours or 7 days following differentiation to each macrophage type. Inflammatory changes and expression of PLIN were investigated. LD size in the macrophage cytosol and the expression of PLIN were histologically assessed. Western blotting was also used for the evaluation of PLIN expression. SiRNA was used to suppress the expression of PLIN1 in cultured macrophages.
Results: In human arterial plaques, PLIN1 was expressed in both plaques from symptomatic stroke patients (n=31) and non-stroke patients (n=34). PLIN2 mRNA expression in the symptomatic group increased to 3.4-fold relative to the non-stroke group. In cultured human M1 macrophages, CD11c (M1 marker) expression increased depending on cholesterol incubation time. PLIN1 were only expressed in day 7th with cholesterol while PLIN2 were identified from 24 hours and enhanced in day 7th. After 24 hours, there were only small LDs covered with PLIN2, and LDs surrounded by PLIN 1 were formed from day 7th. In M2 macrophages, there was no expression of CD11c in the whole period and the expression of CD163 (M2 marker) decreased slowly. PLIN1 emerged as early as 24 hours. LDs became large size formed by PLIN1 after 24 hours, and further grew after 7 days. Differentiated M2 macrophages in the presence of PLIN1 siRNA had small LDs coated with PLIN2.
Conclusion: PLIN2 was mainly expressed in arterial plaques in symptomatic stroke patients. Anti-inflammatory M2 macrophages rapidly formed large LDs by PLIN1 and stored large amount of lipid internally, and that may alleviate lipotoxicity damage to surrounding vascular tissues. In this process, however, pro-inflammatory character was gradually acquired through excess cholesterol stimulation, and the ability of lipid accumulation might have decreased like the small storage in M1 macrophages, covered with PLIN2. It was suggested that these mechanisms could cause plaque rupture.

hsCRP can be precisely calculated by a linear-mixed-model from lysophosphatidylethanolamine (LPE) species in the NUtriGenomics Analysis in Twins (NUGAT) study

M.A. Osterhoff[1,2], R. Schüler[1], T. Frahnow[1], C. Klose[3], M.A. Surma[3], K. Simons[3], H. Silke[1], M. Kruse[1], A.F.H. Pfeiffer[1,2];
[1]Clinical Nutrition, German Institute of Human Nutrition, Nuthetal, [2]Endocrinology, Diabetes and Nutrition, Charité - Universitätsmedizin, Berlin, Germany, [3]Lipotype GmbH, Dresden, Germany.

Background and aims: Recently, we were able to demonstrate a strong association of several lysophosphatidylethanolamine species (LPE) with hsCRP in the NUGAT-study during a high-fat intervention. An increased hsCRP concentration is a known risk marker for type 2 diabetes mellitus and cardiovascular disease. The aim of the present investigation was to quantify the relation between hsCRP and LPE species and to fit a model

for calculation of hsCRP concentration from LPE species and other relevant parameters.
Materials and methods: In the NUGAT-study 46 healthy mono- and dizygotic twin-pairs first were standardized for their nutritional behavior by a carbohydrate-rich low-fat diet for 6 weeks (LF), immediately followed by an isocaloric high-fat diet for 1 week (HF1) and additional 5 weeks (HF6). At each clinical investigation day (CID) plasma was taken for measurement of metabolic parameters, lipid metabolites, cytokines and hsCRP (ELISA). A linear-mixed-model was fitted to calculate the development of hsCRP concentration from lysophospholipid species levels, and further relevant parameters.
Results: Lysophosphatidylethanolamine species (LPE18:0, 18:1, 18:2, 20:4) and hsCRP concentrations were strongly correlated (ρ=-0.323 to -0.382, p=0.014 to 0.040). While LPE species did not change from LF to HF6 in subjects with hsCRP<1 at HF6, all LPE species decreased significantly in those with hsCRP≥1. In a linear-mixed-model to calculate the hsCRP concentration at HF6, CID (LF, HF1, HF6, as fixed factor) as well as hsCRP at LF, LPE18:0, LPE18:1, LPE18:2, LPE20:4, LPE22:6, chemerin, and leptin (at LF, HF1and HF6) revealed as meaningful parameters. The final model allowed an extremely precise prediction of the hsCRP concentrations at HF6. When we correlated the predicted and measured values, the correlation amounted to ρ=0.989 (p<0.001).
Conclusion: Our data demonstrate that mainly LPE species are strongly associated to the concentration of circulating hsCRP. Reasonably, the concentration of LPE-species, which are thought to behave in an anti-inflammatory manner, decreases during the high fat-diet in those subjects with a high hsCRP at the end of the intervention. The exact mechanisms are not known. Possibly, LPE species are converted into lysophosphatidic acid (LPA) by phospholipase D (PLD), which elicits inflammatory potential by binding to LPA-receptors, or there might be a direct interaction between LPE species and hsCRP.

The saturation of membrane phospholipids would be a trigger for K^+ efflux and NLRP3 inflammasome activation in human monocytes/ macrophages

M.A. Gianfrancesco[1,2], J. Dehairs[3], K. Bloch[3], L. L'homme[4], M. Colonval[1], J. Piette[1], J. Swinnen[3], N. Paquot[1,2], N. Esser[1,2], S. Legrand-Poels[1];
[1]Laboratory of Immunometabolism and Nutrition, GIGA-I3, University of Liège, Liège, [2]Division of Diabetes, Nutrition and Metabolic Disorders, University Hospital of Liège, Liège, [3]Department of Oncology, Laboratory of Lipid Metabolism and Cancer, KU Leuven, Leuven, Belgium, [4]Inserm, Institut Pasteur of Lille, U1011 - EGID, University of Lille, Lille, France.

Background and aims: Obesity is worldwide epidemic now recognized as a low-grade inflammatory disease, favoring the development of cardiometabolic diseases. IL-1β production mediated by the NLRP3 inflammasome in adipose tissue macrophages and circulating monocytes plays an important role in the development of insulin resistance in obese patients. We previously demonstrated that saturated fatty acids (SFAs) whose levels are increased in adipose tissue and blood of obese patients are able to induce the activation of NLRP3 inflammasome in human monocytes and macrophages, with a concomitant increase in the percentage of saturated membrane phospholipids. Interestingly, unsaturated fatty acids (UFAs) prevent both events by redirecting SFAs towards triglycerides synthesis. However, the molecular link between the phospholipids saturation and NLRP3 inflammasome activation is not yet elucidated.
Materials and methods: PMA-differentiated THP-1 cells have been treated for 8 hours with BSA (control), BSA/C18:0 alone or combined with BSA/C18:1. Cellular [K^+] and IL-1β secretion were quantified by atomic emission spectrometry and ELISA, respectively. Lipidomic analyses were performed on peripheral blood mononuclear cells (PBMCs) of 14 lean patients and 20 normoglycemic (NG), 14 prediabetic and 8 type 2 diabetic (T2D) obese patients classified according to body mass index, fasting glycemia and HbA1c.
Results: Since K^+ efflux is a common step to many NLRP3 inflammasome activation settings, we tested its involvement in C18:0-mediated NLRP3 inflammasome activation in PMA-differentiated THP-1 cells. We demonstrated that increasing extracellular K^+ concentrations is sufficient to inhibit C18:0-induced NLRP3 inflammasome, suggesting the implication of a K^+ efflux. Indeed, a significant decrease in cellular [K^+] is measured in response to C18:0 vs BSA (85,72 % vs 102,80% of cellular [K^+], p< 0,001) and is strongly correlated with IL-1β production (Pearson r = -0,9790 ; p<0,05). The combined treatment C18:0+C18:1 reverses both K^+ efflux (85,72 % vs 112,00% of cellular [K^+] ; p< 0,001) and IL-1β production. Interestingly, in an ongoing lipidomic study performed on PBMCs from lean and obese patients, we observed a significant increase in the percentage of saturated phosphatidylcholine (PC) that is correlated with the glycemic status in the obese population (11.84% vs 12.62% vs 13.47% of total PC in NG, prediabetic and T2D patients respectively; p<0.05 NG vs prediabetic, p<0.001 NG vs T2D, p<0.05 prediabetic vs T2D).
Conclusion: We propose that stearate (C18:0), by inducing an increase in the saturated phospholipids levels, leads to a K^+ efflux and NLRP3 inflammasome activation. An inhibition of the plasma membrane Na,K-ATPase could explain the K^+ efflux and we are currently investigating this hypothesis. The oleate (C18:1), by maintaining low levels of saturated PC, prevents K^+ efflux and NLRP3 inflammasome activation.

Pro-inflammatory action of omentin through activation of the NFκB, p38 and ERK pathways in primary human adipocytes

C. Niersmann[1,2], K. Röhrig[1,2], M. Blüher[2,3], M. Roden[1,4], C. Herder[1,2], M. Carstensen-Kirberg[1,2];
[1]Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, [2]German Center for Diabetes Research, München-Neuherberg, [3]Department of Medicine, University of Leipzig, Leipzig, [4]Medical Faculty, Heinrich-Heine University, Düsseldorf, Germany.

Background and aims: Omentin was described as anti-inflammatory, insulin-sensitizing and atheroprotective adipokine in mice. In humans, data are controversial and the mode of action of omentin is unknown. As obesity and its pro-inflammatory state are important risk factors for type 2 diabetes and its complications, we aimed to investigate whether and by which mechanisms omentin may affect the secretion of inflammatory proteins by human adipocytes.
Materials and methods: We used human preadipocytes isolated from subcutaneous adipose tissue from five non-diabetic donors. Differentiated adipocytes were treated without or with (i) 500 ng/ml omentin, (ii) 2000 ng/ml omentin or (iii) 20 ng/ml tumor necrosis factor alpha (TNFα) as positive control for 24 h. We analyzed the supernatants for 92 inflammation-related biomarkers using the Proseek®Multiplex Inflammation I kit (Olink Bioscience). Subsequently, we identified potential upstream regulators of the omentin- and TNFα-induced secretion profile using Ingenuity Pathway Analysis. To validate these results, we measured the active forms of these potential regulators in cell lysates using Western blotting.
Results: Omentin dose-dependently induced twenty-nine inflammatory mediators. These biomarkers were upregulated 16.3±4.0-fold (mean ±SEM) by 500 ng/ml omentin and 73.7±22.9-fold by 2000 ng/mL omentin (p<0.0001). In addition, 12 of these proteins were also upregulated by TNFα by 56.1±25.8-fold (p=0.0005). The largest groups of co-regulated proteins were chemokines (e.g. IL-8/CXCL8; monocyte chemotactic proteins 2 and 3/CCL2 and 3) and proinflammatory cytokines

(e.g. IL-6, 7 and 1alpha). Omentin also increased the release of the soluble form of the receptor TNFRSF11B. The pathway analysis identified the nuclear factor 'kappa-light-chain-enhancer' of activated B-cells (NF-κB), the p38 mitogen-activated protein kinase (MAPK) and the extracellular-signal regulated kinase (ERK1/2 MAPK) as upstream regulators for most of the regulated proteins upon stimulation of both omentin and TNFα. On the cellular level, we found that omentin (at 2000 ng/mL) increased the phosphorylation levels of NF-κB p65 (Ser536) by 2.1±0.3-fold ($p<0.05$). Omentin also enhanced the phosphorylation levels of p38 (Thr180/Tyr182) by 2.6±0.4-fold ($p<0.05$) and of ERK1 (T202/Y204)/ERK2 (T185/Y187) by 1.7±0.2-fold ($p<0.01$). TNFα increased the phosphorylation levels of NF-κB p65 (Ser536) by 5.6±0.9-fold ($p<0.001$) and p38 (Thr180/Tyr182) by 4.4±1.0-fold ($p<0.01$).

Conclusion: Omentin induced the release of pro-inflammatory cytokines and chemokines in primary human adipocytes by activation of the inflammatory NF-κB, p38 and ERK pathways. We hypothesize that omentin might act via TNFRSF11B or other receptors of the TNF superfamily which will be investigated in further studies. This might explain the comparable pro-inflammatory effects of omentin and TNFα and might link both proteins with cardiometabolic disease risk.

Lysozyme as new player in obesity-related adipose tissue inflammation

J. Latorre[1], J. Moreno-Navarrete[2], F. Ortega[2], M. Sabater[2], A. Rodriguez[3], S. Berrecil[3], G. Fruhbeck[3], W. Ricart[4], J. Fernández-Real[4]; [1]Institut d'Investigació Biomèdica de Girona (IdIBGi), Salt, [2]Institut d'Investigació Biomèdica de Girona (IdIBGi), CIBER de la Fisiología de la Obesidad y la Nutrición (CIBERobn), Salt / Girona, [3]Clínica Universidad de Navarra, IdiSNA, Pamplona, [4]Institut d'Investigació Biomèdica de Girona (IdIBGi), CIBER de la Fisiología de la Obesidad y la Nutrición (CIBERobn), Universitat de Girona (UdG), Salt / Girona , Spain.

Background and aims: Lysozyme (LYZ) is an antimicrobial enzyme that is expressed in white blood cells. The pathophysiology of obesity implies a chronic low-grade inflammation of adipose tissue associated to macrophages infiltration. To the best of our knowledge no previous studies have examined circulating or adipose tissue (AT) LYZ in human or rodent obesity. In the present study, we aimed to investigate human LYZ in adipose tissue and plasma according to obesity status, inflammation and insulin resistance.

Materials and methods: LYZ gene expression and circulating levels were cross-sectionally analysed in subcutaneous (SAT) and visceral (VAT) adipose tissue (real-time quantitative PCR) and in plasma (ELISA) from subjects with a wide range of fatness and insulin resistance. Adipose tissue LYZ gene expression was also analysed after bariatric surgery-induced weight loss (in humans) and after high-fat diet-induced weight gain (in rats). LYZ was also investigated at mRNA and protein level in human primary mature adipocytes and macrophages before and after lipopolysaccharide (LPS) or LPS-conditioned medium from M1 macrophages (MCM).

Results: The expression of LYZ mRNA was comparable to lipogenic genes in AT (FASN, leptin and PPARG). Although LYZ was expressed in adipocytes, its main expression was detected in cells of the stromal vascular fraction, specifically in $CD14^+$ cells. In both SAT and VAT, LYZ mRNA was increased concurrently with BMI ($p<0.0001$), percent fat mass ($p<0.0001$) and obesity-associated metabolic disturbances (fasting serum glucose, fasting triglycerides, HOMA-IR and C-reactive protein). In addition, AT LYZ mRNA was significantly and positively associated with expression of AT inflammation markers, such as tumor necrosis factor alpha (TNFα), leptin or lipopolysaccharide binding protein (LBP), while negatively with markers of adipogenesis (FASN, GLUT4, PPARG, IRS1). Bariatric surgery-induced weight loss resulted in decreased SAT LYZ mRNA (-68.3% decrease, $p<0.0001$) in parallel to reduction of AT inflammation and the improvement of AT adipogenesis. The high-fat diet-induced weight gain led to increased expression (141.5% increase, $p=0.003$). Similar to adipose tissue LYZ mRNA, plasma LYZ was also increased with obesity and weight gain, and significantly correlated with obesity-associated metabolic disturbances. In vitro experiments revealed that inflammatory factors (LPS or MCM) promoted lysozyme biosynthesis and secretion in both adipocytes and macrophages.

Conclusion: Altogether these findings suggest lysozyme as a new player in obesity-associated adipose tissue inflammation and dysfunction.

Influence of metabolic endotoxaemia on adipose tissue from obese subjects

M. Clemente-Postigo[1,2], W. Oliva-Olivera[1,2], L. Coín-Aragüez[1,2], B. Ramos-Molina[1,2], J. Alcaide-Torres[1,2], F. Cardona[1,2], F.J. Tinahones[1,2]; [1]Instituto de Investigación Biomédica de Málaga (IBIMA), Universidad de Málaga, [2]CIBER Fisiopatologia de la Obesidad y Nutricion (CB06/03), Malaga, Spain.

Background and aims: Circulating lipopolysaccharides (LPS) from gut microbiota have been proposed as a triggering factor for the low-grade inflammation in obesity and metabolic diseases. Likewise, impaired adipose tissue (AT) lipid handling and storage is associated with the development of obesity-related metabolic diseases such as insulin resistance or diabetes. Low-grade inflammatory state has been related to AT dysfunction. Animal studies showed that LPS modify the expression of factors involved in AT function. Here, we aimed to analyze the relationship between LPS and the expression of key factors for adipose function and inflammation in human obesity.

Materials and methods: Visceral and subcutaneous AT (VAT and SAT, respectively) samples were obtained during bariatric surgery from morbidly obese patients to analyze gene expression (n=33) as well as to perform in vitro assays (n=5). Patients were classified according to their LPS levels (high LPS levels, H-LPS group and low-LPS levels, L-LPS group). In vitro differentiated adipocytes from healthy obese subjects were stimulated with a range of LPS doses and gene expression and protein secretion analyzed at different time-points.

Results: H-LPS group had significantly lower mRNA levels of SREBP1 ($p<0.05$), FABP4 ($p<0.01$) and LEP ($p<0.05$) in VAT and FABP4 in SAT ($p<0.01$), but higher mRNA levels of the inflammatory genes CSF3 and IL6 in VAT ($p<0.05$); TLR2, CD14 and MCP1 in SAT ($p<0.05$) than L-LPS group. VAT FASN gene expression also tended to be lower in H-LPS group than in L-LPS group ($p<0.1$). Concordantly, LPS stimulus led to a significant decrease in FABP4 and LEP gene expression as well as in Leptin secretion in visceral and subcutaneous differentiated adipocytes from obese subjects ($p<0.05$). This decrease was related to a significant increase in the gene expression and secretion of MCP1, IL6 and CSF3 ($p<0.05$) in both visceral and subcutaneous differentiated adipocytes.

Conclusion: Metabolic endotoxemia can influence AT physiology by enhancing AT inflammation and impairing the expression of key factors for lipid handling and AT function in human obesity.

Up-regulation of novel proinflammatory adipokine Wnt1 inducible signalling pathway protein 1 (WISP1) in liver fibrosis

M. Markova[1,2], W. Jonas[3,2], M. Rödiger[3,2], C. Tacke[1,4], V. Murahovschi[1,4], K. Kessler[1,4], R. Lichtinghagen[5], C. Sticht[6], N. Gretz[6],

S. Hornemann[1,2], A. Pfeiffer[1,4], O. Pivovarova[1,4], M. Ouwens[7,2], A. Schürmann[3,2], N. Rudovich[1,8];
[1]Clinical Nutrition, German Institute of Human Nutrition (DIfE), Nuthetal, [2]German Center for Diabetes Research (DZD), Potsdam, [3]Experimental Diabetology, German Institute of Human Nutrition (DIfE), Nuthetal, [4]Endocrinology, Diabetes and Nutrition, Charité University Medicine, Berlin, [5]Institute of Clinical Chemistry, Hannover Medical School, Hannover, [6]Center for medical research, Faculty of Medicine Mannheim at Heidelberg University, Mannheim, [7]Institute for Clinical Biochemistry and Pathobiochemistry, German Diabetes Center (DDZ), Düsseldorf, Germany, [8]Endocrinology and Diabetology, Hospital of Buelach, Buelach, Switzerland.

Background and aims: Wnt1 inducible signaling pathway protein 1 (WISP1) is a novel proinflammatory adipokine that was associated with visceral obesity in humans, but not with non-alcoholic fatty liver disease (NAFLD). Animal studies showed that WISP1 is upregulated in liver fibrosis. ADP ribosylation factor related protein 1 (ARFRP1) is a small trans-Golgi-associated GTPase playing critical role in postprandial lipoprotein maturation in liver. Mice lacking the Arfrp1 gene develop fibrosis. We investigated the relationship between WISP1 and fibrosis in liver and adipose tissue in mice and humans.
Materials and methods: Two mouse models with either liver or fat specific Arfrp1 knockout displaying fibrosis in respective tissues were fed standard chow diet for 2 and 12 weeks. Gene expression of WISP1 was measured in liver, muscle and adipose tissue; serum WISP1 levels were determined using ELISA. Moreover, circulating WISP1 levels were detected in 37 patients with type 2 diabetes and NAFLD (age 64 ± 6 years, BMI 30.2 ± 3.6 kg/m², HbA_{1c} 7.0 ± 0.6%, liver fat 15.0 ± 1.8%). Levels of liver enzymes, hyaluronic acid (HA), amino-terminal propeptide of type III procollagen (PIIINP), tissue inhibitor of metalloproteinases 1 (TIMP1), and enhanced liver fibrosis (ELF) score were determined in fasting blood samples. Furthermore, microarrays were performed in adipose tissue biopsies of 15 healthy men (age 45.1 ± 3.8 years, BMI 27.7 ± 1.1 kg/m^2).
Results: In $Arfrp1^{liv-/-}$ mice displaying liver fibrosis, WISP1 gene expression was enhanced in liver ($p < 0.01$), but not in muscle or adipose tissue. In contrast, WISP1 expression was not altered in white subcutaneous and visceral or brown adipose tissues of $Arfrp1^{ad\text{-}ER-/-}$ mice showing fibrotic lesions in white adipose tissue. Additionally, serum levels of WISP1 were increased only in $Arfrp1^{liv-/-}$ mice (3559 ± 144 pg/ml vs. 2397 ± 82 pg/ml in control mice, $p < 0.001$) and not in $Arfrp1^{ad\text{-}ER-/-}$ mice (2598 ± 262 pg/ml vs. 2548 ± 104 pg/ml in control mice). In humans, WISP1 levels were significantly correlated with circulating TIMP1 ($\rho = 0.527$, $p < 0.001$) but not with liver fat content, liver enzymes, HA, PIIINP, and ELF score. Microarray data analysis in adipose tissue samples of healthy humans showed no associations of WISP1 with expression of any markers of fibrosis.
Conclusion: Our data gives further hints for the role of WISP1 in mice with liver fibrosis. In contrast, WISP1 does not seem to play a role in adipose tissue fibrosis in mice. In subjects with NAFLD we observed no association with markers of fatty liver and fibrosis, except TIMP1. Additional research in patients with severe liver disease is needed to confirm these observations.

Effect of acute hyperinsulinaemia on circulating immune cells in type 2 diabetes offspring

M. Šiklová[1], E. Krauzová[1,2], B. Svobodová[1], L. Beranová[1], M. Koc[1], M. Štepán[1,2], V. Šrámková[1], J. Kracmerová[1], V. Štich[1,2], L. Rossmeislová[1];
[1]Department for Study of Obesity and Diabetes, Third Faculty of Medicine, Charles University, [2]Second Department of Internal Medicine, University Hospital Kralovske Vinohrady, Prague, Czech Republic.

Background and aims: Diabetes Type 2 (T2DM) and associated complications as cardiovascular disease are mediated among others by increased inflammatory state. Hyperinsulinemia, which precedes impaired glucose levels in T2DM, may contribute to inflammatory state development, especially in subjects with genetic predisposition to T2DM. Thus, the aim of our study was to investigate/compare the effect of acutely elevated insulin levels on activation of immune cells in offspring of T2DM patients and control subjects.
Materials and methods: 17 non-obese male offspring of T2DM patients and 11 control subjects without family history of diabetes matched for age and BMI (36±7 years, BMI = 25.4 ± 0.9 kg/m^2) were investigated. The subjects were healthy, non-smokers, without hypertension, thyroid or other endocrine disease, and without history of obesity. Family history of diabetes for offspring subjects was considered as at least two first-degree relatives (parents, siblings) or one first-degree relative and two second-degree relatives (grandparents, uncle, aunt) were diagnosed with T2DM. All subjects underwent 2hours' hyperinsulinemic-euglycemic clamp, blood samples were taken before and at the end (generally at 120 min) of the clamp for flow cytometric analysis of lymphocyte and monocyte populations. Markers used for monocyte populations were CD45, CD14, CD 163, CCR2, CD36, TLR2, and TLR4; lymphocytes were analysed by CD3, CD4, CD8, CD193, CD196, and CD183; and cell numbers were expressed as percentage of gated events.
Results: In response to acute hyperinsulinemia, a decrease in CD45+/3+/4+ (T_H) lymphocyte content was observed in both groups of subjects (OFF:-12.7 ± 2.9%, $p<0.001$; CON:-10.2 ± 3.0 %, $p=0.006$). A relative content of T_H lymphocytes subpopulation expressing CD194 (T_H2 and Treg cells) was increased by 15.7 ± 4.4% ($p =0.017$) in a control group, the trend to increase was observed in T2DM offspring (13.9 ± 6.2%, $p=0.07$). T_H2 cell population (defined as CD194+/196-/183-) was increased in control subjects (15.1 ± 4.7%, $p =0.014$). No change in a relative content of monocyte population CD45/14+, and its subpopulations expressing CD163, CCR2, CD36, TLR2 and TLR4 was observed, however, increased expression (MFI) of TLR2 and decreased expression of CD36 scavenger receptor was detected on monocytes in both groups of subjects.
Conclusion: Contrary to hypothesis, hyperinsulinemia induced changes in lymphocyte and monocyte populations / activation status, which cannot be considered as strictly pro-inflammatory. The response of analyzed blood immune cells to hyperinsulinemia was not significantly different in T2DM offspring when compared to control subjects, with the exception of T_H2 lymphocytes, which were increased only in control group.

PS 044 Staging human obesity and diabetes

644

Effect of postpartum weight change on the risk of glucose intolerance three years after delivery

T. Tänczer[1], Z. Szili-Janicsek[2], E. Szabó[3], L. Gerő[2], Z. Kerényi[1], B. Domján[2], M.M. Svébis[2], V. Ferencz[2], Á.G. Tabák[2,4];
[1]Diabetic Outpatient Department, Tóth Ilona Health Care Service, Budapest, [2]1st Department of Medicine, Semmelweis University Faculty of Medicine, Budapest, [3]Department of Medicine, Szent Imre University Training Hospital, Budapest, Hungary, [4]Department of Epidemiology and Public Health, University College London, London, UK.

Background and aims: Both gestational diabetes (GDM) and post-pregnancy weight gain are risk factors for a later development of glucose intolerance (GI). However, little information is known about whether the risk of GI is independently influenced by pre-pregnancy body weight, weight gain during and after pregnancy and the diagnosis of GDM. Our objective was to examine the effect of the weight data of prior GDM and control women (pre-pregnancy weight, weight gain during pregnancy, weight changes after pregnancy) on the development of GI in view of the known risk factors into account,after 3.4±0.7 (mean±SD) years after delivery.
Materials and methods: 94 GDM and 43 control (with normal glucose tolerance during pregnancy) women who gave birth at our hospital in 2005-2006 participated in a nested case-control study, after exclusion of the pregnant women and women with known diabetes at the follow-up. The glycemic status at the time of the follow-up was determined by a standard oral glucose tolerance test (OGTT). The diagnosis of diabetes, impaired fasting glucose and impaired glucose tolerance were defined as GI. The correlation between individual weight parameters, the known risk factors for GI and GI was examined with multiple logistic regression.
Results: During follow-up, GI was diagnosed in n = 37 cases (27%). The weight before pregnancy of current GI women (70.1 ± 14.8 vs. 62.6 ± 10.0 kg, P = 0.007) and their post-pregnancy weight gain (4.0 ± 8.4 vs. -1.9 ± 7.7 kg) was significantly greater than in the case of women with currently normal glucose tolerance (non-GI women). Anamnestic GDM (94 vs. 54%, P <0.0001) and gestational hypertension (22 vs. 3%, P = 0.003) were more common in the GI group. In a multi-variant model, of the three examined weight parameters only pre-pregnancy body weight (OR: 1.04 95% CI: 1.001-1.07) and post-pregnancy weight gain (OR: 1.10 95% CI: 1.04-1.18) were independent predictors. After adjustment of the GDM (OR: 6.56 95% CI: 1.41-30.8) only weight gain after pregnancy remained the independent predictor of GI (OR: 1.09 95% CI: 1.01-1.17) of the weight parameters.
Conclusion: In our study, we confirmed that the important risk factors for the development of glucose intolerance after pregnancy are anamnestic GDM and gestational hypertension, as well as weight gain after pregnancy. The correlation between pre-pregnancy weight and glucose intolerance is explained by the diagnosis of GDM. After pregnancy, to reach and maintain optimum body weight (especially in the case of former GDM) with lifestyle intervention is of primary importance regarding the prevention of glucose intolerance.

A family history of diabetes and placenta

M. Shargorodsky, J. Bar;
Wolfson Medical Center, Holon, Israel.

Background and aims: Heritability of diabetes is associated with hyperinsulinemia, impaired endothelial function and inflammatory up-regulation. However, no studies have examined whether a family history of diabetes effects placental vascular circulation.The present study was designed to investigate the impact of first-degree family history of diabetes (FHD) on placental vascular circulation and inflammatory lesions.
Materials and methods: 339 pregnant women were divided into two groups according to presence of FHD: Group 1 included 255 subjects without FHD, and group 2 included 145 subjects with FHD. Placental histology was performed for vascular circulation, as well as inflammatory lesions of maternal and fetal origin. Maternal and neonatal outcome parameters were collected.
Results: Maternal vascular supply (MVS) abnormalities of the placenta were significantly higher in subjects with FHD, compared to subjects without FHD (p<0.005). Fetal vascular supply (FVS) abnormalities, as well as maternal and fetal inflammatory response did not differ significantly between groups. In the GLM analysis, FHD was an independent and significant predictor of MVS abnormalities and more than doubled the risk of this outcome. Gestational diabetes incidence was significantly higher in subjects with FHD (p<0.0001). Significant by-group differences in gestational diabetes persisted even after adjustment for age and BMI. Although incidence of gestational hypertensive disorders was significantly higher in individuals with a family history of diabetes, after adjustment FHD did not significantly predict this outcome.
Conclusion: A first-degree FHD is significantly and independently associated with an increased rate of maternal vascular perfusion abnormalities and risk of gestational diabetes.
Disclosure: **M. Shargorodsky:** None.

Identification of gestational diabetes and pregnancy outcomes: a population study

C. Lencioni[1], E. Gualdani[2], E. Lacaria[1], P. Francesconi[2], G. Di Cianni[1], G. Seghieri[2];
[1]North-West Tuscany, Department of Diabetes and Metabolic Disease, North-West Tuscany, Lucca and Livorno Hospitals, [2]Epidemiology, Regional Health Agency of Tuscany, Florence, Italy.

Background and aims: According to recommendations of the Regional Health Service of Tuscany, a region in the central Italy, glucose tolerance should be tested by a 75g-2h-oral glucose tolerance test (OGTT) in all pregnant women at higher risk of gestational diabetes (GDM). From the regional database including all screened pregnancies in year 2015, we estimated compliance to guidelines and an algorithm to identify GDM, including also its outcomes at delivery.
Materials and methods: After excluding all those who were diabetic prior to the pregnancy, target population of this study included all women, aged≥15yr, resident in Tuscany, Italy, who delivered, after 22nd week, in year 2015. Deliveries were identified by the certificates of care at delivery (CEDAP). OGTT performance was ascertained by querying regional fluxes of laboratory data and population was divided by eligible or not eligible to be tested by current guidelines. GDM was identified by an algorithm based on adherence to at least one among following criteria: a) insulin prescription during pregnancy, stopped after delivery, b): at least one documented visit by a diabetologist or inclusion into an educational program for patients with diabetes, c): OGTT performed by six months after delivery. Validation of GDM diagnosis was done in two groups of unselected pregnancies whose GDM status was known, and crossing GDM by algorithm with GDM assessed by hospital ICD-9 code (648.8).
Results: Total cohort was composed by 22,730 women and OGTT was tested in 18,006 cases, in 72.38% of non eligible women and in 82% of eligible ones (p<0.0001). Prevalence of OGTT performers increased with age, pre-pregnancy overweight/obesity, higher education degree while housewives and students had a lower chance of receiving an OGTT as compared with employed women. GDM rates, tested by algorithm ,were 11.11% in total population, 14.37% in eligible and 7.02% in non eligible women. Validation of GDM algorithm was similar after matching results with known populations (positive predictive values: 0.805 and 0.920),

and lower after crossing cases by hospital discharges through ICD9 codes (positive predictive value: 0.252). Women with GDM, compared to those without had higher relative risk (RR) of caesarian section (RR:1.22; 95%CI:1.14-1.30), macrosomic newborns (RR:2.22; 1.10-4.47), preterm deliveries (RR:1.56; 1.36-1.78) and neonates with Apgar score<10 (RR:1.31;1.23-1.39); p<0.05 in all cases.

Conclusion: Overall compliance to guidelines seems to be high in this population (more than 80% in eligible women). GDM prevalence, as estimated by an algorithm, was about 11%. The high prevalence in not eligible women and the non optimal outcomes in GDM women, suggest to reconsider the application of selective screening.

Gestational diabetes registers: a study of effectiveness in Australia, the MAGDA study

D.I.R. Boyle[1], V. Versace[2], J.A. Dunbar[2], E.D. Janus[3,4], S.T.F. Shih[2], S. O'Reilly[2], on behalf of the MAGDA Study Group;
[1]Department of General Practice, University of Melbourne, [2]Faculty of Health, Deakin University, [3]University of Melbourne, [4]Western Health, Melbourne, Australia.

Background and aims: The risk of developing Type 2 Diabetes Mellitus (T2DM) within 5-10 years is sevenfold higher in women who have GDM vs no GDM. Australia implemented a National Gestational Diabetes Register (NGDR) in July 2011 as a mechanism to support follow-up of women with GDM history aiming to reduce T2DM progression rates. Registration is not mandated. This study (part of the Mothers After Gestational Diabetes in Australia - MAGDA study) aimed to evaluate the extent to which the NGDR can contribute to diabetes prevention among women diagnosed with GDM.

Materials and methods: This was a retrospective data linkage study in Victoria (VIC) and South Australia (SA) (data available 2008 - 2014) from state birth records, National Diabetes Support Services (NDSS) that runs the NGDR, and principal pathology providers in SA and Victoria. The study utilised GRHANITE™ data acquisition and privacy-preserving record linkage technologies that facilitated the linkage of highly protected databases for the first time. Mothers in Australia are recommended to have a follow-up OGTT test 6 weeks postnatally to detect ongoing diabetes. NGDR posts a screening reminder letter to the GP and mother 8-16 weeks postnatally, 10 months after birth and annually commencing 2 years after birth. Diabetes-related pathology testing (OGTT, GCT, HBA1c, BGLU) were used as indicators of screening follow-up for GDM postnatally. All GDM-diagnosed mothers registered on NGDR who had births between 2010 and 2013 and had a linked, diagnostic laboratory GDM screening test result (i.e. who utilise the labs where we have the data) were followed-up. We compared postnatal diabetes-related testing rates for two years before and after the NGDR inception.

Results: VIC 2010 - 2011 8,076 mothers with GDM diagnosis, screening data available for 37%. Of these 53% had a 6 week OGTT. VIC 2012 - 2013 11,458 with GDM, screening data 52%. 58% had a 6 week OGTT. SA 2010 - 2011 2,484 with GDM, screening data 78%. 43% had 6 week OGTT. SA 2012 - 2013 3,104 with GDM, screening data 82%. 44% had 6 week OGTT. Peak testing occurred in both states at 6 weeks but rates are suboptimal at 58% VIC and 44% SA. The NGDR Register registration rates in the study population 2012-2013 were 90% (VIC), 75% (SA). There was only a 5% increase in screening in VIC after register implementation, 1% in SA. Reminder letters from the register were sent AFTER the peak OGTT testing found at 6 weeks. There was no indication of any screening activity related to the dates NGDR letters were posted at any time.

Conclusion: 6-week postnatal testing rates show negligible improvement regardless of any evolution of patient management processes. The NGDR postnatal reminder letters demonstrate no effect on postnatal diabetes screening at any time in either state. Engaging women who have had GDM in follow-up programs is difficult. Early evidence suggests that managing recall and testing of women who have had GDM at a local level (e.g. GP clinics) is likely to be more effective than letters. NGDR registration rates are high but other strategies must be found to use its information to effect change. Testing mothers before discharge from hospital may be more effective than an under-subscribed 6-week OGTT test.

Identifying women with recent gestational diabetes at greatest need of early post-partum testing for diabetes and intermediate hyperglycaemia

C.D. Castilhos[1], C. Façanha[2,3], M. Drehmer[1,4], M. Nunes[5], A.C. Forti[6,2], B.B. Duncan[1,4], M. Schmidt[1,4];
[1]Clinical Research Center, Hospital de Clínicas de Porto Alegre, Porto Alegre, [2]Ceará State Health Department, Integrated Center for Diabetes and Hypertension, Fortaleza, [3]School of Medicine, Centro Universitário Unichristus, Fortaleza, [4]School of Medicine, Federal University of Rio Grande do Sul, Porto Alegre, [5]Postgraduate Program in Epidemiology, Federal University of Rio Grande do Sul, School of Medicine, Porto Alegre, [6]Department of Internal Medicine, School of Medicine, Federal University of Ceará, Fortaleza, Brazil.

Background and aims: Gestational diabetes (GDM) is a strong risk factor for future diabetes, and prevention efforts should target this group of women. Yet, given the overwhelming duties of recent motherhood, adherence to oral glucose tolerance testing (OGTT) is low, particularly early on. Thus, strategies to prioritize efforts to ensure screening at post-partum of those at highest risk are highly needed. The purpose of this study is to assess diabetes risk over the first 20 months post-partum among women with GDM participating in the LINDA-Brasil study so as to find simple means of identifying those at highest need for early testing.

Materials and methods: LINDA-Brasil, an ongoing clinical trial of diabetes prevention at post-partum, is nested within a cohort of women with recent GDM. The cohort currently comprises 2856 women with GDM recruited from high risk pregnancy clinics. We obtained data on clinical characteristics and pregnancy treatments by chart review and interviews, and detected diabetes post-partum by OGTT. We encouraged all women to perform testing, beginning 8 weeks post-partum, and used various approaches to increase adherence, including no cost testing at nearby labs; phone reminders and free clinic visits. Results are expressed as mean (SD). Cox regression was used to estimate relative risks (RR) of different predictors of diabetes in the early post-partum period.

Results: Mean BMI before pregnancy was 30.1 (6.4) kg/m2 and mean age 31.9 (6.2) y; 19.3% used insulin during pregnancy and an additional 16.3%, oral hypoglycemic agents. At post-partum, among those who completed an OGTT, diabetes prevalence was 2.3% among non-antidiabetic medication users, and 15.8% among antidiabetic medication users. By 20 months post-partum, incidence rates were 4% and 27%, respectively. Use of insulin during pregnancy identified those with a six-fold higher risk of having diabetes (RR 6.0; 95%CI 3.9-9.1); use of oral hypoglycemic medication, 1.9 (95%CI 1.3-2.9). Each 5 unit increase in BMI increased risk by 20% (RR 1.2; 95%CI 1.0-1.4). Most incident cases (82%) used insulin (65%) or oral hypoglycemic agents alone (17%) during pregnancy.

Conclusion: Use of insulin or oral hypoglycemic agents during pregnancy identifies most future cases of diabetes developed over 20 months post-partum. Anti-diabetic medication use during pregnancy constitutes a simple means of identifying women most likely to have or develop diabetes soon after giving birth, and thus most likely to benefit from more intensive efforts to ensure early post-partum testing.

Routine resting energy expenditure measurement increases effectiveness of dietary intervention in overweight and obese patients

S. Massarini[1], A. Ferrulli[1], F. Ambrogi[2], C. Macrì[1], C. Richetti[1], L. Luzi[1,3];
[1]Area of Endocrinology and Metabolic Diseseas, IRCCS Policlinico San Donato, San Donato Milanese, [2]Department of Physical Sciences and Community Health, University of Milan, [3]Department of Biomedical Sciences for Health, University of Milan, Milan, Italy.

Background and aims: Primary outcome of this study was to compare weight changes in two groups of overweight or obese individuals: subjects who had a diet prescribed on the base of Resting Energy Expenditure (REE) measured by indirect calorimetry and subjects whose REE was estimated by a predictive equation. In addition, we analyzed differences in weight and metabolic parameters variation in subjects with and without an adequate to predicted REE and in subjects with Respiratory Quotient (RQ) ≤ 0.9 and with RQ > 0.9.
Materials and methods: We retrospectively analyzed data of a 355 overweight and obese patients: 215 on a diet based on REE measured by indirect calorimetry (IC group) and 140 following a diet based on REE estimated by the Harris-Benedict equation (NO-IC group). Anthropometric and metabolic parameters were evaluated for eighteen months since baseline. A multivariable model was used including age, presence of diabetes, endocrine disorders, hypertension or metabolic syndrome. Propensity score adjustment was used to adjust for known differences between the groups being compared. Coarsened Exact Matching (CEM) method was used to match patients according to the baseline covariates used for estimating the propensity score.
Results: A significant greater decrease of body weight was observed in the group that performed indirect calorimetry compared to the group who did not perform it. Eighteen months after the first clinical visit, weight loss rate in the IC group was -9.54 ± 0.07% vs Baseline, whereas in the NO-IC group was -1.95 ± 0.05% vs Baseline, showing a statistically significant difference between the groups ($p<0.001$). No significant differences were observed between patients with not adequate to predicted REE compared to patients with adequate to predicted REE. Particularly, 18 months since the first visit, weight loss in the subjects with adequate to predicted REE was -9.33 ± 0.06% vs Baseline, and with no adequate to predicted REE was -9.72 ± 0.07% vs Baseline, showing no significant difference between groups. The IC group was further divided in subjects with RQ ≤ 0.9 and with RQ > 0.9. There was no significant difference in the variation through time between the two sub-groups (weight: IC RQ ≤ 0.9 vs RQ > 0.9: p=0.908. BMI: IC RQ ≤ 0.9 vs RQ > 0.9: p=0.921). Finally, we analyzed metabolic biomarkers in IC and NO-IC groups considering variations through time: a significant difference between the two groups was found in triglycerides which decreased faster in the IC group (p=0.03).
Conclusion: A weight reduction program based on indirect calorimetry appears more effective than a dietary program based on predictive formulas. This retrospective study suggests the routine use of indirect calorimetry utilization in all weight reduction procedures.

Food addiction in obese patients

L. Locatelli[1], Z. Pataky[1], L. Boulanouar[2], A. Golay[1];
[1]Service d'enseignement thérapeutique pour maladies chroniques, Hôpitaux universitaires de Genève, Geneva, Switzerland, [2]Service de maladies métaboliques et nutrition, Hôpital universitaire de Toulouse, Toulouse, France.

Background and aims: Food addiction is a controversial concept based on the fact that similar behaviors are found and identical neurobiological pathways (reward circuit and dopaminergic system) are activated in both food intake and psychoactive substance use. This could explain the difficulties of patients presenting symptoms of food addiction to lose control on food consumption, failure in attempts to reduce their food intake and inability to abstain from specific types of food or reduce their consumption. Excessive sugar intake could be a significant component of food addiction due to the activation of the reward circuit in the same way as classic substances (e.g. alcohol, tobacco,cocaine). The prevalence and the role of food addiction in obesity remain unclear and need to be evaluated. The aim of our study was to assess the prevalence of food addiction in obese patients before a weight loss program and to better evaluate the relationship between food addiction and some aspects of eating disorders.
Materials and methods: In a total of 115 participants with obesity, 93 (39 males and 54 females, age 44± 13 yrs, body mass index (BMI) 38.8 ± 8 kg/m2) have been evaluated before starting a weight loss program. The French version of the Yale Food Addiction Scale (YFAS) was used for both the diagnosis and the severity of food addiction. The diagnosis of food addiction was met if participants endorsed three or more criteria as well as at least one of the two clinical significance items (impairment or distress). The severity of food addiction was a simple sum of the seven diagnostic criteria. Different aspects related to eating disorders were evaluated by the French version of the Eating Disorder Inventory-2 (EDI-2) questionnaire.
Results: Ninety-three participants filled up the surveys and 30 of them (32%) presented the diagnosis of food addiction regarding the YFAS score. In a simple regression analysis, we have seen a positive relationship between the severity of food addiction and the severity of bulimia ($p=0.04$, $R^2=0.13$). The same relationship was seen between the severity of food addiction and the lack of confidence in recognizing and accurately identifying emotions and sensations of hunger and satiety, the interoceptive awareness, ($p=0.007$, $R^2=0.23$). Food addiction was not related to body mass index, gender or age.
Conclusion: The prevalence of food addiction in our population of obese patients and the lack of relationship between food addiction and body mass index, gender and age confirm anterior data. The highlighting of two aspects related to eating disorder, the bulimia and the difficulties with interoceptive awareness, can stress out the accuracy of food addiction as a distinct disease compared to other eating disorders. This could give some information for a more adapted care of food addicts focused on both treatment of bulimia and reconnection with hunger and satiety. The food addiction could be of particular importance in patients with diabetes and need to be elucidated.

Serum branched chain amino acids, dietary macronutrients and development of type 2 diabetes in the Finnish Diabetes study

J. Kivelä[1], J. Lindström[1], M. Uusitupa[2], J. Tuomilehto[3], DPS study group;
[1]Chronic Disease Prevention Unit, National Institute of Health and Welfare, Helsinki, [2]Institute of Public Health and Clinical Nutrition, University of Eastern Finland, Kuopio, Finland, [3]Dasman Diabetes Institute, Kuwait City, Kuwait.

Background and aims: Branched chain amino acids (BCAA) have been associated with type 2 diabetes (T2D) risk in some studies. Still it is not known what is the relation between BCAA and T2D and what causes the elevation of serum BCAA's content. We hypothesize that BCAAs mediate the effect of energy-yielding nutrients in T2D.
Materials and methods: An exploratory study comprised 128 men and 279 women who participated in the randomized Finnish Diabetes Prevention Study (DPS) and were provided either intensive or general

lifestyle counselling to reduce T2D risk. Participants were overweight (BMI>25), middle-aged (40-65 years) and had impaired glucose (IGT) tolerance at baseline. For median of 9 years, participants were followed-up with repeat annual oral glucose tolerance tests for detecting T2D. In the present study we used the anthropometric measurements, blood samples, and dietary data (3-day food diaries) from baseline and year 1. BCAA were measured from fasting serum by sandwich ELISA as a part of metabolomics analysis. Sex-specific quartiles of baseline BCAA were used to categorize participants and Cox regression was used to analyze diabetes risk among the BCAA categories. Linear regression was used to analyze the association between BCAA and intakes of macronutrients.
Results: Serum BCAA concentration at baseline was associated with the development of T2D (Quartile (Q)4 vs. Q1 HR=1,72 [1,07-2,75]; Q3 vs. Q1 HR=1,69 [1,05-2,70]; Q2 vs. Q1 HR=1,06 [0,63-1,77]; p for trend 0,03) in a model adjusted for sex, age, education, BMI, intervention/control group. In men, the correlation between baseline BCAA with baseline energy intake was inverse (β=-0,23 p=0,01), adjusted for age, education, BMI. In men, carbohydrate intake was inversely correlated (β=-0,38 p=0,01) with BCAA, but association was attenuated (p=0,07) after adjustment for age, education, BMI. In women, baseline fat intake was correlated with BCAA (β=0,26 p=0,04), but correlation was attenuated after adjusting for age, education and BMI (p=0,08). In women, the change in intake of saturated fat was correlated with change in BCAA (β=0,17 p=0,04) in a model adjusted for energy intake, age, education and BMI.
Conclusion: Our results confirm that high serum BCAA concentration is a risk marker of future T2D in people with IGT. Our results suggest inverse association between carbohydrate intake and BCAA in men and positive association between fat intake and BCAA in women. Macronutrient intake may modify BCAA, and this may in part explain the associations between macronutrients and T2D risk.

PS 045 Preventing and treating diabetes more effectively

652

Preventing progression to type 2 diabetes in women who have had gestational diabetes: Back to the drawing board?

J.A. Dunbar[1], D.A.R. Boyle[2], S.L. O'Reilly[3], V. Versace[4], S. Sophy[1], E.D. Janus[5], MAGDA Writing Group;
[1]Centre for Population Health Research, Deakin University, Burwood, [2]Dept of General Practice, University of Melbourne, Carlton, [3]Institute for Physical Activity and Nutrition, Deakin University, Burwood, [4]Deakin Rural Health, Deakin University, Warrnambool, [5]Dept of Medicine, University of Melbourne, St Albans, Australia.

Background and aims: Women who have had GDM are seven times more likely to develop type 2 diabetes (T2DM) than women who with normoglycaemic pregnancies. Lifestyle modification has been shown to reduce the risk of progression. Mothers after Gestational Diabetes in Australia (MAGDA) was a five year systems approach to the prevention of T2DM conducted in South Australia and Victoria from 2011-2015.
Materials and methods: Using a systems approach comprising three studies, we examined the processes for intervening to reduce their risk of T2DM. The National Gestational Diabetes Register (NGDR) sends reminder letters to women for 6-8 week postnatal OGTT and annual follow-up by their family physician. The performance of NGDR was assessed by comparison with two state perinatal data collections and with blood samples from registered women analysed by pathology laboratories. A Collaborative for 12 months involving 17 family medicine practices established practice based registers and recall systems for blood testing and T2DM prevention plans. A clinical trial of a group based lifestyle modification program involving 573 women was run during the first postnatal year.
Results: One quarter of woman were not registered with NGDR. Neither the reminder letter for 6-8 wk postnatal OGTT nor the annual reminder letters made any difference to follow-up blood testing rates. The Collaborative involving family medicine led to doubling the rates of review and testing of women (from 30 to 60% over 12 months). Specific T2DM prevention plans were offered to these women but the uptake was low (10%). Among the women recruited to the postnatal intervention, at baseline 10% had IGT and 2% IFG. The mean changes (ITT analysis) over 12 months were as follows: -0.23 kg body weight in the intervention group compared with +0.72 kg in the usual care group: change -0.95 kg group by treatment interaction P=0.04. There were no other significant anthropometric or biomedical changes. Only 10% of women attended all sessions, 53% attended one individual and at least one group session, and 34% attended no sessions. Loss to follow-up was 27% and 21% for the intervention and control groups respectively.
Conclusion: The NGDR registration rate can be improved by using the state perinatal data collections to identify low reporting providers. Reminder and recall letters for NGDR do not appear to work but NGDR could be used to populate family practice-based registers which seem more successful. Adoption of the IADPSG guidelines will increase the numbers diagnosed with GDM. The method used to evaluate NGDR could be used in a risk stratification study. A 1 kg weight difference may be significant for reducing T2DM risk but the level of engagement during the first postnatal year was very low. Engagement of women at this life stage has been found to be difficult by many studies and at this stage 90% are not at high risk of progression to T2DM. Interventions should only be offered to women with IFG/IGT or HbA1c in the pre diabetes range. Research should be directed at understanding why uptake among women who have had GDM is low and how it could be increased.

Care of transgender patients with diabetes

P. Kapsner, S. Brar, J. Conklin, N. Sharon, L. Colip;
University of New Mexico, Albuquerque, USA.

Background and aims: Estimated incidence of transgender persons based on self-report is 871 per 100,000 people. The prevalence of Type 1 diabetes (T1D) is estimated to be 230-340 per 100,000 people. Prevalence of Type 2 diabetes (T2D) is as high as 6,700 per 100,000. Trans patients with diabetes mellitus (DM) seek care for gender dysphoria. Patients with DM are at higher risk for cardiovascular disease (CVD), osteoporosis, obstructive sleep apnea (OSA) and depression. It is unclear if cross hormone therapy increases risk of cardiovascular disease in trans women. Studies suggesting increased risk are confounded by use of ethinyl estradiol, known to increase clotting. Although controversial in hypogonadal natal men, data suggest no CVD risk increase in trans men treated with testosterone. There is no data in trans patients with DM. Hormones used in trans patients are known to have effects on lipid profiles, blood pressure, weight and glucose. Androgen therapy and suppression of endogenous estrogen production in trans men is associated with lower bone mass and OSA. Trans women on estrogen have preserved bone density. The dysphoria and psycho-social issues add to the complexity of managing the DM and co-morbidities. Our institution has a multidisciplinary gender health clinic providing care to 300 transgender patients, 4 with T1D and 5 with T2D. To provide optimal care we follow the American Diabetes Association (ADA) recommended guidelines. We describe our transgender patients with DM focusing on ADA targets and discuss management interventions we identified to improve quality of care.

Materials and methods: Trans patients are cared for by a multidisciplinary team with endocrinology, psychiatry, pharmacology, certified diabetes educator, nutrition, nursing and social services involved. Most recent data was accessed in patients with DM. Means and standard deviation (SD) were calculated when appropriate.

Results: Results are shown in Table 1.

Conclusion: Hormone therapy in our patients is associated with increased modifiable risks associated with DM. These risks need to be optimally managed and discussed with patients. Our results suggest that even with our multidisciplinary team, recommended targets for patients with DM are not always achieved. Triglycerides (TG) tended to be high in trans women most likely due to DM and use of estrogens. Low density lipoprotein cholesterol (LDL-C) was higher and high density lipoprotein (HDL-C) lower in T2 obese patients. Statins were not used in the majority of patients, possibly due to their age. Hypertension was not an issue, maybe due to consistent use of spironolactone as an anti-androgen in trans women. Vitamin D levels were lower than what is considered replete and should be addressed to prevent metabolic bone disease. Trans women with T2D were obese and should be aggressively managed in a weight loss program. A high percentage of patients had a current or past diagnosis of substance abuse and nicotine use requiring interventions and support services. Other behavioral disorders were prevalent in our patients making psychiatry an integral component of our team.

Table 1. Description of transgender patients with Type 1 and Type 2 Diabetes

A Randomised trial of a Proactive Inpatient Diabetes Service (RAPIDS) demonstrates decreased adverse glycaemia and hospital-acquired infections

M. Kyi[1,2], P.G. Colman[1], P.R. Wraight[1], J. Reid[1], A. Galligan[1], S. Kumar[1], L.M. Rowan[1], A.J. Nankervis[1], A. Gorelik[3], K.A. Marley[1], D.M. Russell[4], S. Fourlanos[1,4];
[1]Diabetes and Endocrinology, Royal Melbourne Hospital, [2]Department of Medicine - Royal Melbourne Hospital, University of Melbourne, [3]Melbourne EpiCentre, Royal Melbourne Hospital, [4]Department of General Medicine, Royal Melbourne Hospital, Melbourne, Australia.

Background and aims: In hospitalised patients, both hypoglycaemia and significant hyperglycaemia are associated with adverse outcomes. We hypothesised a proactive inpatient diabetes service (IDS), which electronically identifies inpatients with diabetes and provides immediate management, will decrease the incidence of adverse glycaemia & hospital complications.

Materials and methods: RAPIDS (ACTRN12616000265471) was a cluster-randomised trial on 8 wards of a tertiary hospital. Consecutive inpatients with diabetes or new-onset hyperglycaemia (random blood glucose [BG] ≥11.1 mmol/L without known diabetes) were recruited. Networked glucose meters were used to record capillary BG measures from admission until discharge, or day 14 for long-stayers. There was a 10-week baseline observational phase followed by a 12-week active phase during which the wards were cluster-randomised into 4 intervention and 4 control wards. Intervention wards received proactive IDS (endocrinologist or nurse practitioner who aimed to see patients within 24h of admission), while control wards continued usual care (a referral-based consultation service). Primary outcome (incidence of adverse glycaemic days [AGD]: patient-day with any BG <4.0 or >15.0 mmol/L) and secondary outcomes (patient-day mean glucose, hospital-acquired infections and length of stay) were compared between baseline and active phases within each group and subjected to multivariable analysis, adjusting for patient clinical features.

Results: We investigated 1002 patients (87% type 2 diabetes; 29% insulin-treated; HbA1c: 7.5±1.7%) totalling 5447 patient-days & 19062 BG measures. Incidence of AGD decreased significantly in the intervention wards (243 vs. 186 per 1000 patient-days [23% decrease], $p < 0.001$), but there was no significant change in the control wards (291 vs. 261 per 1000 patient-days, $p= 0.08$). On multivariable analysis, proactive IDS was independently associated with 24% decrease in the incidence of AGD ($p=0.005$). Proactive IDS also decreased the patient-day mean glucose (mean [SD]: 9.0 [2.7] vs. 9.5 [3.2] mmol/L, $p<0.001$), and the incidence of hospital-acquired infections (crude incidence: 8% vs. 3%, $p=0.02$; adjusted odds ratio: 0.28, 95% CI: 0.11-0.74, $p = 0.01$). There was no difference in hospital length of stay.

Conclusion: This large randomised trial of a proactive inpatient diabetes service decreased the incidence of adverse glycaemia and hospital-acquired infections. This proactive treatment paradigm may change the approach to inpatient diabetes care.

A randomised clinical trial of electronic secure messages to prompt patients with poorly controlled diabetes to prepare for their primary care visits

R.W. Grant[1], M.T. Vo[1], C.S. Uratsu[1], K.R. Estacio[1], A. Altschuler[1], E. Kim[2], S. Alexeef[1], A.S. Adams[1], J. Schmittdiel[1], M. Heisler[3,4];
[1]Division of Research, Kaiser Permanente Northern California, Oakland, [2]Department of Medicine, Kaiser Permanente Northern California,

Oakland, [3]Department of Internal Medicine, University of Michigan, Ann Arbor, [4]Ann Arbor VA, Center for Clinical Management Research, Ann Arbor, USA.

Background and aims: Despite robust evidence to guide clinical care, most patients with diabetes do not meet all goals of risk factor control. Improved patient-provider communication during time-limited primary care visits may represent one strategy for improving diabetes care.
Materials and methods: We conducted a pragmatic, physician-randomized, multi-site intervention to test the hypothesis that prompting patients with poorly controlled diabetes (A1c > 8.0%) to prepare for their visit would lead to more effective primary care interactions. Patients of physicians in the intervention arm received pre-visit emails asking them to pick and briefly describe their top 1 or 2 visit priorities while patients in the control arm continued with usual care. The study was conducted from 3/1/2015 - 10/21/2016 within a large integrated care delivery system in Northern California. Outcomes included validated measures of visit interactions and changes in A1c.
Results: We enrolled 146 primary care physicians (PCPs, 90.1% consent rate) from 30 primary care practices. Over the course of the study, 609 patients in the treatment arm and 547 patients in the control arm had visits with their PCPs. Among 408 randomly-selected patients completing post-visit surveys (58% response rate), intervention patients were more likely to have prepared a list of questions for their doctor (72.2% vs. 63.3%, p = 0.04), been given choices about diabetes treatment to think about (81.1% vs. 72.9%, p = 0.038), and asked about any medication problems (79.7% vs. 72.3%, p = 0.07). There was no significant difference between study arms in changes in A1c.
Conclusion: A simple pre-visit preparation tool improved primary care visit interactions but not A1c relative to usual care. Translating better primary care visits into better glycemic control may require additional, non-visit based interventions.

Results of a cluster randomised controlled trial to improve primary care management of diabetic peripheral neuropathy symptoms: the Diabetes Telephone study

A.S. Adams[1], J.A. Schmittdiel[1], A. Altschuler[1], E. Bayliss[2], R. Neugebauer[1], L. Ma[1], J. Clark[1], B. Cook[1], D. Willyoung[1], M. Jaffe[3], J.D. Young[4], E. Kim[4], R.M. Hippler[1], R.W. Grant[1];
[1]Kaiser Permanente Division of Research, Oakland, [2]Kaiser Permanente Colorado Institute for Health Research, Denver, [3]Kaiser Permanente South San Francisco Medical Center, South San Francisco, [4]Kaiser Permanente Oakland Medical Center, Oakland, USA.

Background and aims: Diabetic peripheral neuropathy is common among patients with diabetes and difficult to treat given the limited efficacy and tolerability of available medications. We tested the hypothesis that an automated system for eliciting and communicating symptom changes and medication side effects could improve symptom management among newly treated patients.
Materials and methods: Using a cluster randomized controlled trial design, we randomized 1,096 primary care physicians to treatment (3 brief automated calls over six months to monitoring patient symptoms and treatment side effects) or control condition (3 brief non-interactive automated calls over 6 months containing diabetes educational information) and recruited 1,270 of their patients (response rate 83%) newly treated for symptoms to the study. We assessed change in quality of life, patient-provider communication and patient-reported symptoms including pain interference, sleep disruption, and lower extremity function at 8 months and the likelihood of ever receiving a clinically meaningful dose of treatment during the 12-month post intervention period.
Results: Mean patient age was 67 (s.d.11.7) years and 53% were female; 65% had a haemoglobin A1c greater than 7.0%. Demographic and clinical characteristics, as well as baseline quality of life scores, were similar in both arms. Among the 1252 patients with complete data, we found no statistically or clinically significant effects of the intervention on change in quality of life [-0.002 (-0.01, 0.01), p=0.61] or symptoms [pain interference: 0.57 (-0.41, 1.54), p=0.25; sleep disruption: 0.26 (-0.19, 0.85), p=0.21; lower extremity functioning: 0.055 (-0.96, 1.07), p=0.92] or in clinical care [minimum effective dose: 0.04 (-0.20, 0.28); p=0.76]. More than 70% of intervention patient responses to the first call prompted a physician alert, primarily related to medication side effects (51%). Twenty-two percent of intervention patients discontinued treatment by the end of 2 months; the most commonly cited reasons for discontinuation included side effects, lack of symptom relief and concerns about taking too many medications. The majority of patients who continued treatment reported taking medication on a daily basis (>90%) and more than 20% reported self-titrating medications.
Conclusion: This pragmatic trial to monitor and communicate diabetic peripheral neuropathy symptoms as well as treatment associated adverse effects did not significantly improve patient quality of life measurements. The limited exposure of physicians to the intervention and the lack of a training component may have contributed to the absence of an observed effect. We found high rates of medication related adverse effects and low rates of symptom relief despite persistent use of prescribed medications. Given the high prevalence of diabetic peripheral neuropathy and the limited ability of medications to improve symptoms without acceptable adverse events, more research is required to identify effective interventions for improving patient quality of life.

Organisation of diabetes care is associated with systolic blood pressure level: a cross-sectional study of 230,958 people with type 2 diabetes

R. Husdal[1,2], A. Rosenblad[1], J. Leksell[2,3], E. Thors-Adolfsson[4,1];
[1]Centre for Clinical Research Västmanland, Uppsala University, Västerås, [2]Department of Medical Sciences, Clinical diabetology and metabolism, Uppsala University, Uppsala, [3]School of Health and Social Sciences, Dalarna University, Falun, [4]Department of Primary Health Care, Region Västmanland, Hospital of Västmanland, Västerås, Sweden.

Background and aims: Sweden is one of top-performers in Europe in providing diabetes care. People with Type 2 diabetes mellitus (T2DM) is mainly treated within the primary health care system. Several quality improvement strategies has been identified as successful in the management of people with T2DM. However, current research is limited by not adjusting for several important confounders at the primary health care center (PHCC) and individual levels (e.g., clinical, socioeconomic and comorbidity data). The aim of this study aim was to investigate the association between the organization of diabetes care (i.e., personnel resources and organizational features) in primary health care and the level of systolic blood (SBP) among people with T2DM.
Materials and methods: People with T2DM (n = 230 958) attending 846 PHCCs were included in this cross-sectional study. The PHCC level data were based on managers answering the Swedish National Survey of the Quality and Organisation of Diabetes Care in Primary Healthcare (SwedQOP) questionnaire addressing PHCCs' personnel resources and

organizational features. People with T2DM and clinical data were obtained from the Swedish National Diabetes Register and linked to registers containing individual level data on socioeconomic status and comorbidities. Data were analyzed using a generalized estimating equations (GEE) linear model. The final GEE model comprised valid values for 787 PHCCs and 180 928 people with T2DM.

Results: After adjusting for PHCC and individual level confounders, personnel resources at the PHCCs being significantly associated with decreasing SBP levels were number of whole time equivalent (WTE) registered nurse (RN)/500 people with T2DM (-1.02 mmHg; $P < 0.001$) and RNs' number of European Credit Transfer and Accumulation System credits in diabetes-specific education (-0.02 mmHg; $P < 0.001$). PHCCs' organizational features associated with a decreasing SBP were PHCCs providing group education (-0.32 mmHg; $P < 0.001$) and having a system for checking that patients participated at their annual review at general practitioners (GPs) (-0.31 mmHg; $P = 0.027$). The opposite effect (i.e. increasing SBP) was found regarding duration of regular visits to GPs (0.47 mmHg per additional 15 minutes duration; $P < 0.001$) and RNs (0.28 mmHg per additional 15 minutes duration; $P < 0.001$).

Conclusion: The present large sample size cross-sectional study found that personnel resources and organizational features of PHCCs were associated with individual SBP level for persons with T2DM. The findings adds important knowledge, which may stimulate decision-makers to prioritize these factors for achieving a successful diabetes care management.

Patterns of glucose-lowering medication use in patients with diabetes and heart failure: insights from the Diabetes Collaborative Registry (DCR)

S.V. Arnold[1], J.E. Tcheugui[2], C.S.P. Lam[3], S.E. Inzucchi[4], F. Tang[1], D.K. McGuire[5], A. Goyal[6], T.M. Maddox[7], L.S. Sperling[6], G.C. Fonarow[8], F.A. Masoudi[9], M. Kosiborod[1];

[1]Saint Luke's Mid America Heart Institute, Kansas City, [2]Brigham and Women's Hospital, Boston, USA, [3]Duke-National University of Singapore, Singapore, Singapore, [4]Yale University, New Haven, [5]University of Texas Southwestern, Dallas, [6]Emory University, Atlanta, [7]VA Eastern Colorado Health Care System, Denver, [8]University of California Los Angeles, Los Angeles, [9]University of Colorado, Denver, USA.

Background and aims: Although heart failure (HF) and type 2 diabetes (T2D) often coexist, the optimal glucose management strategies in these patients has been challenging to determine, particularly as novel medication classes emerge. Some medications may have safety concerns in patients with HF (TZDs, certain DPP-4i's, sulfonylureas, insulin) while others could be potentially beneficial (metformin, SGLT2i) but may need to be used with caution in particular sub-groups (e.g., advanced kidney disease). We used DCR to evaluate current patterns of glucose-lowering medication use in adults with T2D with and without HF.

Materials and methods: DCR is a US-based outpatient registry of adults with diabetes seen in primary care, cardiology, and endocrinology practices and includes 5114 providers from 374 practices. We compared use of glucose-lowering medications in adults with T2D with vs. without HF. We used hierarchical, modified Poisson regression models to examine whether HF was associated with preferential use of each medication class, adjusting for factors that could impact selection of one medication class over another: age, chronic kidney disease (CKD), coronary artery disease (CAD), number of glucose-lowering medications, and insurance. Site was included as a random effect to account for clustering of patients within sites.

Results: Among 669,308 adults with T2D on at least 1 glucose-lowering medication, 179,133 (27%) had a diagnosis of HF (29% HF with reduced ejection fraction [HFrEF], 71% HF with preserved ejection fraction [HFpEF]). Patients with T2D and HF (compared with no HF) were more likely to be older, men, and to have CAD, atrial fibrillation, and CKD. In unadjusted comparisons, those with HF were more likely to be treated with insulin and sulfonylureas and less likely to be treated with metformin, TZD, DPP-4i, GLP-1 RA, and SGLT2i (Table). These associations remained significant after adjustment for patient factors and site, with the most prominent associations of HF with greater use of insulin and less use of metformin, TZD, and SGLT2i (Table).

Conclusion: In a large US-based outpatient registry, we found that a quarter of adults with T2D had a diagnosis of HF, which was predominantly HFpEF. Although some patterns of T2D medication use in patients with vs. without HF seemed consistent with existing evidence (less use of TZD and, potentially, DPP-4i), others appeared contrary to evidence (less use of metformin and SGLT2i).

Table. Use of Glucose-Lowering Medications in Patients With vs. Without HF

	Unadjusted Use		Adjusted Relative Rate of Use with HF[1]	
	HF n=179,133	No HF n=490,175	Relative Rate[2] (95% CI)	p-value
Insulin	39.6%	25.9%	1.38 (1.35-1.41)	<0.001
Metformin	59.1%	74.3%	0.85 (0.83-0.86)	<0.001
Sulfonylurea	35.3%	29.9%	1.04 (1.03-1.05)	<0.001
Thiazolidinedione	7.2%	8.4%	0.79 (0.75-0.82)	<0.001
DPP-4 inhibitor	14.5%	14.7%	0.94 (0.92-0.96)	<0.001
GLP-1 RA	4.5%	5.3%	0.94 (0.91-0.97)	<0.001
SGLT2 inhibitor	2.6%	3.8%	0.83 (0.79-0.88)	<0.001

PS 046 New approaches reaching glucose target

659

Predicting post one-year durability of glucose-lowering monotherapies in patients with new-onset type 2 diabetes

O.F. Agbaje[1], R.L. Coleman[1], A.T. Hattersley[2], E.Z. Pearson[3], R.R. Holman[1], The MASTERMIND consortium;
[1]University of Oxford, Oxford, [2]University of Exeter, Exeter, [3]University of Dundee, Dundee, UK.

Background and aims: Current NICE guidelines for type 2 diabetes (T2D) recommend identifying the most appropriate glucose-lowering therapy for a given individual. This decision depends not only on the initial glycaemic response, but also the durability of its glucose-lowering effect over time. We investigated the latter by examining possible predictors of post one-year durability for glucose-lowering monotherapies in people with new-onset T2D.

Materials and methods: We used data from 2,339 UKPDS participants who remaining on their randomized glucose-lowering monotherapy at one year and had an HbA1c <7.5% (46% of 5,102 enrolled). Of these, 453 (19%) were treated with chlorpropamide, 391 (17%) glibenclamide, 1,047 (45%) basal insulin, and 448 (19%) overweight participants with metformin. Monotherapy glycaemic failure was defined as either an HbA1c ≥7.5%, or the protocol-driven requirement for glycaemic rescue with the addition of a second glucose-lowering therapy. We calculated the post one-year time-to-failure for each glucose-lowering monotherapy and developed prognostic models to investigate the phenotypic and biomarker characteristics that best predicted this time point. Potential variables were identified firstly by univariate accelerated failure time (AFT) models, and then we performed multivariate AFT regression models to identify those covariates that remained independently and significantly associated with time-to-failure.

Results: Monotherapy failure occurred in 1,712 (73%) of participants, comprising 272 (12%), 267 (11%), 824 (35%) and 349 (15%) respectively for chlorpropamide, glibenclamide, basal insulin and metformin. Median time-to-failure was 4.9 years (IQR 2.0, 10.1) overall, but differed by monotherapy being 7.2 (4.6, 9.6), 5.3 (3.3, 8.7), 5.2 (2.1, 7.1), and, 4.0 (2.4, 6.0) years respectively. The strongest independent predictor of time-to-failure was the one-year HbA1c, with higher values associated with reduced durability for all monotherapies. Additional covariates that contributed independently were: age, sex, fasting plasma glucose (FPG) & insulin for chlorpropamide; total cholesterol, LDL-cholesterol, creatinine, eGFR, HOMA-%B & HOMA-%S for glibenclamide; body mass index (BMI), total cholesterol, FPG, LDL-cholesterol, creatinine & HOMA-%S for basal insulin; BMI & HOMA-%B for metformin. The magnitude and direction of the effect sizes, expressed as time ratios [TR] and 95% CIs are shown in the Figure.

Conclusion: Median post one-year time-to-failure differed between the first-line glucose-lowering monotherapies studied. The one-year HbA1c value was the major time-to-failure determinant for all therapies, with additional factors that differed by monotherapy. Information such as this could be used to develop a time-to-failure calculator that might help guide the selection of glucose-lowering therapies for people with T2D.

Second line treatment after metformin monotherapy of type 2 diabetes in a real life setting 2006 to 2015: nationwide data comparison between Denmark, Norway and Sweden

F. Persson[1], J. Bodegard[2], T. Nyström[3], D. Nathanson[3], M. Thuresson[4], M. Linnemann Jensen[5], M.E. Jørgensen[1], K.I. Birkeland[6,7], H.L. Gulseth[6], A. Norhammar[8], J.W. Eriksson[9];
[1]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [2]AstraZeneca Nordic-Baltic, Södertälje, [3]Södersjukhuset, Stockholm, [4]Statisticon AB, Uppsala, Sweden, [5]QuintilesIMS, Copenhagen, Denmark, [6]Oslo University Hospital, Oslo, [7]University of Oslo, Oslo, Norway, [8]Karolinska Institutet, Stockholm, [9]Uppsala Akademiska Sjukhus, Uppsala, Sweden.

Background and aims: International type 2 diabetes (T2D) guidelines advocate metformin as the first step in pharmacological treatment, followed by a choice of different glucose-lowering drugs (GLD) for 2nd line e.g. sulphonylurea, insulin, dipeptidyl peptidase-4 inhibitors (DPP-4i), sodium glucose cotransporter-2 inhibitors (SGLT-2i), and glucagon-like peptide-1 receptor agonists (GLP1-RA). Although similar health care systems, GLD guidelines differ and it is not known whether treatment patterns vary between countries. The aim was to compare T2D 2nd line GLD treatment patterns after metformin monotherapy fail, using nationwide registries in three Nordic countries with similar demography and public health care systems.

Materials and methods: T2D patients treated with GLD between 2006-2015 were identified in the Registries of Medicinal Product Statistics (Denmark) or Prescribed Drug Register (Norway, Sweden), and linked with National Patient- and/or Cause of Death Registries. Second line treatment was defined as ≥6 months metformin monotherapy, followed by a filled prescription of a new GLD class. Date of 2nd line drug start was defined as index date.

Results: In total, 124,250 patients initiating 2nd line treatment were identified. In 2015, Swedish patients were older at index date (65.0 years) vs Norway (61.7 years) and Denmark (62.0 years), a trend which was stable during the whole observation time. Proportions of female T2D patients receiving 2nd line treatment was similar across all countries (c:a 40%). Antihypertensives [ACEi and ARBs] and statins was more extensively used in Denmark (90%) and Sweden (89%) vs Norway (80%). GLD use show a rapid change in the 2nd line treatment in Denmark and Norway whereas the uptake of newer GLDs is slower in Sweden (Figure). In 2015, newer GLDs (DPP-4i, SGLT-2i and GLP1-RA) were more extensively used in Denmark (70%) and Norway (71%) vs Sweden (44%). Conversely, almost twice as high use of older GLDs (insulin, sulphonylureas and other GLDs [except metformin]) were used in Sweden (56%) vs Denmark (30%) and Norway (29%) when initiating 2nd line.

Conclusion: During the last decade, a rapid increase in the use of newer GLDs was observed in Denmark and Norway but slower in Sweden. The use of older GLDs (such as insulin and SU) was almost twice as high in Sweden vs Denmark and Norway in 2015. Despite neighbouring countries with similar demography and health care systems we found large differences in GLD use highlighting the need for continuous attention to updated treatment guidelines.

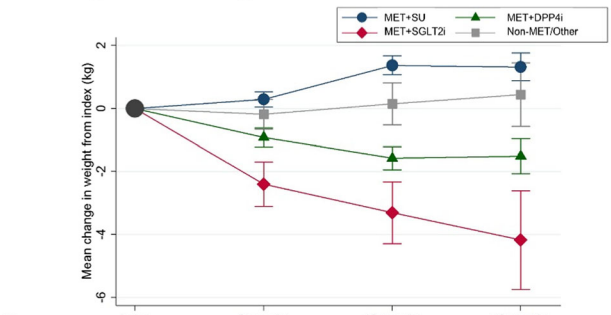
Changes in HbA_{1c} and weight after initiation of second-line therapy in patients with type 2 diabetes in clinical practice

J.P.H. Wilding[1], T. Godec[2], K. Khunti[3], S. Pocock[2], R. Fox[4], L. Smeeth[2], B. Blak[5], P. Clauson[6], P. Fenici[5], N. Hammar[6], U. Rigney[5], J. Medina[7];
[1]University of Liverpool, Liverpool, [2]London School of Hygiene and Tropical Medicine, London, [3]University of Leicester, Leicester, [4]Bicester Health Centre, Bicester, UK, [5]AstraZeneca, Luton, UK, [6]AstraZeneca Gothenburg, Mölndal, Sweden, [7]AstraZeneca Farmacéutica Spain, Madrid, Spain.

Background and aims: Intensification of first-line glucose-lowering therapy is often required in patients with T2DM. This study examined the use of second-line therapies in people with T2DM in UK clinical practice, and the association between second-line therapy and change in HbA_{1c} and weight over 18 months.
Materials and methods: This was a comparison of patients receiving different second-line glucose-lowering therapies in the UK Clinical Practice Research Datalink (CPRD). Patients with T2DM aged ≥18 years who initiated a second-line oral therapy between 1 August 2013 and 30 April 2015 were included.
Results: Patients identified initiating a second-line therapy (N=11,979) had a mean age of 62 years, 58.0% were male, mean (SD) HbA_{1c} 9.0 (1.8) % and mean (SD) body weight 92.8 (22.2) kg. Median time to initiation of second-line therapy was 4.5 years after diagnosis of T2DM, and 2.0 years after initiation of first-line therapy. The first-line therapy for the majority of patients (75.9%) was metformin monotherapy. When considering only those with metformin monotherapy as first-line therapy; second-line therapies were sulphonylureas (SU; 51.2%), dipeptidyl peptidase-4 inhibitors (DPP-4i; 31.9%), and sodium-glucose cotransporter 2 inhibitors (SGLT2i; 4.8%), with 12.1% on non-metformin therapy or other combinations. In those who initiated second-line therapy and remained on this therapy at each time point, mean baseline-adjusted changes in HbA_{1c} at 6 months were: metformin+SU -1.33%, metformin+DPP-4i -1.11%, metformin+SGLT2i -1.26% and non-metformin therapy/other combinations -1.03%. Decreases from baseline values seen at 18 months were: metformin+SU -1.21%, metformin+DPP-4i -1.23%, metformin+SGLT2i -1.46% and non-metformin therapy/other combinations -1.18%. Changes in body weight over 18 months for each second-line therapy are shown in the Figure. The low number of patients included in this analysis at later time points should be taken into consideration when interpreting the data.
Conclusion: In UK clinical practice, intensification of treatment with a second-line therapy occurred when patients had a high HbA_{1c}, and ~2 years after the initiation of first-line therapy. All choices of second-line therapy after metformin monotherapy were associated with reductions in HbA_{1c} over 18 months, while changes in body weight varied by second-line therapy, with sustained reductions seen over 18 months with addition of either SGLT2i or DPP4i to metformin.

Figure. Baseline-adjusted mean (SE) change in body weight from index in those who initiated, and remained on, second-line therapy after metformin monotherapy



N	Index	6 months	12 months	18 months
Metformin+SU	4606	1550	1092	567
Metformin+DPP4i	2880	993	714	359
Metformin+SGLT2i	440	185	103	46
Non-metformin/ other combination	1091	403	220	109

[1]Center for Outcomes Research and Clinical Epidemiology, Pescara, Italy, [2]AstraZeneca, Gaithersburg, USA, [3]University of Nantes, Nantes, France, [4]Evidera, Barcelona, Spain, [5]AstraZeneca, Cambridge, UK, [6]Rio de Janeiro State University, Rio de Janeiro, Brazil, [7]AstraZeneca Gothenburg, Mölndal, [8]Institute of Environmental Medicine, Karolinska Institute, Stockholm, Sweden, [9]University of Leicester, Leicester, UK, [10]Saint Luke's Mid America Heart Institute, Kansas City, [11]University of Missouri, Kansas City, USA, [12]Endocrinology Research Centre, Moscow, [13]I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation, [14]Graduate School of Medicine, Juntendo University, Tokyo, [15]Graduate School of Medicine, Osaka University, Osaka, Japan, [16]London School of Hygiene and Tropical Medicine, London, UK.

Background and aims: Data on treatment patterns in patients with type 2 diabetes are scarce in many countries. DISCOVER is a global, prospective, observational study of patients with type 2 diabetes initiating second-line therapy.
Materials and methods: Data were collected using a standardized case report form. First- and second-line treatments were assessed in 13 379 patients from 32 countries. Multinomial logistic regression models were used to assess factors associated with second-line treatment options among patients initially prescribed metformin (MET) monotherapy.
Results: Over half of patients (59.7%) received MET monotherapy as first-line treatment. Of these, 22.0% received a sulfonylurea (SU) + MET as second-line therapy, and 23.7% received a dipeptidyl peptidase-4 inhibitor (DPP-4i) + MET. A total of 37.2% of patients discontinued MET. Associations between baseline factors and the likelihood of receiving either SU + MET or DPP-4i + MET as second-line therapy are shown in the Figure. Patients with HbA_{1c} > 8.0% (vs. HbA_{1c} < 7.0%) and those in Africa (vs. Europe) were more likely to receive SU + MET than DPP-4i + MET. Close to 50% of the variation in choice of second-line therapy was explained by country.
Conclusion: Substantial variation exists in choice of second-line therapy worldwide. Despite the advent of new drugs, SUs remain widely used as second-line therapy in combination with MET.

Figure. Likelihood of receiving a sulfonylurea (SU) or a dipeptidyl peptidase-4 inhibitor (DPP-4i) as add-on to metformin (MET) at second-line, after receiving first-line MET monotherapy. CI, confidence interval; OR, odds ratio.

Distance from glycaemic goal at the time of treatment intensification in patients with type 2 diabetes failing metformin monotherapy in the UK

G. Fernandes, H. Hannachi, J. Liu, T. Wang, A. McNeill, S. Rajpathak; Merck & Co., Inc., Kenilworth, USA.

Background and aims: Previous clinical trials have shown that intensive blood glucose control can substantially lower the risk of chronic micro- and macrovascular diabetic complications. While there are data to suggest that many patients with diabetes do not adequately achieve glycemic control, it is not well known how distant these uncontrolled patients are from typical glycemic targets. The objective of the study was to quantify the distance from a HbA1c target (<7%) among patients failing metformin monotherapy at the time of treatment intensification.
Materials and methods: Data was extracted from UK Clinical Practice Research Datalink (CPRD) with patients receiving metformin between Jan 2012- Dec 2014 (study period) and at least 12 months of continuous enrollment prior to the first fill of metformin (index date). The study population included patients who failed metformin monotherapy after at least 3 months of therapy (HbA1c ≥7%) and received treatment intensification with an add-on drug. Patients with Type 1 diabetes mellitus, pregnancy/gestational diabetes or other secondary diabetes were excluded. Distance from goal was calculated as the median difference of HbA1c at the time of treatment intensification and HbA1c goal (<7%).
Results: We identified 19,804 T2DM patients meeting study criteria. At the index date, before intensification, patients had a mean age of 64.6 years (Standard Deviation= 12.1 years); 27.4% of patients had a history of microvascular complications; 29.0% had a history of macrovascular complications; 1.3% had a history of severe/recurrent hypoglycemia in the one year prior. Median difference from HbA1c goal was 1.5%, with 25% of patients between 1-2% (n=4884) and 40% greater than 2% (n=7895) from goal. This median difference was 1.6% after exclusion of elderly patients (aged ≥ 65 years), those with microvascular and macrovascular complications and those with a history of severe/recurrent hypoglycemia (total n=6175), for whom a modified goal of 8% may be appropriate rather than 7%.
Conclusion: Among patients failing metformin monotherapy, majority of patients were greater than 1% away from the HbA1c goal of 7%.

Efficacy of self-monitoring blood glucose in the context of a chronic care model for type 2 diabetes patients not treated with insulin

I. Ciullo[1], M. Rossi[2], M. Scardapane[2], A. Giancaterini[1], L. Pessina[1], S. Maino[1], R. Gaiofatto[1], A. Nicolucci[2], N. Musacchio[1], on behalf of the Self-Care study group;
[1]UOS Integrazione Cure Primarie e Specialistiche, Azienda Ospedaliera ICP, Milan, [2]CORESEARCH - Center for Outcomes Research and Clinical Epidemiology, Pescara, Italy.

Background and aims: Patient-centered chronic care models are widely recognized as the most effective approach for the management of chronic diseases, but their implementation in the real world is a challenge. In Italy, the SINERGIA model was developed in one diabetes outpatient clinic and it improved metabolic control and major cardiovascular risk factors in an observational cohort of over 1000 patients. In the SINERGIA model self-monitoring blood glucose (SMBG) represents the core of education. Starting from these findings, the Self-Care study was designed to compare the efficacy of the SINERGIA model vs. usual care in the context of a randomized clinical trial.
Materials and methods: Multicenter, randomized (1:1), controlled clinical trial of 12 month follow-up plus a 12 month observational phase. Eligible patients were: age ≥ 45 years, first referral to diabetes clinic, HbA1c 7.0% - 9.0%, no SMBG and no insulin treatment. Patients allocated to SINERGIA group received the experimental education based on the use of SMBG as key tool to enhance patient empowerment in the context of a chronic care model; all subjects randomized to this group received the same glucose meter, i.e. BGStar®. Patients allocated to usual care group received the standard diabetes education provided by the center; in these patients SMBG was prescribed only if deemed appropriate, based on physician's judgment and patient needs; any glucose meter could be prescribed. Changes after 12 and 24 months from baseline in HbA1c levels, weight, blood pressure, lipid profile and health-related quality of life (HRQoL) scores (i.e. PDM, PHCO, SF-12, DTSQ, ADDQOL, and VAS) were assessed.
Results: Overall, 21 centers randomized 121 subjects to SINERGIA and 120 to control (Drop-out: 9.9% and 11.7%, respectively). Patients had mean age 61.8±8.8 years and diabetes duration 5.8±6.3 years. SMBG was prescribed to 70.8% of individuals allocated to usual care group. HbA1c levels were reduced by -0.47% (95%CI -0.66; -0.29) in SINERGIA vs. -0.32% (95%CI -0.51;-0.13) in usual care (p=0.27) after 12 months (primary end-point) and by -0.39% (95%CI -0.59;-0.19) vs. -0.18% (95%CI -0.39;-0.02) in usual care (p=0.17) after 24 months. Weight and lipid profile improved in both groups. Trends of additional benefits on blood pressure were found with SINERGIA. Psychological well-being (expressed as Mental Health Score - SF12) was unchanged after 12 and 24 months in SINERGIA and worsened in usual care; PDM score, i.e. the level of patient involvement in the decision making process, increased in SINERGIA group only.
Conclusion: The study was unable to demonstrate the superiority of SINERGIA vs. usual care, but suggests that SINERGIA *per se* was effective in improving and maintaining HbA1c levels and cardiovascular risk factors, without worsening psychological well-being at SMBG initiation. The study documents that SMBG training accompanied with education targeted to patient autonomy adds value to current care.

The SMBG study: a randomised controlled trial of self-monitoring of blood glucose in non-insulin treated type 2 diabetes

S.N. Parsons, S.D. Luzio, D.R. Owens, SMBG Study Group;
Diabetes Research Unit Cymru, Swansea University, Swansea, UK.

Background and aims: The benefit of Self-Monitoring of Blood Glucose (SMBG) in people with non-insulin treated type 2 diabetes (T2DM) continues under debate, with inconsistent evidence from observational studies and randomised controlled trials. However, there is growing consensus that structured SMBG can improve glycaemic control and overall well-being. The aim of the SMBG Study was to evaluate structured SMBG (2 days of paired blood glucose daily profiling, weekly) with standardised intervention (trained nurses using standardised treatment algorithms) with and without monthly telecare vs no SMBG in sub-optimally controlled, non-insulin treated people with T2DM.
Materials and methods: A 12 month, multi-centre, randomised controlled trial was performed in people with established (>1 year) T2DM, not on insulin therapy, with poor glycaemic control (HbA1c ≥7.5% ≤ 13%). A total of 666 participants were recruited from 16 primary and secondary care sites across Wales and England with 446 people randomised into one of three groups. Group 1 (G1), a control group that

received usual diabetes care with no SMBG; Group 2 (G2), undertook structured SMBG with clinical review every 3 months; Group 3 (G3), undertook structured SMBG with additional monthly telecare support. In Groups 2 & 3, participants and healthcare professionals were blinded to HbA1c results and glycaemic management was based on SMBG results alone.

Results: The demographic profile and baseline characteristics are detailed in the table. There were no significant differences between the three groups at randomisation. 323 participants attended the final visit at 12 months (G1 n=116; G2 n=99; G3 n=108) with no significant difference in participant withdrawal/loss to follow up. The mean (SD) HbA1c at 12 months was significantly lower for all groups compared to baseline (8.3(1.31)%, 7.4(1.22)% and 7.3(0.89)% for Groups 1, 2 and 3 respectively) with a significant reduction of 0.3% in G1 ($p<0.01$), 1.1% in G2 ($p<0.001$) and 1.3% in G3 ($p<0.001$) at 12 months. The percentage of those achieving HbA1c target of 7% or below was significantly higher ($p<0.001$) in the two SMBG groups compared to the control group (G1=17.2% vs G2=46.5% and G3=43.5%). Those reaching HbA1c of 7.5% or below was also significantly higher in the SMBG groups (G1= 33.6%, G2=63.6%, G3=66.6%, $p<0.001$). There was no statistical difference between groups 2 and 3. There was also no difference in the number of participants prescribed insulin: G1 (3), G2 (4) and G3 (4).

Conclusion: This study demonstrates that the use of structured SMBG with a standardised management algorithm provides significant benefits in terms of glycaemic control with a mean reduction of 0.9% (95% CI -1.18 to -0.62, $p<0.001$) between the combined SMBG groups compared to the control group.

Automated frequent insulin dosage titrations to enhance therapy effectiveness; lessons from the d-Nav® insulin guidance

I. Hodish[1], M. Johnson[2], E. Bashan[3], D.F. Kruger[4], A. Bhargava[5], R.M. Bergenstal[2];
[1]University of Michigan, Ann Arbor, [2]International Diabetes Center, Minneapolis, [3]Hygieia Inc., Livonia, [4]Henry Ford Medical Center Endocrinology, Detroit, [5]Iowa Diabetes and Endocrinology Research Center, Des Moins, USA.

Background and aims: Insulin therapy is used by a quarter of type 2 diabetes patients, yet most do not achieve glycemic goals. Unless dosage is frequently adjusted, variations in insulin requirements hamper its effectiveness. In reality, dosage adjustments are done sporadically due to providers' workload in caring for a large number of patients. d-Nav® has been developed to overcome this barrier by bridging the titration gap. d-Nav is a handheld device that automatically analyzes stored glucose patterns and titrates insulin at least weekly, based on individual needs. Previous experience has underscored the role of care specialists' in supporting effective use of d-Nav. We equipped a diabetes specialty team with d-Nav to assess its impact on insulin management of patients with type 2 diabetes compared to close patient support without automatic dosage titration.

Materials and methods: We conducted a 6-month, multicenter, randomized-controlled trial with 181 sub-optimally controlled patients with type 2 diabetes. Standard care, which was delivered by a diabetes specialist team who contacted patients 7 times (control group), was compared to the same with the addition of d-Nav (d-Nav group).

Results: In the d-Nav group, A1c decreased by 1% from 8.7±0.8% (mean±standard deviation or SD) to 7.7±1.0%, while in the control group A1c decreased by 0.3% from 8.5±0.8% to 8.2±0.9% ($p<0.0001$)(See Figure). In the d-Nav group, clinically significant improvement in A1c (≥0.3%) was seen in 80.7% of subjects and 52.3% achieved A1c≤7.5%. Conversely, in the control group 44.4% improved A1c≥0.3% and 21.0% achieved A1c≤7.5%. In nearly half of the control patients (43.2%), A1c worsened or was unchanged during the study compared to 14.8% in the d-Nav group (see Figure).

Conclusion: When equipped with automated insulin titration capabilities, a diabetes specialist team can deliver an effective insulin therapy to the majority of patients. Automated insulin titration along with provider support can significantly advance the standard of care in insulin users with type 2 diabetes.

Real-world basal insulin intensification patterns in the United States

B. Thorsted[1], V. Divino[2], M. DeKoven[2], G. Guerrero[3], J. Langer[1], J. Yeaw[4];
[1]Novo Nordisk A/S, Sorborg, Denmark, [2]QuintilesIMS, Fairfax, [3]Novo Nordisk Inc., Plainsboro, [4]QuintilesIMS, San Francisco, USA.

Background and aims: Basal insulin is an important component of the intensification treatment strategy in patients with type 2 diabetes mellitus (T2DM). Nevertheless, many patients remain uncontrolled (A1C≥7%) after initiating basal insulin. This study examined the prevalence of patients uncontrolled on basal insulin in a real-world setting and treatment intensification patterns and outcomes.
Materials and methods: Adults diagnosed with T2DM initiating a basal insulin analog (insulin glargine or detemir) with no GLP-1 or bolus insulin use from Jan-2010-Sep-2014 were identified in the QuintilesIMS PharMetrics Plus Health Plan Claims Database linked to ambulatory Electronic Medical Records. Patients were persistent on basal insulin for ≥6 months, and had ≥12 months of continuous health plan enrollment. Intensification patterns (increase in basal dose [of ≥10%], addition of bolus insulin, GLP-1 or a new oral antidiabetic drug) and outcomes were assessed among patients who were uncontrolled (A1C ≥7%) 6-months post-initiation. Kaplan-Meier (KM) analysis evaluated time to treatment intensification. Sensitivity analyses examined the definitions of uncontrolled (A1C≥8% and A1C>9%) and increase in basal dose (10 Unit (U) increase).
Results: Of 427 eligible patients with A1C available at 6 months, 59% were male, mean age was 53.9 years, mean A1C before basal insulin was 9.5%, mean follow-up was 29.4 months and mean basal insulin dose at initiation was 29.6U (median 24U). Six months after initiating basal insulin, 81% of patients (n=346) were uncontrolled (52% A1C≥8%, 27% A1C>9%). Mean 6 month dose was 31.0U (median 25U). Among patients uncontrolled 6 months after basal insulin initiation, 88% (n=306) subsequently intensified treatment over the follow-up (69% [n=238] by 12-months post-initiation). In KM analysis, patients first intensified treatment in a median of 58 days (60 days using A1C≥8%, 50.5 days using A1C>9). Most (67%; n=231) first intensified treatment by increasing the basal insulin dose, and mean basal insulin dose increased to 61.7U (median increased to 38U) at time of intensification. Among patients that first intensified by increasing the basal insulin dose, 92% (n=140 out of 152) with A1C values in the subsequent 6 months remained uncontrolled (76% A1C≥8%, 72% A1C>9%). In KM analysis, only 33.8% added another antidiabetic agent by 1-year post-intensification. When the definition of increased basal dose was changed to a 10U increase, only 47% (n=164) of uncontrolled patients intensified by 12-months post-initiation, with 28% (n=97) intensifying first by increasing the basal insulin dose.
Conclusion: The vast majority of patients remained uncontrolled 6 months after basal insulin initiation. Subsequently, most patients failed to achieve glycemic targets despite gradual uptitration of basal insulin. This suggests that a substantial unmet need exists for more timely insulin uptitration and intensification with other agents among T2DM patients not achieving glycemic control with basal insulin. Further research is needed to uncover potential areas for intervention to improve outcomes for patients uncontrolled on basal insulin.

PS 047 Ultralong acting insulin analogues: new studies

668

Effect of insulin degludec versus insulin glargine on glycaemic control and daily fasting blood glucose variability in insulin-naive Japanese patients with type 2 diabetes

Y. Aso, S. Sakurai, T. Iijima;
Endocrinology and Metabolism, Dokkyo Medical University School of Medicine, Mibu, Japan.

Background and aims: Insulin degludec (IDeg) is an ultra-long-acting insulin that has a smooth time/action profile over more than 42 hours.A pharmacodynamic study demonstrated that day-to-day glucose variability was four-fold smaller in patients with type 1 diabetes receiving IDeg than in those using insulin glargine (IGlar).
Materials and methods: Eligible patients were randomly allocated at a 3:1 ratio to receive once-daily IDeg (n=31) or IGlar (n=12). Both basal insulins were administered before breakfast and titrated to achieve a target FBG < 110 mg/dl. The primary endpoints were the change in HbA1c from baseline to 24 weeks of treatment, as well as the standard deviation (SD) and coefficient of variation (CV) of FBG from 8 to 12 weeks and from 20 to 24 weeks. Secondary endpoints included the QOL evaluated by the Diabetes Therapy-Related QOL questionnaire.
Results: After 24 weeks, HbA1c was decreased by 1.6% in the IDeg group and 1.7% in the IGlar at the same insulin dosage. At 24 weeks, FBG was significantly lower in the IDeg group than in the IGlar group and the CV of FBG was significantly smaller in the IDeg group. The frequency of total and severe hypoglycemic episodes did not differ between the groups. In the IDeg group, QOL showed significant improvement regarding anxiety and dissatisfaction with treatment. At 24 weeks, FBG (measured before breakfast) was significantly lower in the IDeg group than in the IGlar group, P=0.0122).
Conclusion: Treatment with IDeg or IGlar achieved similar improvement in glycemic control in insulin-naïve patients with type 2 diabetes. The day-to-day variation of FBG was smaller in patients receiving IDeg than in those with IGlar.

Effect of insulin degludec on HbA_{1c}, weight and hypoglycaemia: data from the Association of British Clinical Diabetologists (ABCD) nationwide degludec audit

A.N. Lumb[1], R.D. Rea[1], R.E.J. Ryder[2], ABCD nationwide degludec audit contributors;
[1]OCDEM, Oxford, [2]Sandwell and Birmingham Hospitals NHS Trust, Birmingham, UK.

Background and aims: The Association of British Clinical Diabetologists (ABCD) nationwide degludec audit was set up to study the effect of the use of insulin degludec in routine clinical practice in the UK. The aim of this analysis was to look at the effect of switching to insulin degludec from another basal insulin on HbA1c, weight and hypoglycaemia.
Materials and methods: The ABCD nationwide degludec audit currently includes 433 people of whom 253 have type 1 diabetes (T1D) and 173 have type 2 diabetes (T2D). Of those with T1D 154 (61%) were switched to insulin degludec due to hypoglycaemia, and 99 (39%) for other reasons. Of those with T2D 57 (33%) were switched to insulin degludec due to hypoglycaemia, and 116 (67%) for other reasons. Baseline HbA1c and weight were compared with the latest results with 2-sided p-values using a paired t-test. Weight and HbA1c comparisons were grouped according to type of diabetes and whether degludec was started due to hypoglycaemia or for other reasons. Hypoglycaemia was recorded as having decreased, stayed the same or

increased after switching to insulin degludec, and data were compared for those with T1D and T2D where degludec was started due to reasons of hypoglycaemia. For a statistical comparison, it was assumed that where a similar rate of hypoglycaemia was reported using insulin degludec and the other basal insulin there was in fact a lower rate of hypoglycaemia with insulin degludec than the other basal insulin with probability 0.5. 2-sided p-values were calculated testing the hypothesis that a similar proportion of people experience a lower rate of hypoglycaemia on insulin degludec compared with the other basal insulin using the normal approximation to the binomial with a continuity correction. .

Results: Changes in HbA1c and weight are summarised in the attached table. For those switched to insulin degludec for hypoglycaemia in T1D there was a significant reduction in minor, severe and nocturnal hypoglycaemia ($P < 0.0001$ for all). For those with T2D switched to insulin degludec due to hypoglycaemia there was only a significant reduction in minor hypoglycaemia ($p < 0.05$), although it should be noted that the numbers in all groups were small.

Conclusion: For people with T1D, there was a significant reduction in HbA1c if insulin degludec was started for reasons other than hypoglycaemia, and a significant reduction in minor, severe and nocturnal hypoglycaemia if hypoglycaemia was the reasons for switching to insulin degludec. In either case there was no significant change in weight. For people with T2D, there was a significant reduction in HbA1c where insulin degludec was started for reasons other than hypoglycaemia, with no significant change in weight. For those with T2D switched to insulin degludec for hypoglycaemia, there was significant weight loss and a significant reduction in minor hypoglycaemia.

Type of diabetes	T1D		T2D	
Reason for starting degludec	Hypoglycaemia	Other	Hypoglycaemia	Other
Change in HbA1c after degludec (mean +/- SE)	+0.9+/- 1.4 mmol/mol (ns) n=99	-7.9 +/- 1.9 mmol/mol (p=0.0002) n=69	-2.4+/-1.8 mmol/mol (ns) n=40	-11.7+/-2.4 mmol/mol P<0.0001) n=99
Change in weight after degludec (mean +/- SE)	-0.20 +/- 0.60 kg (ns) n=83	+1.00 +/- 0.54 kg (ns) n=52	-2.37 +/- 0.91kg (P=0.01) n=37	-0.61 +/- 0.70 kg (ns) n=73

Insulin degludec (IDeg) shows consistent risk reductions across hypoglycaemia definitions vs insulin glargine U100 (IGlar U100) in the SWITCH 1 and 2 trials

C.H. Wysham[1], J. Gumprecht[2], W. Lane[3], L. Nørgård Troelsen[4], D. Tutkunkardas[4], S. Heller[5];
[1]Rockwood Clinic, Spokane, USA, [2]Medical University of Silesia, Zabrze, Poland, [3]Mountain Diabetes and Endocrine Center, Asheville, USA, [4]Novo Nordisk A/S, Søborg, Denmark, [5]University of Sheffield, Sheffield, UK.

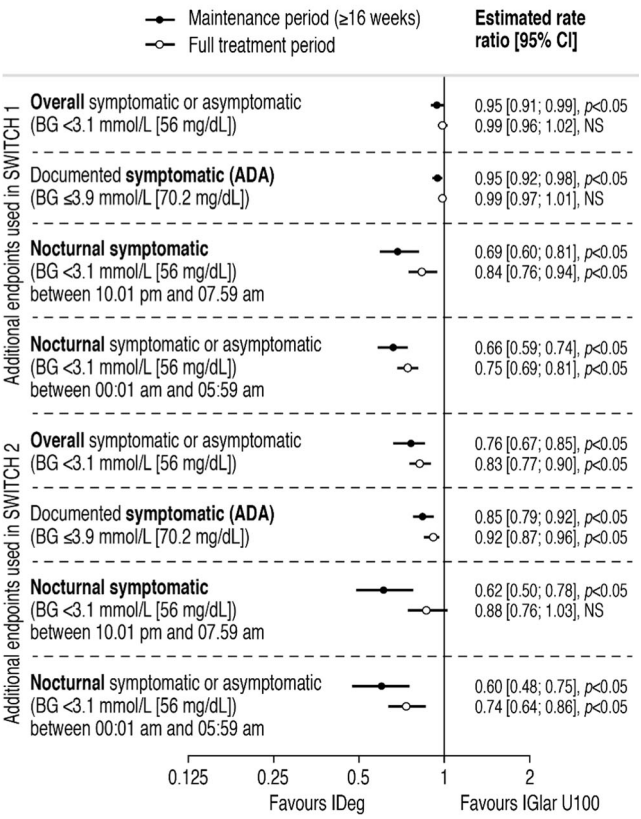
Background and aims: Insulin degludec (IDeg) is a basal insulin with a long duration of action and a flat glucose-lowering profile. The risk of hypoglycaemia with IDeg vs. insulin glargine U100 (IGlar U100) was compared in two trials in patients with type 1 (SWITCH 1) or type 2 diabetes (SWITCH 2) using a range of clinically relevant definitions of hypoglycaemia.

Materials and methods: Two 2x32-week, double-blind, treat-to-target crossover trials compared the risk of overall (severe [requiring third-party assistance and external adjudication] or blood glucose [<3.1 mmol/L (56 mg/dL)] confirmed) symptomatic (accompanied by typical symptoms of hypoglycaemia) hypoglycaemia, nocturnal (severe or blood glucose-confirmed; between 00:01 and 05:59 am) symptomatic hypoglycaemia and severe hypoglycaemia with IDeg once daily (OD) vs. IGlar U100 OD. *Post hoc* analyses investigated the risk of asymptomatic hypoglycaemic episodes, hypoglycaemia during sleep, and the American Diabetes Association (ADA) definition of symptomatic confirmed (blood glucose ≤3.9 mmol/L [70.2 mg/dL]) hypoglycaemia between treatments (Figure). All endpoints were analysed in the 16-week maintenance period and the full treatment period (32 weeks).

Results: HbA_{1c} non-inferiority was confirmed in both trials. SWITCH 1 and SWITCH 2 had significant reductions in overall symptomatic hypoglycaemia and nocturnal symptomatic hypoglycaemia in both the maintenance and the full treatment periods with IDeg vs. IGlar U100. SWITCH 1 had a significant reduction in severe hypoglycaemia with IDeg in the maintenance and the full treatment periods; in SWITCH 2 the rate ratio of severe hypoglycaemia was significantly lower with IDeg in the full treatment period. Significant risk reductions with IDeg vs. IGlar U100 were found in the maintenance period for overall and nocturnal symptomatic or asymptomatic hypoglycaemia. When the definition of the nocturnal period was expanded to 10:01 pm-07:59 am, rates of nocturnal symptomatic hypoglycaemia during sleep were again significantly lower with IDeg vs. IGlar U100 in the maintenance period. The finding of significantly lower rates of hypoglycaemia in the maintenance period with IDeg was retained when the ADA definition of symptomatic hypoglycaemia was used. For both SWITCH 1 and SWITCH 2, results were pointing in the same direction in the full treatment period for all definitions.

Conclusion: Hypoglycaemia reductions were consistent across hypoglycaemia definitions, especially during the nocturnal period, in SWITCH 1 and SWITCH 2.

Figure. Rate ratios of hypoglycaemia across different definitions



BG, blood glucose; CI, confidence interval; IDeg, insulin degludec; IGlar U100, insulin glargine U100; Nocturnal, severe or BG confirmed hypoglycaemia occurring at nighttime during sleep; NS, not significant; Overall, severe or BG confirmed hypoglycaemia; Severe, an episode requiring third-party assistance and external adjudication.

Converting to IDegLira is efficacious regardless of pre-trial insulin dose in patients with type 2 diabetes uncontrolled on insulin glargine U100

L.F. Meneghini[1], E. Jaeckel[2], L.A. Leiter[3], I. Lingvay[1], J.N. Harvey[4], K. Begtrup[5], K. Chandarana[5], T. Vilsbøll[6,7];
[1]University of Texas Southwestern Medical Center, Dallas, USA, [2]Hannover Medical School, Hannover, Germany, [3]University of Toronto, Toronto, Canada, [4]Bangor University, Wrexham, UK, [5]Novo Nordisk A/S, Søborg, [6]Steno Diabetes Center Copenhagen, University of Copenhagen, Gentofte, [7]Center for Diabetes Research, Gentofte Hospital, Copenhagen, Denmark.

Background and aims: This post hoc analysis of the DUAL V study investigated the safety and efficacy of initiating the fixed-ratio combination insulin degludec/liraglutide (IDegLira) once daily at 16 dose steps/units (U) (16 U IDeg; 0.58 mg liraglutide) in adults with type 2 diabetes (T2D) uncontrolled on 20-50 U of insulin glargine U100 (IGlar U100), vs continued IGlar U100 up-titration, across pre-trial daily insulin dose groups (20-<30; ≥30-<40; ≥40-≤50 U). This analysis aimed to confirm that there is no loss of glycaemic control when switching to 16 U IDegLira from a higher pre-trial basal insulin dose.
Materials and methods: DUAL V was a 26 week open-label, treat-to-target trial that randomised patients (n=557) with T2D uncontrolled (HbA_{1C} 7-10%) on IGlar U100 (20-50 U) plus metformin to either IDegLira or continued IGlar U100 titration**.**
Results: HbA_{1c} reductions from baseline to end of trial (EOT) were significantly greater with IDegLira vs IGlar U100 for all dose groups (Table). For all dose groups, compared with IGlar U100, IDegLira was insulin sparing, resulted in body weight loss vs body weight gain, and was associated with lower rates of hypoglycaemia (p<0.05, all treatment contrasts). There were no clinically relevant increases in self-measured plasma glucose levels when converting from any dose group to 16 U IDegLira, and no withdrawals due to hyperglycaemia with IDegLira in first 8 weeks. Fasting plasma glucose reductions were similar between treatment arms for all dose groups. For all endpoints except EOT insulin dose, treatment effect was consistent across dose groups.
Conclusion: In conclusion, regardless of pre-trial insulin dose group, IDegLira resulted in significantly greater HbA_{1c} and body weight reductions and lower hypoglycaemia rates vs IGlar U100 at a lower EOT insulin dose. Importantly, there was no loss of glycaemic control when converting from any dose between 20-50 U of IGlar U100 to the starting dose of 16 U IDegLira. This maintenance of glycaemic control at a lower insulin dose is likely attributable to the liraglutide component.

Real-world use of IDegLira is effective at moderate doses in patients with type 2 diabetes across all baseline treatment regimens and reduces concomitant antidiabetic therapy

B. Schultes[1], H. Price[2,3], R. Prager[4], A.-M. Catarig[5], B.L. Thorsted[6], M. Blüher[7];
[1]eSwiss Medical and Surgical Center, St. Gallen, Switzerland, [2]The Royal Bournemouth and Christchurch Hospitals NHS Foundation Trust, Bournemouth, [3]Southern Health NHS Foundation Trust, Bournemouth, UK, [4]Department of Metabolic Disorders and Nephrology, Hietzing Hospital, Vienna, Austria, [5]Novo Nordisk Region Europe A/S, Copenhagen, [6]Novo Nordisk A/S, Copenhagen, Denmark, [7]University of Leipzig, Leipzig, Germany.

Background and aims: IDegLira is a once-daily, fixed-ratio combination of insulin degludec and liraglutide, the glucagon-like peptide-1 receptor agonist (GLP-1RA), for which the safety and efficacy has been demonstrated in the DUAL clinical trial programme. Results from the observational study, EXTRA, have demonstrated the effectiveness of IDegLira in a real-world setting. This analysis examined the titration of IDegLira and concomitant changes to treatment regimen associated with these glycaemic improvements, in patients grouped according to their baseline regimen.
Materials and methods: This European, multicentre, retrospective chart review, included 611 patients with type 2 diabetes, aged ≥18 years, who started IDegLira at least 6 months prior to data collection. Patients were grouped according to baseline regimen: non-injectable therapies, GLP-1RA, insulin + GLP-1RA (free combination), basal insulin, and multi-dose insulin, all subgroups were ± oral antidiabetic drugs (OADs). Clinical characteristics were assessed at baseline (BL, defined as the most recent recording during the 6-month period prior to first prescription of IDegLira) and follow-up (F/U; 6 months ± 45 days for each time point) after commencing IDegLira.
Results: After 6 months, IDegLira was titrated to a moderate dose in all subgroups (mean 30.2 dose steps/U; Table). The association between IDegLira dose at BL (and F/U) and change in HbA_{1c} was not significant (p=0.7610 [BL] and p=0.2447 [F/U]). Across all F/U IDegLira doses (<10; ≥10-<20; ≥20-<30; ≥30-<40; ≥40-<50; ≥50 dose steps), HbA_{1c} was reduced (-2.0; -0.9; -0.8; -1.0; -1.1; -0.8%). GLP-1RA dose was significantly reduced following IDegLira initiation in GLP-1RA and free combination subgroups. Total daily insulin dose was significantly reduced in patients receiving multi-dose insulin at BL; this was largely due to 60.5% (78/129) of patients discontinuing prandial insulin following IDegLira initiation. Of the 481 patients across all subgroups using ≥1 OAD at BL, 154 (32%) discontinued ≥1 OAD following IDegLira initiation. At F/U 11.0% (62/566) reached the max dose of 50 dose steps, and the majority came from the free combination (31) or multi-dose insulin group (15).
Conclusion: The clinical benefit of initiating once-daily IDegLira in a real-world setting is observed irrespective of F/U IDegLira dose at 6 months, regardless of previous therapy, and associated with a reduction in concomitant antidiabetic therapy, both total daily insulin dose and non-insulin agents.

More consistent antilipolitic and antiketogenetic action of insulin Glargine U300 vs U100 in type 1 diabetes

P. Lucidi, P. Candeloro, A. Marinelli Andreoli, P. Cioli, G.B. Bolli, C.G. Fanelli, F. Porcellati;
Internal Medicine, University of Perugia, Perugia, Italy.

Background and aims: To compare PK/PD of insulin (I) glargine U300 (Gla300) and U100 (Gla100) during euglycemic clamp.
Materials and methods: We studied 18 T1DM subjects (8M, age 40±12 yrs, DM duration 27±12 yrs, BMI 23.3±2 kg/m^2, A1C 7.06±0.4 %) after 3 month treatment with Gla100 or Gla300 titrated to fasting euglycemia (randomized, crossover). In the clamp, subjects received the dose of Gla100 (0.30±0.04 U/kg) or Gla300 (0.37±0.07 U/kg) they had daily at 8 PM.
Results: N=10 subjects. Both Gla100 and Gla300 maintained euglycemia for 24 h. Plasma I was initially lower (0-12h, 8.7±3.5 vs 9.2 ±4.7 μU/ml) (p=0.068), but later greater on Gla300 vs Gla100 (12-24h, 7.6±2.4 vs 5.5±1.7 μU/ml) (p=0.022), whereas plasma glucagon was similar (51±9.2 and 50±12 pg/ml, p>0.2). Glucose infusion rate (GIR) was lower in initial 0-12 h but greater later at 18-24 h with Gla300 vs Gla100 (p<0.05), although 24h GIR was no different. Serum FFA concentration was lower for 24 h (319±70 vs 459±120 μmol/L), as 3-B-OH-butyrate (412±98 vs 641±138 μmol/ml) with Gla300 vs Gla100 (p<0.05). Serum alanine and lactate were not different.
Conclusion: As compared to Gla100, Gla300 (~23% higher dose, but equivalent glucose effect) modulates 24h glucose metabolism more physiologically, and is also more effective in suppressing lipolysis and ketogenesis for 24 h without affecting glucagon concentration, likely the result of more physiological plasma 24 h plasma I replacement with Gla300.

Device-supported vs routine titration of insulin glargine 300 U/ml (Gla-300) in type 2 diabetes: efficacy and safety

F. Flacke[1], S. Edelman[2], S. Bain[3], C. Hasslacher[4], G. Charpentier[5], G. Vespasiani[6], H. Goyeau[7], M. Woloschak[8], M. Davies[9];
[1]Sanofi, Frankfurt am Main, Germany, [2]University of California, San Diego, USA, [3]Institute of Life Science, College of Medicine, Swansea University Medical School, Swansea, UK, [4]Diabetes Institute Heidelberg, Heidelberg, Germany, [5]Department of Medicine, Sud-Francilien Hospital, Corbeil-Essonnes, France, [6]Centre for Outcomes Research and Clinical Epidemiology, Pescara, Italy, [7]Sanofi, Chilly-Mazarin, France, [8]Sanofi, New York, USA, [9]Diabetes Research Centre, University of Leicester, University Hospitals of Leicester, Leicester, UK.

Background and aims: Insulin self-titration may help people with T2DM reach glycaemic targets. MyStar DoseCoach™, a combined titration device/blood glucose meter, aids self-titration by providing automated insulin glargine dosing suggestions.
Materials and methods: AUTOMATIX, a randomised, parallel-group, multicentre treat-to-target trial, evaluated the efficacy and safety of device-supported vs routine (investigator recommended) Gla-300 titration regimens. Primary endpoint: percentage of participants reaching a fasting SMPG (FSMPG) target of 5.0-7.2 mmol/l at week 16 without severe hypoglycaemia. Secondary endpoints included: percentage of participants reaching target FSMPG at week 16 without confirmed or severe hypoglycaemia; change in mean FSMPG, HbA_{1c} and daily insulin dose (baseline to week 16). Number of participants experiencing hypoglycaemia and adverse events were also reported.
Results: In total 151 participants with T2DM (insulin naïve/insulin pre-treated) were randomised 1:1 to device-supported or routine titration with Gla-300. Although not significant, a higher proportion of participants using device-supported vs routine titration achieved the primary endpoint (**Table**). Between titration arms, comparable numbers of participants experienced hypoglycaemia and TEAEs/SAEs (**Table**).
Conclusion: The results show that device-supported titration with Gla-300 has a good efficacy/safety profile and may aid glycaemic target achievement.

Table. Outcomes from the AUTOMATIX study

	Device-supported titration (on-treatment period) (n=75)	Routine titration (on-treatment period) (n=76)
Participants[a] reaching mean FSMPG target range (5.0–7.2 mmol/) at week 16, estimated[b] %		
Without severe hypoglycaemia	45.9	36.8
Estimated weighted difference (95% CI)[c]	9.04 (−6.748 to 24.829)[NS]	
Without confirmed (≤3.9 mmol/l)) or severe hypoglycaemia	34.3	14.5

More physiological circulating insulin and modulation of hepatic glucose production with insulin Glargine U300 vs U100 in type 1 diabetes

F. Porcellati, P. Lucidi, A. Marinelli Andreoli, P. Cioli, P. Candeloro, G.B. Bolli, C.G. Fanelli;
Internal Medicine, University of Perugia, Perugia, Italy.

Background and aims: To compare PK/PD of insulin (I) glargine U300 (Gla300) vs U100 (Gla100).
Materials and methods: We studied 18 Type 1 DM subjects (8M, age 40 ±12 yrs, DM duration 7±12 yrs, BMI 23.3±2 kg/m^2, A1C 7.06±0.4 %) after 3 month treatment with Gla100 or Gla300 titrated to fasting plasma glucose (PG) 100 mg/dl (random crossover). In the euglycemic clamp, the subjects' individual daily doses (Gla100 0.30±0.04 U/kg, Gla300 0.37±0.07 U/kg) were given at 8 PM.
Results: Plasma I was initially lower (0-12h, 8.7±3.5 vs 9.2±4.7 μU/ml) (p=0.07), but later greater on Gla300 vs Gla100 (12-24h, 7.6±2.4 vs 5.5 ±1.7 μU/ml) (p=0.02). Both Gla100 and Gla300 maintained PG for 24 h (100±2 and 100±1 mg/dl, p=0.44). With Gla300 vs Gla100 G infusion rate (GIR) was initially lower [AUC ratio T/R (95% CI)], $GIR_{0\text{-}12h}$, 0.61 (0.41 to 0.91, p=0.02)] and later greater [$GIR_{18\text{-}24h}$, 2.2 (1.2 to 4.0, p=0.02), although $GIR_{0\text{-}24h}$ was not different [0.94 (0.66 to 1.3, p=0.66)]. Hepatic G production (HGP) was less suppressed on Gla300 for initial 12 h (4.3±2.6 vs 3.5±2.1 μmol/Kg/min), but more so on Gla300 over last 6 h (1.8±1.3 vs 4.9±2.6 μmol/Kg/min) (both p<0.05).
Conclusion: Gla300 (~23% higher dose, equivalent G efficacy) results in more physiological plasma I and HGP vs Gla100. The higher nocturnal

HGP may reduce risk for nocturnal/morning hypoglycemia, the lower afternoon HGP may favor better predinner G control with Gla300 vs Gla100.

Background and aims: This study aims to evaluate a physician-targeted educational intervention for improving basal insulin (BI) use in China.
Materials and methods: BEYOND II is a prospective cohort study conducted at 73 endocrinology departments at hospitals in China. Participating physicians undergo a 6-month intervention comprising face-to-face training based on a guideline-recommended BI treatment pathway, reinforced by self-audit and peer-to-peer feedback on clinical practice. Pre- and post-intervention, ~100 adults (≥18 years) with type 2 diabetes mellitus (T2DM) receiving BI for ≥3 months are enrolled at each study centre to assess glycaemic control and BI use. The primary endpoint is the proportion of centres meeting individual improvement goals set by the Study Committee. This is a planned interim analysis.
Results: Patient profiles are summarised in the Table. Of 37 centres completing the study as of December 2016, 24 (64.9%, 95% CI; 47.5 to 79.8%) achieved post-intervention improvement targets. The post-intervention cohort had a higher proportion achieving HbA1c <7% (25.2 vs. 38.5%) and FPG <6.1 mmol/L (14.7 vs. 19.8%), a lower mean HbA1c and FPG, and a lower mean daily insulin dose than the baseline cohort (Table). Hypoglycaemia occurred in <5% of patients in both cohorts. The proportion of physicians (n=353) self-rating as 'confident in most cases' about insulin initiation (77.3 vs. 87.3%; p<0.001), titration (81.0 vs. 85.0%; p=0.022) hypoglycaemia management (77.6 vs. 90.1%; p<0.001) increased post-intervention.
Conclusion: The BEYOND II intervention led to improvements in glycaemic control at 64.9% of study centres by encouraging adoption of guideline recommendations for BI use in clinical practice.

Variable[a]	Baseline cohort (N=3537)	Post-intervention cohort (N=3524)	P-value[b]
Age, years	59.7 (11.6)	59.2 (11.5)	0.086
Males, n (%)	1877 (53.1)	1890 (53.6)	0.634
BMI, kg/m^2	25.1 (3.3)	24.8 (3.1)	<0.001
Disease course, years	10.7 (7.1)	10.5 (7.1)	0.362
Basal insulin dose, IU/kg/day	0.24 (0.10)	0.23 (0.10)	0.033
HbA1c, %	8.16 (1.70)	7.63 (1.49)	<0.001
HbA1c <7%, n (%)	893 (25.2)	1355 (38.5)	<0.001
FPG, mmol/L	9.15 (3.50)	8.30 (3.00)	<0.001
FPG <6.1mmol/L, n (%)	521 (14.7)	699 (19.8)	<0.001
Incidence of hypoglycaemia, n (%)	165 (4.7)	154 (4.4)	0.551

Impact of treatment persistence on glycated haemoglobin A_{1c} (HbA_{1c}) trends among patients with type 2 diabetes newly initiated on basal insulin

L. Xie[1], F.L. Zhou[2], C. Pan[3], N. Vaidya[2], F. Ye[4], R. Preblick[2], L. Meneghini[5];
[1]STATinMED Research, Ann Arbor, [2]Sanofi US, Inc., Bridgewater, [3]PRO Unlimited, Boca Raton, [4]TechData Service, LLC, King of Prussia, PA, [5]University of Texas Southwestern Medical Center and Parkland Health and Hospital System, Dallas, USA.

Background and aims: Previous studies have suggested that greater treatment persistence is associated with improved clinical outcomes in patients with T2D; however, the relationship between persistence with basal insulin therapy and glycaemic control over time has yet to be investigated.
Materials and methods: This retrospective observational study assessed the impact of treatment persistence on HbA_{1c} levels over time in US insulin-naive patients with T2D newly initiating insulin glargine 100 U/mL or insulin detemir between January 1, 2011 and December 31, 2013. Patients were identified from the Clinformatics database, and HbA_{1c} values were extracted quarterly for each patient. Data were assessed 12 months prior to (baseline) and 18 months after insulin initiation. Non-persistence was defined as a basal insulin refill gap of > 90 days during 18 months follow-up. A generalized estimating equations regression model accounting for the correlation of repeated HbA_{1c} measurements and missing data for each patient during the follow-up period was used to compare HbA_{1c} trends between persistent and non-persistent patients.
Results: In this analysis 3,993 patients with ≥1 HbA_{1c} measure at baseline and ≥1 HbA_{1c} measure at follow-up (mean 2.71 HbA_{1c} measures per patient) were identified. Patients were further categorized as persistent (n = 1,715) or non-persistent (n = 2,278). Approximately 73% of non-persistent patients discontinued basal insulin within 6 months of initiation. Persistent patients had significantly greater HbA_{1c} reduction during the 18-month follow-up period. After controlling for potential confounders in the generalized estimating equations model, persistence was associated with an additional 0.05% decrease in HbA_{1c} per quarter, with an accumulated additional 0.3% decrease in HbA_{1c} over 18 months, compared with non-persistent patients ($P = 0.0004$).
Conclusion: These data suggest that for patients with T2D newly initiated on basal insulin, being persistent with treatment is associated with a consistent decrease in HbA_{1c} over time in real-world clinical settings.

Cost analysis of initiating basal insulin for 6 months in type 2 diabetes patients in China: an observational registry study

P. Zhang[1], D. Zhu[2], X. Li[2], J. Ji[2], J. Lu[3], W. Jia[4], L. Ji[5];
[1]Diabetes Research Program, The George Institute for Global Health at Peking University Health Science Center, [2]Biostatistics and Economic Evaluation Program, The George Institute for Global Health at Peking University Health Science Center, [3]Department of Endocrinology, General Hospital of the People's Liberation Army, Beijing, [4]Department of Endocrinology, Shanghai Sixth People's Hospital, Shanghai, [5]Department of Endocrinology and Metabolism, Peking University People's Hospital, Beijing, China.

Background and aims: The short-term cost changes after adding-on basal insulins (BIs) therapy in routine clinical practice is still unknown. This study aims to determine the economic impact of converting patients with T2DM from an oral antidiabetic drug (OAD)-only regimen to a BI+ OAD regimen.
Materials and methods: Based on a multicenter, 6-month prospective registry study design, 18,995 patients with type 2 diabetes inadequately controlled (HbA1C ≥7%) by OADs and willing to initiate BI therapy were enrolled from 209 hospitals of eight geographic regions of China from December 2011 to June 2013. Interviews were conducted at baseline (0 month—V1), month 3 (V 2) and month 6 (V 3). Type and dose of BI were at the physician's discretion and patients' willingness. The treatment cost included cost of OAD medication, insulin therapy, and self-monitoring of blood glucose (SMBG). Daily treatment cost per person before and after adding BIs was evaluated. Clinical outcomes such as HbA1c and hypoglycemia were also recorded.
Results: After adding on BIs, the mean ± SD daily treatment cost for insulin-naïve T2DM patients increased from $1.24 ± $2.04 (baseline) to $2.67 ± $1.76 at 3 months and $2.57 ± $1.81 at 6 months, a median (Q1, Q3) increase of 1.51 (0.39, 4.07) times over 6 months. The cost and clinical outcomes in different subgroups are shown in Table 1. The times of cost increased proportionally with the baseline HbA1c level (from 1.33times to 2.08times) and declined as diabetes duration prolonged (from 1.64 times to 1.30 times). The times of costs increase were higher in the insulin glargine 1.59(0.48,4.14) and detemir 1.80(0.58,4.88) groups compared with the NPH group 0.94(0.07,3.17). However, NPH subgroup had the highest increase in percentage of hypoglycemia (7.2%) compared with subgroup of Glargin (1.3%) and Detemir (6.5%). Insulin cost accounted for the highest proportion (48.3%) of costs, with OAD costs ranking the second (36.7%), followed by needles (7.9%) and SMBG (6.9%) costs.
Conclusion: Adding-on BI therapy may increase the daily treatment cost by 1.5 times at 6 months, followed by significant improvement in blood glucose control.

Table 1. Daily treatment cost ($) change and clinical outcomes after initiating basal insulin for 6 months in different subgroups

Group variable	Absolute cost increase (v3-v0)	Times of cost increase at 6 months,	HbA1c reduction (%)	Increase in hypoglycemia (%)	Weight gain (kg)
Total	1.35 ± 2.19	1.51(0.39, 4.07)	2.15±2.07	2.9	0.10±2.94

Clinical benefit of simultaneous initiation of basal insulin and GLP-1 in patients with type 2 diabetes and elevated HbA_{1c} as supported by real-world evidence

B. Guerci[1], D. Raccah[2], E. Lew[3], J. Meyers[4], A. Shaunik[5], M. Ajmera[4], K.L. Davis[4], L. Blonde[6];
[1]Department of Diabetology, Metabolic Diseases, and Nutrition, University of Lorraine, Vandoeuvre-les-Nancy, [2]Department of Diabetology, University Hospital Sainte-Marguerite, Marseille, [3]Sanofi, Chilly-Mazarin, France, [4]Health Economics, RTI Health Solutions, Research Triangle Park, [5]Sanofi, Bridgewater, [6]Department of Endocrinology, Ochsner Medical Center, New Orleans, USA.

Background and aims: Many guidelines tend to recommend a stepwise treatment approach that may be associated with uncontrolled HbA1c between steps. However, timely and durable glycemic control is a key goal of T2DM treatment. This study compared longitudinal HbA1c in patients with uncontrolled T2DM receiving combination treatment with GLP-1 and basal insulin (BI) initiated either sequentially or simultaneously.
Materials and methods: Patients with T2DM from 1/1/2007-12/31/2014 were identified in the GE Centricity database. Patients receiving combination GLP-1/BI were selected (initiation of combination GLP-1/BI termed index date). Patients were required to have 6 months pre- and 1 year post-index date physician history and pre-index date HbA1c > 7%. Patients were classified as having simultaneous GLP-1/BI initiation if they started both medications within 14 days of each other, otherwise patients were considered sequential initiators. In addition, patients were required to receive combination treatment (i.e., overlapping prescription orders for both medications) for a minimum of 30 of the first 60 days of the post-index date period. HbA1c was compared from 6 months pre- to 1 year post-index date.
Results: A total of 5,453 patients initiated BI first, 3,930 patients initiated GLP-1 first, and 1,823 patients initiated GLP-1/BI simultaneously. Patients were of similar age across all study cohorts (mean [SD] age 56.7 [11.8] years among BI first, 57.0 [10.7] among GLP-1 first, and 55.9 [11.8] years among simultaneous initiators). Baseline HbA1c was similar across all study cohorts (mean [SD] HbA1c 9.1 [1.6] among BI first, 9.1 [1.6] among GLP-1 first, and 9.0 (1.7) among simultaneous initiators), and the change in HbA1c during 1 year follow-up was similar across cohorts (0.7 for both simultaneous initiators and BI first, 0.8 for GLP-1 first). Among the subgroup of patients with baseline HbA1c > 10.0 (N=1,172 BI first, 882 GLP-1 first, and 378 simultaneous initiators), baseline HbA1c was similar (9.6 [2.2] among BI first, 9.3 [2.0] among GLP-1 first, and 9.1 [1.9] among simultaneous initiators), and simultaneous initiators had the largest decrease in HbA1c during follow-up (mean [SD] change in HbA1c was 2.3 [2.1] for simultaneous initiators, 1.8 [1.7] for GLP-1 first, and 2.0 [2.0] for BI first).
Conclusion: Patients with very high HbA1c (i.e., HbA1c > 10) were found to have the largest HbA1c decrease if they simultaneously initiated GLP-1 and BI, indicating that patients may benefit from simultaneous over stepwise treatment initiation.

Use of regular insulin U-500 in type 2 diabetes treatment with pump therapy

E. Deberles[1], J. Hardouin[2], A. Penfornis[3], A. Cristea[4], J. Morera[1], A. Rod[1], M. Joubert[1], P. Benhamou[4], Y. Reznik[1];
[1]Diabetes and Endocrinology, Caen University Hospital, CAEN, [2]Diabetes and Endocrinology, Laval Hospital, LAVAL, [3]Diabetes, Corbeil-Essonnes Hospital, Corbeil, [4]Diabetes, Grenoble University Hospital, Grenoble, France.

Background and aims: Insulin therapy intensification by insulin pump is helpful in insulin resistant type 2 diabetes. The use of concentrated insulin may help improving glycemic control but few studies are available. We retrospectively report on the utilization of regular insulin 500 U/ml (Eli Lilly, France) in a pump device over a 5-yr period.
Materials and methods: Patients on MDI (basal-bolus) or pump therapy, both using U-100 rapid acting insulin analog, were recruited in two circumstances : i) HbA1c>8% and/or insulin dose >100 UI/d. After U-500 therapy initiation, follow-up was performed at 1 week, 3-6, 12, 18-24, 30-36, 42-48 and 54-60 months for HbA1c, total daily dose (TDD), body weight, incidence of hypoglycemia, treatment drop off.
Results: 52 patients were included, M/F ratio 28/24, age 62,9±8,8, diabetes duration 19±8 yrs, TDD 199±58 UI/d, BMI 39±6 kg/m², HbA1c 8.9 ±1.3%. Mean follow up on U-500 was 20±15 months with 10 drop off. HbA1c decreased by - 0,96% (p=0,001), - 0.95% (p<0,001), - 0,99 % (p= 0,001), - 1.38% (p=0,001), - 1% (NS) and - 2.15% (NS) at 3-6, 12, 18-24, 30-36, 42-48 and 54-60 months. Body weight remained stable and TDD increased by 11-25% among the study period. Non severe hypoglycemia occured in 21% subjects on U-100 and 55% subjects on U500 at 6 months (p=.0.01). 0ne severe hypoglycemia occured during the study period.
Conclusion: Pump therapy delivering U-500 regular insulin durably improves glycemic control in insulin refractory patients with type 2 diabetes who remain uncontrolled with U-100 intensified insulin regimens. Hypoglycemia may be prevented by careful education of U-500 users.
Disclosure: **E. Deberles:** None.

Associations between insulin dose titration over one year and hypoglycaemia: a descriptive study using 4-T data

A.J. Farmer[1], M.-M. Lee[1], J. Oke[1], A. Reutens[2], J. Shaw[2], R.R. Holman[3];
[1]Department of Primary Care Health Sciences, University of Oxford, Oxford, UK, [2]Baker Heart and Diabetes Institute, Melbourne, Australia, [3]Diabetes Trials Unit, University of Oxford, Oxford, UK.

Background and aims: Insulin titration algorithms for type 2 diabetes are well established, but their implementation and the insulin doses used are poorly described. In the 4-T study, participants were randomly allocated to three different insulin regimens, one of which was a basal insulin with daily injections of insulin detemir adjusted with an algorithm based recommendation. Comparing reports of the actual insulin dose used with that recommended provide a means of examining adherence to recommendations for insulin dose.
Materials and methods: In a cohort of people with T2D starting treatment with insulin detemir in the 4-T study, participants received standardized recommendations for dose adjustment from a computerised algorithm. Insulin dose was increased if more than one-third of blood glucose readings in the preceding two weeks were above the target range of 4.0 to 5.5mmol/l and reduced where hypoglycaemia or blood glucose levels of <3.9mmol/l were experienced. Data on recommended insulin doses and subsequent reported actual doses, and reports of hypoglycaemia were recorded. Sequential random intercept logit models, based on whether the reported dose was the same as the recommended dose were used to explore associations with gender, insulin dose taken, pre-breakfast glucose and occurrence of hypoglycaemia.
Results: Insulin dose data were available on 233 (99.6%) of 234 participants in the 4-T trial allocated to detemir insulin. 143 (61.1%) were men. Mean (SD) age was 61.9 (10.0) years and HbA_{1c} 8.4 (0.8)%. Over one year 4,976 paired records of insulin doses recommended and taken were compared. For 3,934 (79.1%) paired records, the insulin dose reported as being taken at the next study contact was the same as the prior recommendation. 24 (10.3%) participants reported taking the recommended

insulin dose for all study visits. In 1042 (20.9%) records the dose reported did not match the recommended dose. Of these, 667 (64.0%) were for a higher dose of insulin and 375 (36.0%) were for a lower dose of insulin than that recommended. For those experiencing hypoglycaemia following the dose recommendation, the proportion of people taking less insulin than recommended was higher than among those not experiencing hypoglycaemia [Figure]. The odds ratio (95% CI) for associations between taking less (relative to taking more) insulin than recommended and the following factors were: more hypoglycaemia (3.65, 2.35-5.65); higher glucose level (0.86, 0.79-0.93); trend over time (1.06, 1.04-1.09); male *vs.* female (0.59, 0.41-0.86) and insulin dose taken 0.98 (0.98-0.99).
Conclusion: These data confirm that around 20% of insulin dose recommendations to people over one year in a clinical trial were not followed, but where the dose was discrepant, a greater rather than a smaller dose of insulin than recommended was more likely to be used.

Patterns and trends in insulin intensification among patients with type 2 diabetes in Western Pacific region

A. Jabbar[1], W. H-H Sheu[2], C. Deerochanawong[3], R. Mirasol[4], R. Ozaki[5], W. M. I. Wan Mohamed[6], R. Qi[7], T. Treuer[8];
[1]Eli Lilly and Company, Dubai, United Arab Emirates, [2]Taichung Veterans General Hospital, Taichung, Taiwan, [3]Rajavithi Hospital, Rangsit Medical School, Bangkok, Thailand, [4]St. Luke's Medical Center, Quezon City, Philippines, [5]The Chinese University of Hong Kong, Hong Kong, China, [6]Hospital Universiti Sains Malaysia, Kelantan, Malaysia, [7]Eli Lilly and Company, Indianapolis, USA, [8]Eli Lilly and Company, Budapest, Hungary.

Background and aims: Verifying Insulin Strategy and Initial Health Outcome Analysis (VISION) was an 18-month observational study that explored treatment approaches in patients with type 2 diabetes mellitus (T2DM) initiating insulin in the Western Pacific (WP) region. We summarise demographic and clinical characteristics, patterns of insulin initiation and intensification, health care professional profile and patient-reported outcomes (PROs).
Materials and methods: Patients aged ≥18 years with T2DM initiating insulin therapy in normal clinical course after oral drugs failure were enrolled from 5 WP countries. A total of 1065 patients were enrolled from Hong Kong (n=143), Malaysia (n=237), Philippines (n=188), Taiwan (n=163) and Thailand (n=334). Participant data were recorded by the treating physicians and PROs were assessed using questionnaires.
Results: Mean age of patients was 57.2 years with mean glycosylated haemoglobin (HbA1c) of 9.9%. About 59% of patients had HbA1c >9% at insulin initiation despite 81% being on 2 or more oral anti-diabetic (OAD) agents. Hypertension and dyslipidaemia were the most frequent comorbidities in 70% and 62.9% patients, respectively. Sixty-four percent were being followed by endocrinologist and the rest by non-endocrinologists. More than 70% were using metformin and sulfonylureas (SU) and 26.3% were on DPP4 inhibitors (DPP4i). Basal insulin was initiated in 72% and premixed insulin in 27%. OADs were continued by most of the patients, initiated on basal insulin; whereas, SU use decreased from 51% at baseline to 14.4% in patients initiated on premixed insulin. Intensification of insulin therapy (switching from basal to premixed insulin, adding mealtime bolus doses and/or increasing the dosing frequency) was observed in 66.4% patients on initial basal insulin and 53.1% of patients on initial premixed insulin. By the end of study, proportion of patients with HbA1c ≤9% increased from 33.4% to 54.8% but only 24.7% achieved HbA1c of ≤7.5% after intensification of insulin treatment by their physicians. The proportion of patients completely satisfied with their insulin treatment increased from 19.0% to 28.6% in the first 6 months and remained stable till the end of the study. The quality of life (QoL), EQ-5D-3L Visual Analogue Scale mean scores increased from baseline by the end of the study.
Conclusion: VISION study highlights clinical inertia and importance of early insulin initiation and intensification. More than half of patients had an HbA1c >9% at the time of insulin initiation and only a quarter managed to achieve HbA1c of ≤7.5% by the end of 18 months. About 15% patients were continued on SU despite being on premixed insulin which is not recommended in most guidelines. Insulin regimen change was more frequently needed in the basal group compared to the premixed group. Improvement in treatment satisfaction score and other PROs suggests that in most patients, insulin treatment does improve QoL.

Impact of human versus analog insulins on occurrence of myocardial infarction

P.J. O'Connor[1], J. Schmittdiel[2], K. Reynolds[3], E. Schroeder[4], J.R. Desai[1], M. Ho[5], G. Vazquez-Benitez[1], J.P. Anderson[1], W. Dyer[2], L. Loes[1], R. Neugebauer[2];
[1]HealthPartners Institute, Minneapolis, [2]Kaiser Permanente Northern California Division of Research, Oakland, [3]Kaiser Permanente Southern California Department of Research and Evaluation, Pasadena, [4]Kaiser Permanente Colorado Institute for Health Research, Denver, [5]VA Eastern Colorado and University of Colorado (Anschutz) Medical Center, Denver, USA.

Background and aims: Prior studies have shown mixed results on the cardiovascular safety of insulin analogs compared to human insulins. This observational study uses rigorous causal inference methods of Comparative Effectiveness Research to emulate a trial evaluating the cardiovascular safety of analog versus human insulins.
Materials and methods: Study subjects were 127,600 adults with type 2 diabetes receiving care between 1/12005 and 12/31/2013 at 4 U.S. health care delivery systems, classified on date of insulin initiation (index date) as using (a) analog insulins with or without human insulin, versus (b) human insulins only. Subjects were followed from index date to first

occurrence of: myocardial infarction (MI), death, health plan disenrollment, or 12/31/2013. In order to estimate the differences between the two groups had patients remained on their insulin regimen (a per-protocol analysis), we used Inverse Probability Weights (IPW) and marginal structural modeling (MSM) analyses in which patients' data were right-censored if they crossed-over to the other exposure group or interrupted insulin therapy during follow-up. Effect estimates were obtained based on two logistic MSM parameterizations for counterfactual hazards. To address concerns over potential residual confounding, we replicated the same analytic approach using three nested sets of covariates assumed to potentially affect (a) both the outcome and the exposure/censoring events, (b) the outcome, and (c) either the outcome or exposure/censoring events.

Results: The mean follow-up time was 21 months. Hazard ratios and cumulative risk differences comparing the two groups were not statistically significant. The estimates of the hazards ratio and its 95% confidence interval were 1.2214 [0.9877;1.4551]; 1.08 [0.8642;1.2959]; and 1.0779 [0.7692;1.3866] for each covariate adjustment set, respectively. The estimates of the cumulative risk difference at 2 years and its 95% confidence interval were 0.0037 [-8e-04;0.0082]; 0.0011 [-0.0034;0.0057]; and -6e-04 [-0.0055;0.0044] for each covariate adjustment set, respectively.

Conclusion: In this large comparative effectiveness analysis using marginal structural modeling with three covariate adjustment sets, we were not able to identify statistically significant excess occurrence of myocardial infarction in those using analog, compared to human insulins.

1,5-anhydroglucitol correlates with postprandial glucose in subjects with type 1 diabetes irrespective of HbA_{1c} responder status

S. Heller[1], K. Bowering[2], P. Raskin[3], A. Liebl[4], K. Buchholtz[5], M. Demissie[5], T.R. Pieber[6];

[1]University of Sheffield, Sheffield, UK, [2]Department of Medicine, University of Alberta, Edmonton, Canada, [3]University of Texas Southwestern Medical Center, Dallas, USA, [4]Centre for Diabetes and Metabolism, m&i-Fachklinik Bad Heilbrunn, Bad Heilbrunn, Germany, [5]Novo Nordisk A/S, Søborg, Denmark, [6]Division of Endocrinology and Diabetology, Medical University of Graz, Graz, Austria.

Background and aims: Serum 1,5-anhydroglucitol (1,5-AG) levels decrease (<12 μg/mL) during periods of hyperglycaemia (>180 mg/dL) and reflect plasma glucose control over the previous 1-2 weeks. 1,5-AG is considered particularly useful in evaluating postprandial glucose (PPG) excursions in well- or moderately controlled patients (defined by HbA_{1c}), as 1,5-AG levels can reflect both fasting and postprandial hyperglycaemia in poorly controlled patients. The aim of this *post hoc* analysis was to assess if the extent to which 1,5-AG levels reflect PPG control depends on HbA_{1c} responder status.

Materials and methods: Post hoc analysis of onset 1, a 26-week, phase 3 trial in which subjects with type 1 diabetes (mean HbA_{1c} 7.6%) were randomised to double-blind mealtime fast-acting insulin aspart (faster aspart), insulin aspart (IAsp) or open-label post-meal faster aspart (20 min after the start of the meal), all in combination with insulin detemir. In this analysis, subjects from the three treatment arms were pooled to examine the correlation between absolute values of 1,5-AG and 2-h PPG from 7-9-7 self-measured plasma glucose profiles at week 26 according to HbA_{1c} status (<7% or ≥7%) at week 26.

Results: In onset 1, HbA_{1c} was reduced in all treatment arms; primary endpoint was HbA_{1c} change from baseline at 26 weeks (est. treatment difference [ETD] [95% CI]: mealtime faster aspart vs. IAsp −0.15% [−0.23;−0.07]; post-meal faster aspart vs. IAsp 0.04% [−0.04;0.12]). Glycaemic differences were reflected in 1,5-AG change from baseline (ETD [95% CI]: mealtime faster aspart vs. IAsp 0.50 μg/mL [0.24;0.76]; post-meal faster aspart vs. IAsp -0.16 μg/mL [-0.42;0.10]). 1,5-AG correlated with 2-h PPG for subjects with HbA_{1c} <7% (r=-0.20; $p<0.001$) and HbA_{1c} ≥7% (r=-0.19, $p<0.001$) at week 26. In both HbA_{1c} responder groups, the correlation between 1,5-AG and 2-h PPG was similar within each treatment arm.

Conclusion: These results are consistent with the usefulness of 1,5-AG as a marker of short-term glycaemic control, irrespective of HbA_{1c} responder status.

Figure. Correlation between absolute values of 1,5-AG and 2-h PPG (SMPG) at week 26 by HbA_{1c} responder status

Treprostinil causes local vasodilation, is well tolerated, and results in faster absorption of insulin lispro

J. Leohr, E. Pratt, C. Heilmann, J. Johnson, W. Landschulz;
Eli Lilly and Company, Indianapolis, USA.

Background and aims: The purpose of this study was to test if an increase in local blood flow induced by s. c. administration of a known vasodilator (treprostinil) at a tolerated dose would speed absorption of insulin lispro.
Materials and methods: This was a phase 1, randomised, placebo-controlled, 2-part exploratory study in healthy subjects. Part A was a dose-escalation study (4 to 2000 ng) of s. c. treprostinil (n=11), a prostacyclin analogue approved for the treatment of symptomatic pulmonary arterial hypertension, versus placebo, to assess safety, tolerability, and local vasodilation. Laser Doppler flowmetry was used to assess local blood flow. Part B was a 4-period, complete crossover, euglycaemic clamp (N=16) to assess the pharmacokinetics and glucodynamics (GD) of insulin lispro (15 U) when administered with 3 concentrations of treprostinil or placebo.
Results: Treprostinil was rapidly absorbed and eliminated with detectable exposure only at the highest dose levels. Local blood flow increased from baseline and had similar magnitude for the 4-hour duration for all treprostinil doses (Figure 1), except the 4 ng dose level in which blood flow returned to baseline at ~3 hours postdose. There was no obvious difference in adverse events (AEs) across treatments and, importantly, no clinically significant increase of those AEs was associated with systemic absorption of treprostinil. There was no suggestion of treatment-related changes in laboratory values, vital signs, or ECG parameters with treprostinil. When insulin lispro was combined with treprostinil, the insulin lispro area under the concentration curve versus time from 0 to 30 min increased up to 92% ($p<0.0001$) and the time to onset of insulin action was reduced up to 29% ($p<0.0001$) compared with when insulin lispro was used alone; however, the total glucose infused was similar.
Conclusion: Coadministration of microdoses of treprostinil increased local blood flow and accelerated the absorption and GD action of insulin lispro without compromising safety, and may represent a way to achieve an ultra rapid prandial insulin.

Figure 1. Mean change from baseline in local blood flow, as measured by Laser Doppler Flowmetry, versus time by treprostinil dose level.

Ultra-rapid BioChaperone Lispro improves post-prandial blood glucose excursions versus insulin lispro in a 14-day treatment study in subjects with type 1 diabetes

G. Meiffren[1], O. Soula[1], A. Ranson[1], M. Gaudier[1], B. Alluis[1], G. Andersen[2], D. Lamers[2], T. Heise[2];
[1]Adocia, Lyon, France, [2]Profil, Neuss, Germany.

Background and aims: We investigated safety and efficacy of BioChaperone Lispro (BCLIS), an ultra-rapid formulation of insulin lispro (LIS), in a double blind randomised, cross-over study in 36 subjects with type 1 diabetes treated with multiple daily insulin injections (mean ±SD age: 45±12 yrs; BMI: 24.3±2.6 kg/m²; HbA1c: 7.2±0.7%).
Materials and methods: Post-prandial glucose (PPG) excursions were assessed with individualised solid mixed meal tests (MMT) (50% carbs, 30% fat, 20% proteins) with insulin administrations immediately (T0), 15 minutes before (T-15) and 15 minutes after (T+15) meal start on days 1, 2 and 3 and with T0 administration on day 14. Pharmacokinetics (PK) were assessed only for T0 MMTs. Subjects also used individualised BCLIS or LIS doses immediately before meals during two 14-day outpatient periods with unchanged basal insulin regimen.
Results: BCLIS showed similar safety and tolerability to LIS with 12% less hypoglycaemic episodes in the outpatient period. No injection site reactions were observed. PK showed identical total exposure for both formulations, but a higher early exposure (table) and a faster insulin lispro absorption with BCLIS than LIS (early $T_{0.5max}$ Day 1: 0.259 vs. 0.365 h, Day 14: 0.261 vs 0.345 h, $p<0.0001$). In MMTs with T0 administrations, significant reductions in 1-2h PPG excursions by 30-50% were observed with BCLIS vs LIS (table). Both accelerated absorption and better PPG control were sustained over 14 days. In addition, no differences in PPG control were seen between BCLIS injected at T+15 and LIS at T0.
Conclusion: BCLIS was well-tolerated and safe over 14 days of MDI in subjects with type 1 diabetes, significantly improved post-prandial glucose excursions vs LIS at mealtime and could additionally offer the flexibility of post-meal administration.

Table:

	Parameter	Treatment	LS Means T0	LS Means T+15	LS Means T0 (day 14)	p-value T0 BCLIS vs T0 LIS	p-value T+15 BCLIS vs T0 LIS

Exploration of the mechanism of accelerated absorption for a novel insulin lispro formulation

J.S. Moyers, C. Zhang, A.M. Siesky, A.L. Cox, A.E. Sperry, R.J. Hansen, M.E. Christe, M.W. Farmen, H. Wu, C.D. Paavola, M.D. Michael;
Eli Lilly and Company, Indianapolis, USA.

Background and aims: Potential benefits of a prandial insulin with a faster onset and offset compared to currently available insulin analogues include better prandial glycaemic control, less hypoglycaemia and weight gain, and better overall utility in closed-loop artificial pancreas systems. Modelling and simulation suggested that increasing absorption rate would have more influence on the insulin pharmacokinetics (PK) than modulating insulin clearance. To achieve this goal, the excipients citrate and treprostinil were included in LY900014 (LY)—a novel formulation of insulin lispro—to accelerate insulin lispro absorption for improvement of postprandial glucose. Herein we describe the physiological mechanisms that contribute to accelerated absorption and provide pre-clinical evidence of faster insulin lispro absorption.

Materials and methods: An *in vitro* assay was used as a model of transport across the endothelial monolayer, where human dermal microvascular endothelial cells were grown in Transwell® plates and quantitation of the transport of FITC-insulin lispro across the cell monolayer was performed. The Miles assay was used to test vascular permeability in rats following an intravenous dose of Evans Blue dye, which binds tightly to albumin. Test excipients were administered by subcutaneous (sc) injection, and vascular permeability was assessed by measurement of the dye in skin biopsies. Laser Doppler imaging was used to measure vasodilation in the skin of rats following sc dosing of test excipients. To determine the impact of the excipients on glucodynamics and insulin lispro PK, LY was administered by sc injection to diabetic miniature swine. A mixed effects ANOVA was performed with Dunnett's pairwise comparisons of LY to the marketed U100 formulation of insulin lispro.

Results: In the vascular endothelial cell-based permeability assay, citrate induced a dose-dependent increase in permeability of FITC-insulin lispro. In the Miles assay, injection of citrate into the sc tissue of rats resulted in a localised increase in vascular permeability. The vasodilator treprostinil, a prostacyclin analogue approved for clinical use, had little effect in either of these assays. On the other hand, sc injection of very low doses of treprostinil induced localised vasodilation in rats without causing systemic vasodilation. Citrate had minimal effects on vasodilation. When administered by sc injection to diabetic miniature swine, LY resulted in significantly faster glucose lowering at time points up to 30 min post dose, and key PK parameters (t_{max}, early 50% t_{max}, late 50% t_{max}) were significantly faster as compared to the marketed U100 formulation of insulin lispro.

Conclusion: Taken together these results demonstrate that insulin lispro absorption can be accelerated through modulation of injection site blood flow and vascular permeability and provide a mechanistic understanding for the ultra rapid insulin lispro profile that LY has demonstrated in clinical trials.

Efficacy and safety of fast-acting insulin aspart are maintained over 52 weeks: comparison with insulin aspart in onset 1

C. Mathieu[1], B. Bode[2], E. Franek[3], A. Philis-Tsimikas[4], L. Rose[5], T. Graungaard[6], A. Østerskov[6], D. Russell-Jones[7];
[1]UZ Leuven, Leuven, Belgium, [2]Atlanta Diabetes Associates, Atlanta, USA, [3]Mossakowski Medical Research Center, Polish Academy of Sciences, Warsaw, Poland, [4]Scripps Whittier Diabetes Institute, San Diego, USA, [5]Diabetes Research Center, Münster, Germany, [6]Novo Nordisk, Søborg, Denmark, [7]Royal Surrey County Hospital, Guildford, UK.

Background and aims: onset 1 was a phase 3a trial evaluating fast-acting insulin aspart (faster aspart) in adults with type 1 diabetes (T1D) over 52 weeks vs. insulin aspart, in two 26-week treatment periods. The aim of the additional 26-week period was to assess long-term safety and efficacy of faster aspart.

Materials and methods: In the initial 26-week treatment period of onset 1, subjects were randomised to either double-blind mealtime faster aspart, insulin aspart (IAsp) or open-label post-meal faster aspart, each with once- or twice-daily insulin detemir. Subjects on mealtime faster aspart (n=381) and mealtime IAsp (n=380) then continued to the additional 26-week treatment period.

Results: After 52 weeks, mean HbA_{1c} change from baseline was −0.08% with faster aspart and +0.01% with IAsp, with significant est. treatment difference (ETD) favouring faster aspart (ETD: −0.10% [95% CI: −0.19;−0.00]). Following a standardised meal test, change from baseline in 1-h postprandial plasma glucose (PPG) increment significantly favoured faster aspart (−1.05 mmol/L) compared with IAsp (−0.14 mmol/L) (Table). A similar trend toward better efficacy with faster aspart vs. IAsp was seen in change from baseline in 2-h PPG increment after the meal test (Table). The improvements in PPG control were also reflected in 7-9-7 self-measured plasma glucose profiles, with significant difference between treatment arms in favour of faster aspart for mean overall plasma glucose (PG) change from baseline (ETD [95% CI]: −0.23 mmol/L [−0.46;−0.00]), driven by 2-h PPG increments after breakfast and dinner. No statistically significant differences were observed across all meals (Table). The significant increase from baseline to 52 weeks in 1,5-anhydroglucitol with faster aspart compared with IAsp (Table) also suggested fewer hyperglycaemic excursions with faster aspart. Median total insulin dose was 61.3 U/0.77 U/kg with faster aspart and 68.5 U/0.83 U/kg with IAsp. No difference was observed for body weight change (+1.18 kg [faster aspart] vs. +1.05 kg [IAsp]; ETD: 0.13 kg [95% CI: −0.38;0.65]). After 52 weeks, adverse events were similar between faster aspart and IAsp, and as expected for IAsp. Overall severe or blood glucose-confirmed hypoglycaemia rates (PG <3.1 mmol/L) were similar (faster aspart: 53.29 events/patient-year; IAsp 53.19 events/patient-year) (estimated ratio: 1.01 [95% CI: 0.88;1.15]).

Conclusion: No long-term safety issues were identified with faster aspart. Glycaemic control was significantly improved after 52 weeks with faster aspart vs. IAsp. Approaching a profile closer to physiology with faster aspart achieves lower PPG and HbA_{1c} in T1D vs. IAsp.

Table. Estimated treatment differences between faster aspart vs. insulin aspart in change from baseline to 52 weeks in onset 1

	Estimated treatment difference in change from baseline (mealtime faster aspart – mealtime insulin aspart) [95% CI]
Mean HbA_{1c}	−0.10% [−0.19;−0.00]*
Standardised meal test	
1-h PPG increment	−0.91 mmol/L [−1.40;−0.43]* −16.48 mg/dL [−25.17;−7.80]*
2-h PPG increment	−0.42 mmol/L [−1.11;0.27] −7.60 mg/dL [−19.98;4.78]
7-9-7 point SMPG	
Overall PG	−0.23 mmol/L [−0.46;−0.00]* −4.14 mg/dL [−8.23;−0.06]*

689

Improved glycaemic control with carbohydrate counting for adjustment of fast-acting insulin aspart versus insulin aspart in subjects with type 1 diabetes

A. Philis-Tsimikas[1], B.W. Bode[2], E. Franek[3], L. Rose[4], K. Buchholtz[5], M. Demissie[5], T.R. Pieber[6];
[1]Scripps Whittier Diabetes Institute, San Diego, [2]Atlanta Diabetes Associates, Atlanta, USA, [3]Mossakowski Clinical Research Center, Warsaw, Poland, [4]Institute of Diabetes Research, Münster, Germany, [5]Novo Nordisk A/S, Søborg, Denmark, [6]Division of Endocrinology and Diabetology, Medical University of Graz, Graz, Austria.

Background and aims: Insulin delivery based on carbohydrate counting is the gold standard for improving glycaemic control in type 1 diabetes (T1D). The aim of this *post hoc* analysis was to assess the impact of dose adjustment methodology on the efficacy and safety of mealtime fast-acting insulin aspart (faster aspart) and insulin aspart (IAsp) in subjects with T1D.
Materials and methods: *Post hoc* analysis of onset 1, a 26-week, phase 3 trial in which subjects were randomised to double-blind mealtime (0-2 min before the meal) faster aspart or IAsp, both with once- or twice-daily insulin detemir. In onset 1, subjects with previous experience continued carbohydrate counting (baseline HbA_{1c}, faster aspart and IAsp 7.6%) and remaining subjects used a simple bolus algorithm (baseline $HbA_{1c,}$ faster aspart 7.5%, IAsp 7.6%). In this *post hoc* analysis, subjects were grouped by dose-adjustment method.
Results: Faster aspart showed a statistically significant greater reduction in HbA_{1c} vs. IAsp, and non-inferiority was confirmed (Table). With carbohydrate counting, HbA_{1c} reduction was statistically significantly greater for faster aspart vs. IAsp (est. treatment difference: −0.19% [95% CI: −0.30;−0.09]), but was similar for both treatments with the simple bolus algorithm. Rates of hypoglycaemic episodes and bolus insulin dose were similar between treatments across adjustment methods. No significant differences in total insulin dose or weight gain were observed between treatments with either adjustment method.
Conclusion: Faster aspart was effective in glycaemic control regardless of adjustment method. For patients with T1D capable of dosing based on carbohydrate counting, faster aspart may offer improved glycaemic control vs. IAsp, with similar weight gain and insulin dose, and without an increased risk of hypoglycaemia.

Table. Outcome measures after 26 weeks of mealtime faster aspart vs. IAsp for all subjects and by dose adjustment methodology.

		Faster aspart	IAsp	Estimated treatment difference (faster aspart – IAsp), [95% CI]
Change from baseline HbA_{1c} (%)*	All subjects	−0.32	−0.17	−0.15 [−0.23;−0.07]
	Carbohydrate counting	−0.27	−0.08	−0.19 [−0.23;−0.09]
	Bolus algorithm	−0.38	−0.30	−0.08 [−0.21;0.04]
Change from baseline body weight (kg)	All subjects	0.67	0.55	0.12 [−0.30;0.55]
	Carbohydrate counting	0.43	0.48	−0.05 [−0.61;0.50]

Greater early postprandial suppression of endogenous glucose production is achieved with fast-acting insulin aspart compared to insulin aspart

T.R. Pieber[1], A. Basu[2], A.K. Hansen[3], S. Sach-Friedl[1], K.M.D. Thomsen[3], R. Basu[2], H. Haahr[3];
[1]Medical University of Graz, Graz, Austria, [2]Mayo Clinic, Rochester, USA, [3]Novo Nordisk, Søborg, Denmark.

Background and aims: Fast-acting insulin aspart (faster aspart) is insulin aspart (IAsp) in a new formulation containing two well-known additional excipients, L-arginine and niacinamide, which result in a stable formulation with accelerated initial absorption after subcutaneous administration. Previous clinical trials have shown that faster aspart provides greater early absorption leading to improved postprandial glucose control compared with IAsp. The aim of the present trial was to investigate the mechanisms behind the lower postprandial glucose achieved with faster aspart versus IAsp.
Materials and methods: In a randomised, double-blind, crossover trial design, subjects with type 1 diabetes (N=40; 21 women/19 men; mean±SD age 42±12 years, BMI 24.1±2.2 kg/m^2, HbA_{1c} 7.3±0.7%) received identical subcutaneous single doses of faster aspart and IAsp (individualised by subject; 0.06-0.28 U/kg) at the start of a standardised mixed meal (containing 75 g carbohydrate labelled with [1-^{13}C] glucose). Postprandial glucose turnover was assessed by the triple-tracer meal method using continuous, variable [6-^{3}H] glucose and [6,6-$^{2}H_2$] glucose infusion.
Results: Early insulin exposure ($AUC_{IAsp,0\text{-}30min}$ and $AUC_{IAsp,0\text{-}1h}$) was greater for faster aspart versus IAsp, leading to smaller postprandial glucose increment at 1 hour (ΔPG_{1h}) (Table). The smaller ΔPG_{1h} with faster aspart was due to greater suppression of endogenous glucose production (EGP) and higher glucose disappearance (ΔAUC_{Rd}) with faster aspart versus IAsp during the first hour post-dose. The greater early suppression of EGP with faster aspart accounted for 78% of the smaller ΔPG_{1h} with faster aspart versus IAsp. Suppression of free fatty acid levels ($AOC_{FFA,0\text{-}1h}$) was 36% greater for faster aspart versus IAsp.
Conclusion: Faster aspart provides improved postprandial glucose control compared with IAsp partly through earlier and greater suppression of endogenous glucose production.

Pharmacokinetic and pharmacodynamic results for faster aspart versus IAsp

Endpoint	Treatment difference Faster aspart-IAsp	Treatment ratio Faster aspart/IAsp	95% CI	P-value
Pharmacokinetics				
$AUC_{IAsp,0\text{-}30min}$		1.93	[1.59;2.34]	<0.001
$AUC_{IAsp,0\text{-}1h}$		1.32	[1.18;1.48]	<0.001
t_{max} (min)	-18.8		[-28.5;-9.0]	<0.001
Plasma glucose				
ΔPG_{1h} (mmol/L)	-0.59		[-1.19;0.01]	0.055
Suppression of endogenous glucose production				
Suppression of $EGP_{0\text{-}30min}$		1.96	[1.13;4.43]	0.017
Suppression of $EGP_{0\text{-}1h}$		1.12	[1.01;1.25]	0.040
Glucose disappearance				
$\Delta AUC_{Rd,0\text{-}1h}$		1.23	[1.05;1.45]	0.012
Free fatty acids				
$AOC_{FFA,0\text{-}1h}$		1.36	[1.01;1.88]	0.042

Suppression of EGP: Calculated as the pre-dose adjusted area over the EGP curve divided by time period (to obtain mean pre-dose adjusted EGP) and then divided by pre-dose EGP.
$AOC_{FFA,0\text{-}1h}$, area over the serum free fatty acid concentration-time curve from 0 to 1 hour; $AUC_{IAsp,}$ area under the serum insulin aspart concentration-time curve; $\Delta AUC_{Rd,0\text{-}1h}$, pre-dose adjusted area under the rate of glucose disappearance-time curve from 0 to 1 hour; ΔPG_{1h}, postprandial plasma glucose increment at 1 hour; EGP, endogenous glucose production; Faster aspart, fast-acting insulin aspart; IAsp, insulin aspart; t_{max}, time to maximum observed concentration.

Liver-preferential effect of oral basal insulin 320 shows benefit under "overdose" conditions

M.C. Moore[1], M. Smith[1], C.L. Brand[2], T. Kjeldsen[2], P. Madsen[2], H. Refsgaard[2], K. Wassermann[2], E. Nishimura[2], S.G. Nielsen[2], J. Gregory[1], P. Williams[3], A.D. Cherrington[1];
[1]Molecular Physiology and Biophysics, Vanderbilt University, [2]Novo Nordisk A/S, Måløv, Denmark, [3]Surgery, Vanderbilt University, Nashville, USA.

Background and aims: Insulin 320 (I320) is an acylated basal insulin analog designed for oral administration. In assessing the safety and mechanism of action of this analog, we examined the response of dogs to an overdose (ie, simulated over-absorption) of I320.

Materials and methods: In order to eliminate variations in bioavailability of I320, it was infused at 40 pmol·kg^{-1}·min^{-1} (basal dose) i.v. for 45 min/day for 3 days before study in all dogs to achieve steady state basal levels. On day 4, ^{3}H-glucose was infused i.v.; after ^{3}H equilibration and basal sampling, dogs were randomly assigned to 1 of 5 groups. Four groups (n=5/group) received a 45-min hepatic portal vein infusion (simulating oral absorption) of I320 at the basal rate or "overabsorption" rates of 80, 120, or 160 pmol·kg^{-1}·min^{-1}. The 5th group (n=3) received regular human insulin (HI) at 24 pmol·kg^{-1}·min^{-1}, a lower dose than the basal I320 dose due to differences in tissue distribution. Sampling continued for 315 min after the insulin infusion ended.

Results: During daily treatments, venous plasma glucose (mM) fell from 5.9±0.1 to 5.4±0.1 (day1), 5.7±0.1 to 5.2±0.1 (day2), and 5.7±0.1 to 5.1 ±0.1 (day3). On day4, basal arterial glucose (6.2±0.1 mM) and endogenous glucose R_a (EndoR_a; 15.0±0.6 µmol·kg^{-1}·min^{-1}) were the same among groups; see Table for glucose parameters during and after insulin infusion. All HI dogs required glucose infusion to maintain arterial glucose ≥2.5 mM, while none of the I320 dogs did. Notably, none of the I320 doses stimulated GlcR_d, while HI increased it >2-fold. Arterial glucagon increased ≤1.8-fold in the I320 groups, while it increased 2.7 fold with HI (P<0.05 vs 40 and 160 I320 doses). Peak arterial cortisol was greater (P<0.05) in HI than in any other group (28±10, 83±16, 157±37, 116±14, and 194±6 nmol/L for 40, 80, 120, and 180 I320 infusion rates and HI, respectively), while peak arterial epinephrine was 752±222, 2943±1800,* 4622±543,* 5251±1646,* and 13280±7472* pmol/L for 40, 80, 120, and 180 I320 infusions and HI, respectively (*P<0.05 vs 40 dose of I320). Arterial glycerol concentrations (reflecting lipolysis) increased dose-dependently in the I320 groups, but HI had the greatest effect (Δ vs. basal: 9±12, 24±18, 51±22, 75±12,* and 112±30* µmol/L with 40, 80, 120, and 180 I320 infusion rates and HI, respectively; *P<0.05 vs 40 dose of I320).

Conclusion: Even the highest dose of I320 did not result in severe hypoglycemia, while all HI-treated dogs required glucose rescue. Over-absorption of I320 during chronic treatment appears to be well tolerated, since the analog stimulates GlcR_d less than HI, allowing more effective counterregulation. Due to the high retention of I320 in the central (blood) compartment, its primary effect appears to be at the liver, which is well equipped to respond to over-insulinization.

Table: 4th day results (mean±SEM) during and after insulin infusion

Insulin infusion (pmol·kg^{-1}·min^{-1})	Arterial glucose nadir (mM)	EndoR_a (µmol·kg^{-1}·min^{-1})		Glucose R_d (peak; µmol·kg^{-1}·min^{-1})	Glucose clearance (peak; ml·kg^{-1}·min^{-1})
		nadir	peak		
40 (I320)	5.7±0.2	12.3±1.3	15.7±1.0	15.5±1.2	2.7±0.1
80 (I320)	4.0±0.5*	10.5±0.9	15.3±0.7	15.8±0.5	3.9±0.4*
120 (I320)	2.9±0.2*	7.1±1.0*	13.6±1.2	15.0±0.9	4.7±0.5*
160 (I320)	2.9±0.2*	7.0±1.2*	14.0±1.3	15.3±1.2	4.8±0.7*
24 (HI)	2.5±0.1*‡	9.6±0.6*	24.2±4.5†	33.3±4.2†	8.8±1.1†

*P<0.05 vs 40 (I320); †P<0.05 vs all other groups; ‡required exogenous glucose for 12-24 min to maintain glycemia ≥2.5 mM

The effects of local subcutaneous inflammation on insulin pharmacokinetics

M.T. Novak, R.R. Radford, K. Riley, J. Alarcón, A. Harvey, R.J. Pettis;
BD Technologies and Innovation, Research Triangle Park, USA.

Background and aims: Continuous subcutaneous insulin infusion (CSII) therapy has clinical benefits for diabetes management yet is impacted by an abbreviated 3 day infusion set usage life. As set wear times increase, patients experience altered pharmacokinetic (PK) and pharmacodynamic (PD) profiles, adverse tissue reactions and loss of glycemic control. Previous research has demonstrated that insulin phenolic excipients, m-cresol and phenol, induce acute inflammatory cytokine release *in vitro*. Coupled with inflammation from the indwelling catheter itself, these data build a compelling case for investigating the potential deleterious effect of local inflammation on insulin delivery. This study shows for the first time that local subcutaneous inflammation negatively impacts insulin PK, thereby providing a basis for studying inflammation as a cause of limited CSII set lifetime.
Materials and methods: Female Sinclair swine (n≥5, full crossover design) were given one of two treatments: (1) a 100 μL subcutaneous injection of lipopolysaccharide (LPS) at 10 EU/kg or (2) a 100 μL subcutaneous saline injection (negative control). As a known initiator of the inflammatory cascade, LPS was used to mimic local CSII-induced tissue effects. Twenty-four hours following dose treatment, an insulin PK study was performed by subcutaneously injecting 4 U of U100 insulin lispro into the treated site. Glucose levels were maintained via catheter fluid therapy of 5% dextrose at a rate of 300 mL/hr. Blood samples were taken periodically for six hours following injection, serum separated and analyzed for lispro content via a lispro-specific radioimmunoassay. At the end of the study, biopsies were taken and analyzed via histopathology for inflammatory cell content. PK metrics (C_{max}, t_{max}, AUC and AUC_{60}) and histology data were statistically compared across treatments using either a paired t-test for normally distributed data or a Wilcoxon signed-rank test for non-parametric data ($p \leq 0.05$).
Results: Figure 1 demonstrates the effects of LPS-induced inflammation on subcutaneous insulin PK. C_{max} and AUC_{60} were decreased, while time to reach maximal concentration, t_{max}, was increased in the LPS case ($p<0.05$ for all). These findings suggest that inflammation not only decreases the amount of insulin absorbed, but also slows the rate of insulin absorption. PK changes were accompanied by an increase in nuclei density for the LPS case, confirming inflammatory effect of the treatment. Mechanisms for limited absorption include decreased diffusion in the inflamed tissue as well as degradation of insulin by inflammatory cells.
Conclusion: Here we present for the first time an *in vivo* study demonstrating the effects of inflammation on subcutaneous insulin PK. Results establish that local inflammation induces adverse changes to insulin PK metrics. As shifts in PK/PD and loss of glycemic control are correlated to limited set lifetime, these findings suggest that local inflammation should be further studied as a factor affecting clinical device performance.

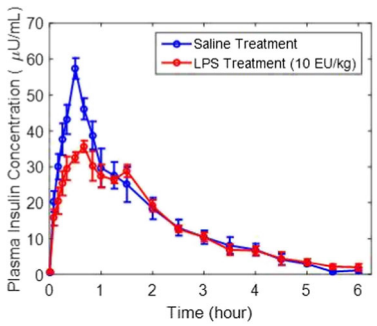

Figure 1: Subcutaneous insulin PK (mean±SEM, n≥5) following site pre-treatment with either 10 EU/kg LPS (red) or saline (blue).

A meta-analysis comparing glycaemic outcomes with insulin glargine in treat-to-target trials with clinical practice

M. Haglund, A. Wihl;
Landskrona Hospital, Landskrona, Sweden.

Background and aims: The "treat-to-target" approach is a key paradigm in clinical development of novel insulins. Typically, an investigational product and a comparator insulin are titrated aggressively to a predefined uniform glycaemic target over a period of 6 to 12 months, during which safety and efficacy parameters are assessed. However, the glycaemic target used in a treat-to-target trial is almost invariably lower than that commonly used in daily clinical practice, and titration of insulin to reach said target is more aggressive. This meta-analysis was conducted in order to generate a better understanding of potential differences between treat-to-target trials and clinical practice in terms of glycaemic outcomes and insulin dosing.
Materials and methods: A Medline search was conducted focusing on identifying observational studies or real world evidence collected on glargine users. Glycaemic outcomes (HbA1c and fasting plasma glucose (FPG)) as well as insulin doses were recorded and a trial-level meta-analysis was conducted. Similarly, phase III treat-to-target trials of novel insulins (degludec, glargine U300 and LY2605541) were meta-analysed separately. Only trials and English language publications including insulin-naïve patients starting treatment with insulin glargine with a follow-up period of 3 to 12 months were included.
Results: A total of 207 publications were identified for analysis. After exclusion of irrelevant publications and publications lacking data on the key outcomes, 24 publications encompassing a total of 34,648 patients were included in the meta-analysis. The average HbA1c and FPG achieved at the end of the treat-to-target trials in which patients were treated with glargine was 7.12% (54.3 mmol/mol) and 6.4 mmol/l, and the average insulin dose was 0.49 U/kg/day. These outcomes were significantly different from those achieved in the publications based on real world clinical practice, where HbA1c and FPG at end of follow-up was 7.45% (57.9 mmol/mol) and 7.2 mmol/l and the average daily insulin dose was 0.21 U/kg/day.
Conclusion: There are significant and important differences between treat-to-target trials and everyday clinical practice. Patients in treat-to-target trials typically achieve better glycaemic outcomes, but this meta-analysis indicates that the difference may be less pronounced than might have been expected. Furthermore, the improvement in glycaemia should be viewed in the context of a significantly greater amount of basal insulin. The safety and efficacy characteristics of basal insulins in everyday clinical practice may not be readily extrapolated from treat-to-target trials because of differences in insulin dosing and glycaemic outcomes. In order to better understand insulin characteristics in everyday clinical practice, we suggest that drug developers and regulators work together to promote the use of pragmatic randomized insulin trials (PRINT). Combined with evidence from clamp studies and treat-to-target trials, PRINTs would potentially contribute important information to facilitate clinical decision making.

Which C-peptide predicts better the insulin necessity?

R. Capitão, C. Ferrinho, F. Santos, C. Bello, C. Barreiros, C. Saraiva, C. Vasconcelos, S. Duarte;
CHLO, Lisbon, Portugal.

Background and aims: C-Peptide is co-secreted with insulin and is used to evaluate insulin dependency in Diabetes Mellitus (DM). It can be measured in serum (SCP) or urine as concentration (UCP) or total amount in 24h urine (24-UCP). The aim of this study is to evaluate which method better correlates with the need of insulin for treatment in DM.
Materials and methods: We evaluated the measurements of SCP, UCP and 24-UCP performed at our Hospital in 2007-2016. The presence and type of DM were recorded as well as the patients under non-insulin treatments, named insulin independent (II-DM), and patients treated with insulin, named insulin dependent (ID-DM). The total daily units in ID-DM patients was also recorded. Values of $p \leq 0.01$ were considered statistically significant.
Results: A total of 692 C-peptide assays (354 SCP, 166 UCP and 172 24-UCP) were analyzed in 233 patients. Of these, 73 had no diagnosis of DM, 29 were classified as DM-1 and 131 as DM-2. The results of the various methods used are shown in the table I. Mann-Whitney test showed statistically significant differences in ID-DM compared to II-DM patients using the 3 methods ($p \leq 0.01$). The Spearman correlation found a statistically significant correlation between the 3 tests and the total daily insulin units ($p \leq 0.01$; $r = -0.34$; -0.402; -0.316 for SCP, UCP and 24-UCP respectively). The ROC curves were all statistically significant and the areas under curve were 0.72, 0.69 and 0.63 for SCP, UCP and 24-UCP respectively. All patients with SCP, UCP and 24-UCP under 0.4 ng/mL, 12.6 ng/mL and 12.9 μg/24h respectively were treated with insulin.
Conclusion: The value of C-peptide is different in ID-DM patients and correlates with the dose of insulin. SCP seems to be the best predictor of ID-DM and the UCP is the one that best correlates with the dose of insulin administered. The cutoff for the necessity of insulin treatment, at least at our laboratory, seems to be 0.4 ng/mL, 12.6 ng/mL and 12.9 μg/24h for SCP, UCP and 24-UCP respectively.

		SCP (ng/mL)	UCP (ng/mL)	24-UCP (μg/24h)
II-DM	Mean	3,4	54,1	95,9
	Min./Max.	0,4 / 34	12,6 / 181	12,9 / 312,6
ID-DM	Mean	1,8	26,3	57,2
	Min./Max.	0,1 / 16,3	0,1 / 140	0,2 / 442,8
No DM	Mean	1,8	64,9	81,8
	Min./Max.	0,4 / 56	15,2 / 181	12,9 / 235,3
Total	Mean	2.7	37,1	69,2
	Min./Max.	0,1 / 56	0,1 / 140	0,2 / 442,8

Insulin treated patients titrated to HbA_{1c} target require insulin dose titration every 39 days on average to maintain glucose control

A.S. Rhinehart, J. Clarke, R. Booth;
Glytec, Waltham, USA.

Background and aims: Effective management of insulin dosing has traditionally proven to be complex and highly individualized. Therapeutic inertia by both providers and patients results in prolonged treatment with non-insulin therapies and presentation of beta cell inadequacy before initiating or intensifying insulin. Standard methods for manual titration of insulin typically follow a one-size fits all approach, with a weight-based or fixed unit starting dose, that increases a fixed amount at set time intervals. It is also unclear as to how frequently patients need dose titrations to sustain improvements in HbA1c or whether conditions, such as the resolution of hyperglycemia-induced oxidative stress, impact a patient's insulin dose after glucose control is achieved. The typical practice is to see a patient back for follow-up every 3-6 months once A1c is controlled. Glucommander is a FDA-cleared and CE marked, integrated, and personalized diabetes therapy management software intended to assist healthcare providers with subcutaneous insulin dose titration by analyzing blood glucose data and calculating patient-specific insulin recommendations for basal, mealtime, and correction doses. Prior studies have demonstrated that Glucommander can assist providers in helping patients safely and effectively achieve their target HbA1c. In one study, 42 patients were titrated to their glucose target range in an average of 11 days and sustained a 2.6% HbA1c improvement over 6 months. Another study of 41 patients showed a 2.7% HbA1c improvement at 3 months. A literature review identified limited evidence to help guide providers in regards to how frequently to review glucoses and titrate insulin after a patient has achieved glucose control. Once patients achieve their target glucose range, Glucommander recommends an increased time interval between interventions with continued remote monitoring with the use of integrated cellular and Bluetooth enabled blood glucose meter partners. The intention of our study was to fill a perceived research gap in regard to insulin titration intervals once a patient has achieved their target HbA1c.
Materials and methods: This retrospective study evaluated 71 patients with both type 1 and type 2 diabetes mellitus, who had their insulin doses adjusted by a healthcare professional who used Glucommander Outpatient to analyze blood glucose data and calculate each dose titration. Patients were on either basal insulin only, or basal and nutritional insulin. We then calculated the average number of days between dose titrations in those patients who reached their A1c target and were followed on Glucommander for greater than 12 weeks.
Results: Patients were managed with Glucommander guided insulin titration for an average of 39 weeks. The average time to achieve target glucose was 12 days; average HbA1c improvement at 12 weeks was 2.6%. After the first three months of treatment, the basal insulin dose was adjusted an average of every 39 days and a nutritional bolus adjustment was made an average of every 38 days.
Conclusion: The current practice of 3-6 month follow-up of a patient after achieving glucose control is insufficient to maintain that control and may put a patient at risk for hypo or hyperglycemia. Our study would suggest that remote glucose monitoring accompanied by insulin titration every 4-6 weeks is ideal in order to maintain adequate glucose control.

Insulin dependency with and without glucagon: marked difference in insulin requirement between patients with total pancreatectomy and type 1 diabetes

Y. Hiromine[1], S. Noso[1], N. Babaya[1], H. Ito[1], F. Niwano[1], I. Matsumoto[2], Y. Takeyama[2], Y. Kawabata[1], H. Ikegami[1];
[1]Department of Endocrinology, Metabolism and Diabetes, Kindai University Faculty of Medicine, Osaka-sayama, [2]Department of Surgery, Kindai University Faculty of Medicine, Osaka-sayama, Japan.

Background and aims: Patients with total pancreatectomy are completely deprived of not only insulin, but also glucagon. Type 1 diabetes mellitus is also completely deprived of insulin, but glucagon is preserved. Patients with total pancreatectomy and type 1 diabetes are thus similar in absolute insulin deficiency, but different in glucagon, providing unique opportunity to study the contribution of glucagon on glucose metabolism in insulin-dependent state. To investigate the contribution of glucagon on energy metabolism in complete absence of insulin in vivo, insulin requirement and metabolic profiles in patients with total pancreatectomy was studied in comparison with those in type 1 diabetes.
Materials and methods: Subjects studied were 28 individuals with type 1 diabetes and 10 individuals with total pancreatectomy. All individuals were completely deficient in endogenous insulin (fasting CPR < 0.0066 nmol/L) and were hospitalized to optimize their glycemic control with insulin pump. Total, basal and bolus insulin requirements as well as time-

to-time pattern of basal insulin infusion rate were compared between total pancreatectomy and type 1 diabetes.
Results: Insulin requirement in patients with total pancreatectomy were markedly smaller in total daily dose (21.9 vs 35.9 units/day, P=0.003), basal insulin (3.7 vs. 11.4 units/day, P=0.00001) and proportion of basal insulin to total daily dose (16% vs. 33%, P=0.00003) than in type 1 diabetes. In contrast, bolus insulin requirement was comparable between the two groups. Dawn phenomenon as assessed by the difference between the maximum and the minimum insulin infusion rate during night was less remarkable in total pancreatectomy than in type 1 diabetes (P=0.001). Fasting plasma glucagon concentration was markedly lower in total pancreatectomy than in type1 diabetes (P=0.00007), and was positively correlated with basal insulin requirement (P=0.038).
Conclusion: These data indicated marked difference in basal insulin requirement between total pancreatectomy and type 1 diabetes, suggesting the contribution of glucagon to basal insulin requirement and dawn phenomenon.

Efficacy of sensor-augmented insulin pump with predictive low glucose suspension: a multicentre clinical experience in adults and children in Spain

P. Beato-Víbora[1], L. Lázaro-Martín[1], C. Quirós[2], M. Martín-Frías[3], R. Barrio-Castellanos[3], E. Gil-Poch[4], F. Arroyo-Díez[4], M. Giménez[2];
[1]Department of Endocrinology, Badajoz University Hospital, Badajoz, [2]Diabetes Unit, Hospital Clinic i Universitari., Barcelona, [3]Paediatric Diabetes Unit., Ramón y Cajal Hospital, Madrid, [4]Department of Paediatrics, Badajoz University Hospital, Badajoz, Spain.

Background and aims: A sensor-augmented pump with predictive low glucose suspend function (SAP-PLGS), the Medtronic MiniMed 640G®, has been commercially available in Europe since May 2015. The aim of the study was to analyse the effect of SAP-PLGS on glycaemic control in real-life clinical practice in adult and paediatric patients in 4 Paediatric and Diabetes Department at 3 referral hospitals in Spain.
Materials and methods: A retrospective evaluation of all the type 1 diabetes patients treated with SAP-PLGS was performed. Baseline HbA1c and HbA1c at 3, 6, 12 and 18 months were analysed.
Results: 170 patients were included, age: 32 ± 16 years, 48 (28%) patients < 18 years-old, 60% female, diabetes duration: 19 ± 13 years, median time on SAP-PLGS: 6 months [3-12]. 145 patients had at least 3 months of follow-up. Main indication for SAP-PLGS were problematic hypoglycaemia and/or hypoglycaemia unawareness (57%, n = 96), poor glycaemic control (18%, n = 31), high glycaemic variability (14%, n = 23), pregnancy planning (4%, n = 6) and need to improve quality of life (8%, n = 14). 28% (n = 48) of the patients had a previous history of severe hypoglycaemia. Previous treatment is shown in the Table. CSII was funded for all patient, 57 patients (34%) were self-funding the sensors and 113 (66%) were getting reimbursement for them. 7 patients had discontinued SAP-PLGS during follow-up, due to lack of benefit (n = 5), skin reaction (n = 1) and poor compliance (n = 1). In the group of patients with baseline HbA1c > 7% in adults and > 7.5% in children (n = 67), HbA1c was significantly lower than HbA1c before the start of SAP-PLGS at 3 months (7.9 ± 0.6% *vs* 7.5 ± 0.6%, n = 59), 6 months (7.9 ± 0.6% *vs* 7.5 ± 0.6%, n = 53), 12 months (8.2 ± 0.7% *vs* 7.6 ± 0.8%, n = 26) and 18 months (8.3 ± 0.7% *vs* 7.3 ± 0.3%, n = 8), all p = 0.001. Percentage of patients with HbA1c ≤ 7% in adults and ≤ 7.5% in children increased from 45% to 60% at 3 months (n = 45, p = 0.017) and from 57% to 61% at 12 months (n = 57, p = 0.001), without significant differences at 6 months (n = 63) or 18 months (n = 18).
Conclusion: Sensor-augmented insulin pump with predictive low glucose suspension improves glycaemic control in children and adults with type 1 diabetes in a real-world clinical setting.

Treatment prior to SAP-PLGS	n	(%)

Foetal outcomes in pregnancies complicated by type 1 diabetes treated with multiple daily injections of insulin and insulin pumps: a systematic review and meta-analysis

P. Rys[1], A. Ludwig-Galezowska[2], M.T. Malecki[2];
[1]HTA Consulting, Krakow, Poland, [2]Department of Metabolic Diseases, Jagiellonian University, Medical College, Krakow, Poland.

Background and aims: An adequate glycemic control in pregnant women with type 1 diabetes mellitus (T1DM) constitutes the most important part of diabetes management, minimizing the risk of maternal or foetal complications. Apart from pre-pregnancy care and proper patient education, the key role in pregestational diabetes management constitutes the mode of insulin delivery. Randomized clinical trials has shown the advantage of continuous insulin infusion (CSII) over multiple daily injections (MDI) in the general T1DM population in terms of glycemic control and the reduction in severe hypoglycaemic episodes. However, it is not clear whether there are any differences in fetal outcomes in pregnancies complicated by type 1 diabetes (T1DM) that are treated with MDI and those treated with CSII. Therefore we performed a systematic review based on RCTs (randomized controlled trials) and non-RCTs to compare both methods of insulin delivery in pregestational T1DM.
Materials and methods: The systematic search of major medical databases (PubMed, EMBASE, CENTRAL) was performed to identify original papers regardless of their methodology (randomized and observational) and publication type (full text and conference abstract). Studies met the inclusion criteria if they compared CSII vs. MDI in pregnant women with T1DM. The studies were pooled in the meta-analysis to provide the point estimate with 95% confidence intervals as well as heterogeneity and publication bias assessment.
Results: The systematic search retrieved 38 original papers, including 15 conference abstracts. The majority of studies were open label, nonrandomized controlled trials with high risk of selection bias. Overall, the studies reported on 4499 pregnancies complicated by T1DM. Meta-analysis of available studies has shown that CSII and MDI provide similar results with respect to the risk of perinatal mortality (RR = 0.88 [0.52; 1.47]), congenital malformation (RR = 1.19 [0.90; 1.57]) and percentage of caesarian sections (RR = 1.04 [0.94; 1.15]). The risk of any kind of abortion did not differ significantly between the CSII and MDI group (RR = 1.16 [0.92; 1.46]), however, spontaneous

abortions were observed more frequently in the CSII group (RR = 1.54 [1.05, 2.25]), which could be due to reporting bias as women in the MDI group booked later (8-9 vs 6 weeks) to antenatal clinics and therefore early cases probably were detected less often than in patients in the CSII group. In the CSII group, we observed a higher percentage of neonates with birth weight large for gestational age defined as >90th percentile (RR = 1.20 [1.07; 1.35]) as well as percentage of macrosomic births defined as >4000 g (RR = 1.32 [1.05; 1.65). No significant difference between CSII and MDI was noticed for other neonatal complications, including respiratory distress syndrome, hypoglycemia, hyperbilirubinemia, shoulder dystocia and ICU admissions. No evidence of publication bias was observed.

Conclusion: In conclusion, the use of CSII in pregestational T1DM compared to MDI may increase the risk of macrosomia, but not other fetal complications.

Disclosure: **P. Rys:** None.

A quality improvement project to reduce the prevalence of insulin omissions among adults with diabetes admitted to a Hospital NHS Trust

V. Oguntolu, F. Jozsa, M. Morgan, S. Wijetunge;
Medway Hospital NHS Trust, Gillingham, UK.

Background and aims: Data from the national diabetes in-patient audit from 2016 reported that insulin errors are observed in 46% (nearly half) of adults patients treated with insulin. The national patient's safety agency issued a patient safety alert in 2011 following a review of patient safety incidents involving insulin over a six years period. Six deaths and 12 incidents resulting in severe harm were reported. 20% were due to drug omission particularly insulin. Inappropriate insulin omission in in-patients can result in serious harm. Insulin should never be stopped due to the risk of complications such as DKA and prolonged in-patient stay. The latest report from the NADIA 2016, showed that in England and Wales, the prevalence of insulin errors is high, we observed similar trend. The aims of our project are to review the prevalence of insulin omission among diabetes patients in our local hospital and to introduce measures to reduce the incidence by 50%.

Materials and methods: This is a 2-phase project, in the first phase; we retrospectively reviewed patient's case-files for all insulin-treated diabetic patients on 4 wards over 3 weeks for baseline data's. In the second phase, we introduced quality improvement pathways aim at reducing insulin omission; this was followed by prospective data collection similar to the first phase. The pathways are: coloured posters on the ward and drugs trolleys informing nursing staffs about insulin omission and implementation of a novel clinical reporting pathway on insulin errors. Data was also collected from a separate medical ward as a control. Result were analysed and the data was compared to control data.

Results: The prevalence of insulin omission on our wards was around 40%, p 0.001, similar to national average. Following quality improvement measures there was a statistically significant 81% decrease in insulin omissions p 0.0001. The control ward showed no statistically significant change in insulin omissions. p 0.117

Conclusion: Insulin omission is national safety issue that could result in serious harm to patients. The most common reason for insulin omission is the fear of hypoglycaemia. Introducing quality improvement measures in our hospital have shown significant reduction in insulin omission, therefore reducing the risk to patients. Similar quality measure could be adapted to other hospitals. Increasing awareness of the importance of timely insulin administration through pathways such as visual posters and educational reminders is very effective and inexpensive tool for reducing inappropriate insulin omission rates.

Trends in BMI, diabetes and obesity-associated comorbidities after explantation of the Duodenal-Jejunal Bypass Liner

N. Riedel[1], K. Laubner[2], A. Lautenbach[1], P. Gijbels[3], R. Stengel[4], T. Eberl[5], F. Dederichs[6,7], J. Aberle[1], J. Seufert[2];
[1]Department for Endocrinology and Diabetology, University Hospital Hamburg-Eppendorf, Hamburg, [2]Division of Endocrinology and Diabetology, Department of Internal Medicine II, University Hospital of Freiburg, Medical Faculty, Freiburg, [3]Obesity Centre Düsseldorf, St. Martinus-Krankenhaus Düsseldorf, Düsseldorf, [4]Diakonissenanstalt Emmaus, Niesky, [5]Donau-Ries-Klinik, Donauwörth, [6]Department of Internal Medicine/Gastroenterology, Marienhospital Gelsenkirchen, Gelsenkirchen, , [7]Department of Internal Medicine/Gastroenterology, Kath. Kliniken Hagen, Hagen, Germany.

Background and aims: A novel approach for treatment of obesity and diabetes mellitus type 2 (T2DM) is represented by the temporary endoscopic duodenal-jejunal bypass liner (DJBL). Recent data from the German DJBL registry provided evidence for substantial efficacy of the DJBL during the implantation period in obese patients with T2DM. However, little is known about the trends of comorbidities and BMI after explantation of the DJBL, which have been investigated in the registry in this report.

Materials and methods: For this analysis, patients from the registry were selected if they had a data-set at implantation, explantation and at least one time-point after explantation of the DJBL. We analyzed a group of patients with data at at least 11 months after explantation of the DJBL (n = 35).

Results: HbA1c and BMI re-increased after explantation of the DJBL but stayed significantly below the postexplantation visit as compared to baseline. However, a concomitant increase of the mean number of antidiabetic drugs, which were reduced during the implantation period, was observed. There was a deterioration seen for blood pressure, total cholesterol, LDL-cholesterol and number of daily intake of antihypertensive and lipid lowering drugs over the postexplantation period.

Conclusion: With this data we show that improvement of HbA1c and BMI can be maintained over a time of nearly one year postexplantation of the DJBL. However, for HbA1c this may be biased by intensified medical treatment. However, effects deteriorate with time after explantation. These results suggest that implantation of the DJBL needs to be integrated in a long-term weight management program as most of other interventions in obese patients with T2DM.

Clinical Trial Registration Number: EBRD 001

Efficacy, safety, tolerability and sustainability outcomes of endoscopic proximal intestinal exclusion with EndoBarrier: 1st UK NHS EndoBarrier service for diabesity

R.E.J. Ryder[1], M. Yadagiri[1], S.P. Irwin[1], W. Burbridge[1], H. Gandhi[2], R.A. Allden[3], J.P. Bleasdale[4], E.N. Fogden[3], M.R. Anderson[3], P. Sen Gupta[1];
[1]Diabetes, City Hospital, Birmingham, UK, [2]Dietetics, City Hospital, Birmingham, UK, [3]Gastroenterology, City Hospital, [4]Anaesthetics, City Hospital, Birmingham, UK.

Background and aims: Our institution leads a UK, multicentre, randomised controlled trial investigating the interaction of Endobarrier

therapy, a 60cm endoscopically implanted proximal intestinal liner, with glucagon-like peptide-1 drug therapy. Our aim was to evaluate whether acquired experience could translate into establishment of an effective and safe UK National Health Service (NHS) Endobarrier service for type 2 diabetes and obesity.

Materials and methods: i) We initiated the 1st NHS Endobarrier service for patients with suboptimally controlled type 2 diabetes and obesity. ii) We primed patients to maintain improvements after, by instituting behaviour changes during, the period of up to 1 year of Endobarrier. iii) We established a secure online registry to monitor outcomes.

Results: Since service initiation 65/153 (42%) referred have been accepted for treatment. 50 patients have had an Endobarrier implanted. 31 patients (see table) have had Endobarrier removed after treatment with the device. Mean±SD HbA1c fell by 24.7±24.1 mmol/mol from 81.4±23.4 to 56.7±11.6 mmol/mol (p<0.001), weight fell by 15.6±9.2 kg from 120.5 ±28.3 to 104.9±29.4 kg (p< 0.001) and systolic blood pressure from 137.3±13.7 to 124.9±15.8 mmHg (p<0.001). Serum alanine aminotransferase (ALT) reduced from 33.5±20.8 to 18.8±10.7U/L (p<0.001). In the 17 patients on insulin, median (IQR) total daily insulin dose reduced from 100 (40-130) to 30 (0-62) units (p=0.003) with 6/17 (35%) discontinuing insulin. Of 17 patients who have reached the 6 months post Endobarrier, 11/17 (65%) had sustained the substantial improvement achieved with Endobarrier. Of the 6 whose weight and/or HbA1c deteriorated after removal, 5/6 (83.3%) had big depression problems. 2/31 (6.5%) patients had early Endobarrier removal, one for gastrointestinal haemorrhage at 10 weeks having not complied with proton pump inhibitor therapy advice and one due to liver abscess at 7 months. Early removal led to resolution in both cases. All other patients achieved a full year of Endobarrier treatment. 93.8% patients would be extremely likely to recommend this service to friends and family.

Conclusion: This inaugural NHS service demonstrates Endobarrier to be highly effective in patients with refractory diabesity, with high patient satisfaction levels and an acceptable safety profile. After Endobarrier removal, 65% were able to sustain the benefits in HbA1c, weight, insulin dose and reduction in liver fat (as suggested by ALT reduction), and they reported considerable improvements in wellbeing, energy, and exercise ability. As endoscopy units are ubiquitous, our service could be readily disseminated, with the registry useful for on-going monitoring worldwide.

Parameter	Baseline	At Removal	Difference	P value (n=31)
Age (years)	51.3±7.3			
Sex (%male)	58.0			
Ethnicity (%Caucasian)	48			
Diabetes Duration (years)	13.3 (8.0-20.0)			
Taking insulin (%)	54.8			
Weight (Kg)	120.5±28.3	104.9±29.4	-15.6±9.2	<0.001
BMI (Kg/m^2)	41.5±8.7	35.8±8.8	-5.7±3.5	<0.001
HbA1c (mmol/mol)	81.4±23.4	56.7±11.6	-24.7±24.1	<0.001
HbA1c (%)	9.6±2.1	7.3±1.1	-2.3±2.2	<0.001
Systolic Blood Pressure	137.3±13.7	124.9±15.8	-12.4±17.1	<0.001
Total Daily Insulin Dose* [median(IQR), n=17]	100(40-130)	30(0-62)	-70	0.003

Table: Baseline characteristics of the 31 patients who completed treatment with Endobarrier along with outcomes at the time of removal as mean±SD or median(interquartile range [IQR]). P-values reflect change from baseline.
Removal at 1 year in 29/31 (94%) patients, with early removal due to complications in 2/31 (6%) patients.

Performance of a non-invasive glucose monitoring device for people with prediabetes and type 2 diabetes

K. Bahartan[1], A. Gal[1], E. Naidis[1], A. Rozner[1], A. Drexler[2], K. Horman[1], T. Lin[1];
[1]Integrity Applications Ltd., Ashdod, Israel, [2]Division of Endocrinology, Diabetes and Hypertension, David Geffen School of Medicine, Los Angeles, USA.

Background and aims: Tight glycemic control is essential for delaying and even preventing the complications associated with type 2 diabetes mellitus (T2DM). Self-monitoring of glucose levels is a key component for achieving this goal. The positive effect of self-monitoring has also been demonstrated on pre-diabetic subjects whose state has deteriorated to T2DM (i.e., newly diagnosed T2DM individuals). Therefore, it is suggested that people with prediabetes may also benefit from self-monitoring and tight glycemic control. However, a major challenge in diabetes management is increasing the limited compliance with self-monitoring. This may be achieved by adopting a non-invasive approach, which aims to alleviate the pain associated with invasive devices. The present study evaluated the performance of GlucoTrack®, a truly non-invasive glucose monitoring device, in all intended use diabetes populations: people with prediabetes, persons newly diagnosed with type 2 diabetes and individuals with long-duration of type 2 diabetes.

Materials and methods: Device performance was evaluated on 32 subjects, including people with prediabetes (N=7), people with newly diagnosed type 2 diabetes (diabetes duration < 5 years; N=9) and people with long-duration type 2 diabetes (N=16). The accuracy of the device was clinically evaluated using Consensus error grid (EG) analysis and numerically evaluated using mean and median absolute relative difference (ARD) and mean absolute difference (MAD).

Results: Overall, 99.6% of 224 points were in the clinically accepted A and B zones of the Consensus EG. Similar proportions were found in the pre-diabetes, newly diagnosed and long-duration type 2 diabetes (100%, 98.4%, and 100%, respectively; Table 1). Mean ARD, median ARD and MAD results for all tested groups are presented in Table 1.

Conclusion: This study demonstrates high accuracy of GlucoTrack device. Clinical and numerical accuracies were comparable between all groups, indicating that the device is suitable for people with long and short durations of type 2 diabetes as well as prediabetes. Due to its non-invasive nature, the device has the potential to enhance compliance of glucose self-monitoring and improve glycemic control, and therefore reduce diabetes-related complications and in certain cases even prevent the development of diabetes in individuals with prediabetes.

Table 1: study results for all tested groups

	Consensus Error Grid			Mean ARD	Median	MAD
	A+B	A	B	(%)	ARD (%)	(mg/dL)
Pre-diabetes	100	93.9	6.1	18.3	13.9	20.5
Newly diagnosed diabetes (up to 5 years)	98.4	92.1	6.3	16.4	14.0	22.8
Long duration diabetes (over 5 years)	100	92.9	7.1	16.6	12.7	25.3

Clinical Trial Registration Number: NCT00889668

A prospective pragmatic clinical trial in type 2 diabetes to compare the V-Go insulin delivery device with standard treatment optimisation

M. Cziraky[1], S. Abbott[2], M. Nguyen[2], P. Strange[3], T. Wasser[1], L. Nowalk[1], K. Larholt[1];
[1]HealthCore, Wilmington, [2]Valeritas, Bridgewater, [3]IMD, Princeton Junction, USA.

Background and aims: This prospective multicenter clinical study was conducted in a real world community-based practice setting. The study objective was to evaluate patients treated with the V-Go insulin delivery device compared to standard treatment optimization control (STO).

Materials and methods: The trial utilized cluster randomization where study sites rather than individual patients were randomized to V-Go or STO. Patients in the United States with type 2 diabetes taking insulin were enrolled and treated according to routine practice by their healthcare provider for up to 4 months. Patients initializing V-Go stopped using other insulin delivery devices while insulin and other diabetes treatments were continued and optimized in control patients. All treatments, medications and supplies were obtained by usual care utilizing patient insurance. The primary outcome was the difference in the change in A1C from baseline to end of study (EOS).

Results: The analysis population included 415 patients, 246 STO and 169 V-Go across 52 sites. Mean age was 59.8 years and weight was 220.7 lbs (100.1 kg). The study population was 62.4% Caucasian and 25.8% African American. The baseline A1C ranged from 7.9 to 14.2%. Nearly all patients (96.4%) had at least one comorbid condition. There were significant A1C decreases from baseline with V-Go (-0.95%, p<0.001) and STO (-0.46%, p<0.001) and for V-Go vs. STO (p<0.002) despite a significant reduction (p<0.001) in mean total daily insulin dose (TDD) with V-Go. V-Go baseline TDD was 71.3 U/Day (0.76 U/Kg) which decreased to 54.03 U/Day (0.57 U/Kg) at EOS. STO baseline TDD was 72.2 U/Day (0.72 U/Kg) which was unchanged at EOS (71.8 U/Day; 0.72 U/Kg). Baseline A1C was higher for V-Go vs. STO (9.88% vs. 9.34%; p<0.001) indicating a possible selection bias by study investigators randomized to the V-Go group of more advanced diabetes patients initiating V-Go given the a priori randomization of treatment sites. The figure describes the relationship between insulin dose (U/Day) and A1C response. Data were analyzed using a mixed model with site as a random effect. Treatment groups are presented by decile boundaries. The distribution graph shows the higher baseline A1C in the V-Go group compared to SOC at similar insulin doses. SOC had minor change in A1C with minimal change in TDD; V-Go had a resultant shift to lower A1Cs and TDD with the lower A1C deciles nearing guideline A1C goals at a modest TDD.

Conclusion: This prospective pragmatic clinical trial provides evidence of increased glycemic control coupled with decreased total insulin requirements in type 2 diabetes patients initiating V-Go.

Equivalent efficacy of intensive self-monitoring of blood glucose to real time continuous glucose monitoring in adults with type 2 diabetes

Y. Takano[1], Y. Namiki[1], H. Sasaki[1], Y. Murohashi[2], H. Takamine[1], K. Inazumi[1], U.N. Osada[1];
[1]Saiseikai Yokohamashi Nanbu Hospital, [2]Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Background and aims: Self-monitoring of blood glucose (SMBG) improves patients' adherence and glycemic control in diabetes. Use of real time continuous glucose monitoring (RT-CGM) in combination with SMBG brings even better glycemic control than SMBG alone. However, effectiveness of RT-CGM compared with more intensive SMBG is not clear. The aim of this study is to analyze the effectiveness of RT-CGM, retrospective CGM and, intensive SMBG in adults with type 2 diabetes.

Materials and methods: This is the interim analysis of the investigator-initiated randomized, open-labelled clinical trial. Patients were type 2 diabetes adults admitted to our hospital from August 1, 2016 to March 2, 2017. Patients of age over 85 years, pregnant, admission less than 1 week, or emergency hospitalization were excluded. Patients were randomized to SMBG with RT-CGM using the Medtronic MiniMed 620G, SMBG with retrospective CGM using Medtronic iPro2®, or SMBG alone. Randomization was performed by computer generated number according to predefined block size. Both CGMs were worn for the maximum period of 6 days. SMBG was done 6 times a day at every pre-meal and 2 hours post-meal. Primary outcome was the change in HbA1c from baseline to 12weeks. As the secondary outcomes, change in mean glucose level from the day of admission to discharge day, and frequency of in-hospital hypoglycemia (glucose level<70mg/dl from SMBG data) were evaluated. We also evaluated patients' satisfaction to treatment using Diabetes Treatment Satisfaction Questionnaire (DTSQ), Problem Area in Diabetes Survey (PAID).

Results: Fifty-seven patients were enrolled and 16 patients were allocated to RT-CGM group, 11 to retrospective CGM group, and 30 to SMBG group. Among these 57 patients, 35 (61.4%) were male, mean age was 65.8±10.8 years, diabetes duration was 7.7±7.6 years, BMI was 26.0±5.2 kg/m^2, and HbA1c was 9.1±1.9%. Overall, glycemic control was improved after treatment for both HbA1c and the mean glucose level; HbA1c from 9.1±1.9% to 6.8±1.1%, mean glucose level from 191 ±63mg/dl to 135±19mg/dl. However, the changes were not significantly different between the groups. (Table1) As the safety profile, hypoglycemia was rarely seen during hospitalization with no difference in frequency between the groups (P=0.54). There were no differences in patients' satisfaction to treatment assessed by DTSQ, PAID at hospital discharge date, either.

Conclusion: Among adults with type 2 diabetes, intensive SMBG may have the equivalent effect to RT-CGM and retrospective CGM.

(Table1)

Insulin treatment and glucose patterns of 29,673 patients with diabetes using a tubeless insulin pump system and a cloud-based data management system

J.E. Layne, J. He, Y. Zheng, T.T. Ly;
Insulet Corporation, Billerica, USA.

Background and aims: Use of data management systems (DMS) by patients with diabetes can provide valuable insights for clinicians and patients to guide treatment decisions; however, there is little real world data surrounding their use. This study characterized blood glucose (BG) profiles and self-management patterns of a large cohort of patients with diabetes treated with a tubeless insulin pump using a cloud-based and mobile diabetes DMS.

Materials and methods: Anonymized data from patients with diabetes treated with a tubeless insulin pump and ≥3 mo data downloaded from their personal diabetes manager (PDM) to the DMS were analyzed. Analyses were also performed for subsets of patients with CGM use >15 days and with self-reported, de-identified demographic profiles. Variables included mean BG, percent time <70 mg/dL, total daily dose (TDD) of insulin, basal/bolus ratios, frequency of fingerstick BG testing,

percentage using advanced pump features >1x/mo and estimated A1c. Mean sensor glucose and percentage time 70-180 and >180 mg/dL over 24-hr and overnight (20:00 to 8:00) were also examined for CGM users.
Results: Data were available for 29,673 patients from January 2015 through February 2017. The mean±SD BG was 185.8±40.6 mg/dL, time <70 mg/dL 9.0%±11.0, TDD 43.2±21.6 U/d, 53% basal delivery, BG testing 4.2±2.4 x/d, 34.7% advanced pump feature use and estimated A1c 8.1%. Glycemic profiles for CGM users overall (n=2,509, 8.4%) and subsets of CGM patients stratified by age group are presented in the Table. CGM users reported BG testing 4.6±2.5 x/d and 63.8% used advanced pump features. Estimated mean A1c was 7.8%, 7.6% and 7.1% for pediatric, adolescent and adult CGM users, respectively. The type 1 diabetes cohort with self-reported demographic data (n= 4,239, 14.3%) included 25% pediatric, 18% adolescent and 57% adult patients. Overall the type 1 diabetes cohort was age 28.0±18.6 yr, 55% female, mean BG 184.3±39.6, TDD 38.9±19.3 U/d, 50.1% basal delivery, BG testing 4.8 ±2.4 x/d, 42.9% advanced feature use, estimated A1c 8.0%, with insulin pump and DMS use of 28.0 and 11.7 mo, respectively. Patients with type 2 diabetes (n=393) were age 56.8±10.9 yr, 46% female, mean BG 173.3 ±40.5, TDD 57.4±25.4 U/d with 59.8% basal delivery, blood glucose testing 3.4±1.4 x/d, 21.9% advanced feature use, estimated A1c 7.7%, with insulin pump and DMS use of 22.0 and 12.8 mo.
Conclusion: These real world data characterizing a large cohort of patients with diabetes provide insight to self-management patterns and glycemic profiles with current technology use. For patients with type 1 and type 2 diabetes across all age groups the use of a tubeless insulin pump and a cloud-based DMS with or without CGM use was associated with frequent fingerstick BG testing and a high prevalence of advanced insulin pump feature use. The mean BG levels in the cohort overall compared favorably to U.S. national averages with the lowest BG levels observed in the subset of patients using CGM.

Table. Glycemic Profile of the CGM Cohort

	Total (n=2,504)	Pediatric 0 to <13 yr (n=192)	Adolescent 13 to <18 yr (n=83)	Adult ≥18 yr (n=481)
Age, yr	33.4±19.8	8.3±2.7	14.1±1.2	42.7±13.6
TDD insulin, U/d	38.7±19.6	22.8±12.4	43.0±16.2	40.9±19.7
Basal insulin, U/d (%)	19.3±10.9 (50)	9.9±5.7 (43)	19.8±8.6 (46)	21.1±11.0 (52)
Bolus insulin, U/d (%)	19.4±11.7 (50)	13.0±7.5 (57)	23.3±10.0 (54)	19.8±11.2 (48)
Sensor BG, mg/dL	163.5±30.6	177.8±27.7	171.4±29.5	157.1±30.3
Time 70-180 mg/dL, % (24-hr)	61.6±16.5	53.8±13.8	58.3±16.2	64.8±16.6
Time <70 mg/dL, % (24-hr)	3.9±3.9	3.1±3.2	2.5±2.5	4.4±4.1
Time >180 mg/dL, % (24-hr)	33.9±11.9	39.9±11.5	38.0±10.7	31.6±11.6
Time 70-180 mg/dL, % (20:00-8:00)	60.9±17.2	53.7±15.0	58.5±17.1	63.2±18.1
Time >180 mg/dL, % (20:00-8:00)	35.3±18.6	43.5±16.7	39.0±18.2	32.4±19.4

706

Frequency of blood glucose monitoring and glycaemic outcomes with adoption of Continuous Glucose Monitoring (CGM)

T.C. Walker[1], T.D. Riddlesworth[2], D. Price[1];
[1]Dexcom, Inc., San Diego, [2]Jaeb Center for Health Research, Tampa, USA.

Background and aims: Diabetes treatment-related decisions, such as determining an insulin dose, have historically relied on self-monitored blood glucose (SMBG) results. Due to improved accuracy, one CGM system is now indicated (CE Mark and FDA approval) for non-adjunctive use – it can replace SMBG measurements for routine diabetes management decisions. Numerous studies have associated CGM use with reductions in both hypoglycemia and HbA1c. In six of these studies (Table), SMBG frequency was found to decrease with CGM use. However, none of the studies reported the association of SMBG reduction and glycemic benefit or risk. We examined the relationship between the extent of SMBG frequency reductions and glycemic outcomes in the DIaMonD Study.
Materials and methods: The DIaMonD randomized controlled trial introduced CGM to subjects who were using multiple daily injections. In this group, there were 175 subjects (99 with T1D, 76 with T2D) for whom SMBG meter data were available at baseline and followup. Data from this study were retrospectively analyzed to relate reductions in SMBG testing frequency and changes in HbA1c. We compared HbA1c changes observed with larger vs. smaller reductions in SMBG frequency using an analysis of covariance model adjusted for baseline HbA1c and clinical site as a random effect.
Results: Subjects' mean±SD baseline HbA1c was 8.6±0.6% and age was 52±14 years. Baseline SMBG frequency was 4.7±1.6/day and decreased to 3.3±1.5/day at week 24, a 30% reduction. Mean HbA1c reduction from baseline was similar in the 75 subjects who reduced their SBMG frequency by >1 test/day compared to the 100 subjects who reduced it by ≤1 test/day (-0.9 percentage points in both groups; p=0.36). Further, when comparing subjects in the top quartile of SMBG reduction (mean decrease of at least 2.2 tests/day; n=43) to subjects in the lowest quartile of SMBG reduction (mean decrease of no more than 0.4 tests/day; n=43), mean HbA1c reduction was similar (-0.9 percentage points in both groups; p=0.56). Findings were similar in participants with T1D and T2D (p=0.39). There was only 1 severe hypoglycemic event in each SMBG group (SMBG reduction of >1 and ≤1 test/day).
Conclusion: These data demonstrate that reduction of SMBG frequency with CGM use does not impact glycemic control, suggesting that nonadjunctive use of CGM does not diminish the safety and effectiveness of CGM.

Efficacy and safety of an insulin decision support system in the treatment of steroid hyperglycaemia in patients with graft-versus-host-disease: a randomised pilot trial

F. Aberer[1], J. Holzgruber[1], N.J. Tripolt[1], A. Zebisch[2], H. Greinix[2], H. Sill[2], J.K. Mader[1], T.R. Pieber[1], A. Wölfler[1], H. Sourij[1];
[1]Endocrinology and Diabetology, Medical University of Graz, [2]Haematology, Medical University of Graz, Graz, Austria.

Background and aims: Graft-versus-host-disease (GvHD) is a common and life-threatening complication in patients undergoing allogeneic stem cell transplantation. Since high-dose systemic glucocorticoids are the established first-line therapy, about half of these patients develop steroid-induced hyperglycaemia, which has been associated with adverse outcome in this patient population. Adequate glucose control in these patients proved to be challenging. Over the last decades, decision support systems (DSS) were developed to standardise and facilitate insulin treatment for patients during hospitalisation. To date, there is still only sparse data available on the performance of decision support systems in patients with steroid-induced hyperglycaemia. We aimed to investigate whether glucose control with an electronic algorithm-based decision support system for insulin therapy (GlucoTab®) is effective and safe in this patient group.

Materials and methods: We randomly assigned 10 patients with acute GvHD and hyperglycaemia (2 independent fasting glucose values >7.8 mmol/L) while receiving corticosteroid therapy to either an electronic algorithm-based decision support system (GlucoTab®, GT) or conventional treatment (CON) according to local standards. Glycaemic control was assessed by frequent capillary blood glucose (BG) measurements during hospital stay. Follow-up period was 6 months.
Results: Mean total daily insulin dose was 36.8 ± 28.0 U (GT) vs 11.6 ± 12.0 U (CON). Mean daily prednisolone or equivalent dose was 74.1 ± 44.3 mg (GT) vs. 95.2 ± 65.3 mg (CON). The percentage of glucose values within the target range (3.9-10.0 mmol/L) was 68.2% for GT vs. 64.2% for CON. Numbers of hypoglycaemic events (BG <3.9 mmol/l) were 3 (GT) and 30 (CON) (p=0.026), respectively.
Conclusion: Insulin treatment guided by GlucoTab® was effective and safe in GvHD patients with steroid induced hyperglycaemia during hospital stay. As compared to standard care, the DSS based regimen showed a higher percentage of values in target range and was associated with lower hypoglycaemia rates. Further optimisation of the algorithm for high-dose steroid treatment is about to be processed. To explore whether good glycaemic control might also improve patients' outcome, larger studies are needed in this Population.

Carbohydrate-to-insulin ratio: a major factor that could influence daytime glucose control of a hybrid closed-loop system

A. Roy[1], B. Grosman[1], N. Parikh[1], D. Wu[1], S.W. Lee[2], F.R. Kaufman[2]; [1]IIM - R&D, Medtronic Diabetes, [2]Clinical, Medtronic Diabetes, Northridge, USA.

Background and aims: The MiniMed™ 670G hybrid closed-loop (HCL) system was designed to automatically adjust basal insulin delivery every 5 minutes based on sensor glucose (SG) values and insulin delivery history. The system includes the MiniMed 670G pump, Guardian® Sensor 3, and a proprietary control algorithm. During the HCL pivotal trial, subjects needed to calibrate the sensor, notify the system of exercise, and enter mealtime carbohydrate estimates in order to deliver meal-boluses. The HCL pivotal trial data was analyzed to study the effect of a more aggressive carbohydrate-to-insulin (CHO:I) ratio (i.e., more insulin for a given carbohydrate estimate) on daytime glucose control during the study period.
Materials and methods: A ten-center pivotal trial was conducted with 124 type 1 diabetes patients. The study protocol consisted of a 2-week Manual Mode (run-in phase) followed by a 3-month in-home Auto Mode (study phase) of HCL control. Percentage of daily insulin administered as meal bolus (which is a reliable indicator of the aggressiveness of meal bolus) and SG data during the daytime period (6:00am-11:59pm) was analyzed.
Results: The figure represents the daytime mean SG value with respect to the percentage of daily insulin administered as meal bolus, during the study period. A Pearson's correlation coefficient shows a significant (p<0.001) inverse correlation between daytime mean SG value and percentage of daily insulin administered as meal bolus (R=−0.5), thus demonstrating a higher daily percentage of meal bolus due to the more aggressive CHO:I ratio resulting in lowered daytime mean SG values.
Conclusion: The post-hoc analysis of subjects in the HCL pivotal trial demonstrates a significant effect of a more aggressive CHO:I ratio on automatic insulin delivery that impacts overall daytime glucose values. Overall, the 670G system was safe for unsupervised at-home use by adults and adolescents. Additionally, the system resulted in a significant decrease in HbA1C levels, especially when the initial HbA1C at baseline was >7.0%.

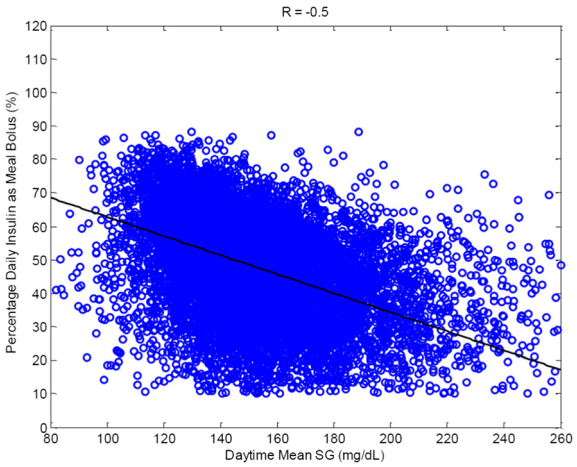

Figure: The x-axis represents daytime mean sensor glucose values and the y-axis represents percentage of daily insulin administered as meal bolus. The blue circles represent each day in the study period for all the 124 subjects. The black solid line is a linear fit of the data.

Determining duration of closed-loop studies: evidence from a randomised day-and-night three month trial

L. Leelarathna[1], H. Thabit[2], M.E. Willinska[2], S. Dellweg[3], J.K. Mader[4], S. Hartnell[5], C. Benesch[3], M. Holzer[4], H. Kojzar[4], M.L. Evans[2], S. Arnolds[3], T. Pieber[4], R. Hovorka[2], On behalf of AP@home consortium; [1]Manchester Diabetes Centre, University of Manchester, Manchester, [2]Wellcome Trust-MRC Institute of Metabolic Science, University of Cambridge, Cambridge, UK, [3]Profil, Neuss, Germany, [4]Division of Endocrinology and Metabolism, Department of Internal Medicine, Medical University of Graz, Graz, Austria, [5]Department of Diabetes and Endocrinology, Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK.

Background and aims: Randomised clinical trials of closed-loop insulin delivery have ranged from a single day to 3 months. The time required by closed-loop systems to achieve stable glucose control including behavioural adaptation to take place is currently unknown. We addressed this aspect by comparing outcomes after 1 week, 4 weeks, and 12 weeks (reference) of day-and-night closed-loop insulin delivery.
Materials and methods: Analysis was performed retrospectively on data from an open-label, three-centre, multi-national randomised two-period crossover day-and-night hybrid closed-loop study. Thirty-three adults with type 1 diabetes on insulin pump therapy (age 40.0±9.4years, duration of diabetes 20.9±9.3years, baseline HbA1c 8.5±0.7%, duration of pump therapy 7.8±5.9years) were recruited and underwent automated hybrid closed-loop for 12 weeks within a randomised clinical trial. Sensor-based glucose outcomes during closed-loop intervention after 1 week and 4 weeks were compared with outcomes after 12 weeks using paired samples T-tests or Wilcoxon signed rank tests.
Results: Compared with 12 weeks, there was no difference in time spent hypoglycaemia <3.9 mM at 1 and 4 weeks (Table). In contrast, a small increase in time spent <3.0 mM was noted between 4 and 12. Nadir of mean glucose and time spent >10mM were shown at 1 week, whilst modest increase noted at 4 and 12 weeks. Total daily insulin and time in target were not statistically different between time points.
Conclusion: Glucose control settles rapidly after start of closed-loop, with comparable outcomes at 1, 4 and 12 weeks. An increase in mean glucose and time spent >10mM of borderline clinical significance was

present at 12 weeks compared to 1 and 4 weeks. A trend towards more time spent hypoglycaemia <3.0mM at 12 weeks was observed although absolute percentages were low. We conclude that closed-loop trials of 4 weeks may be sufficient to provide representative data for majority of glucose outcomes, but assessment of time spent hypoglycaemia <3.0mM may warrant longer trial duration. System use over longer periods may change which warrants longer studies to take place.

Table: Closed-loop performance over 12 weeks (reference) versus 1 week, and 12 weeks (reference) versus 4 weeks

	12 weeks	1 week	P Value[1]	4 weeks	P Value[2]
Percentage of time with sensor glucose					
3.9 to 10mM	67.7±9.2	69.6±11.6	0.091	68.6±11.6	0.078
>10mM	29.2±11.4	27.0±12.4	0.050	28.4±11.6	0.12
<3.9mM	2.9 (1.4, 4.5)	2.9(1.4, 4.9)	0.64	2.5(1.5, 4.6)	0.64
<3.0mM	0.4 (0.1, 1.0)	0.2 (0, 1)	0.33	0.2 (0.1, 0.8)	0.04
Mean glucose (mM)	8.7± 1.1	8.5±1.1	0.014	8.6±7.6	0.059
Total daily basal Insulin (U/day)	48.8±16.1	47.3±16.2	0.091	47.9±15.6	0.219

FreeStyle Libre use for self-management of diabetes in children and adolescents

F. Campbell[1], O. Kordonouri[2], N. Murphy[3], C. Stewart[4];
[1]Leeds Children's Hospital, Leeds, UK, [2]Childrens Hospital Auf der Bult, Hannover, Germany, [3]Chilren's University Hospital, Dublin, Ireland, [4]Antrim Area Hospital, Antrim, UK.

Background and aims: The impact of using the FreeStyle Libre™ Flash Glucose Monitoring System has been reported in adults with diabetes. This study aimed to evaluate the use of FreeStyle Libre as a replacement for self-monitoring of blood glucose (SMBG) in young people (4-17 years) with type 1 diabetes (T1D).
Materials and methods: Patients (n=76, 58% CSII users, 46% males) enrolled in a 10 week single arm European study (UK, Ireland and Germany) and underwent 2 weeks baseline masked (blinded) wear, followed by 8 weeks open use according to labelling. The primary endpoint was non-inferiority of glycaemic control assessed using time in range. Patients were aged 10.3±4.0 years (mean±SD) with baseline HbA1c 62.9±11.1 mmol/mol (7.9 ±1.0%), T1D duration 5.4±3.7 years and self-reported SMBG tests 7.3±2.7/day.
Results: Time in range (3.9-10.0 mmol/L) significantly improved vs. baseline by 1.0±2.8 hours/day (mean±SD), p=0.0056. HbA1c significantly improved vs. baseline, -4.4±5.9 mmol/mol (-0.4±0.6%), p<0.0001. Time in hyperglycaemia (>10.0 mmol/L) significantly reduced vs. baseline by -1.2±3.3 hours/day, p=0.0038, while no statistically significant changes were observed for time in hypoglycaemia (time <3.9 mmol/L, baseline, 1.1±1.2 hours/day). Total daily insulin dose increased by 1.4 ±3.5 units (p=0.0010). Scan frequency of FreeStyle Libre was on average 12.9 times daily, whereas SMBG tests dropped from a median of 8.0 (baseline) to 1.0 per day during open use. Diabetes Treatment Satisfaction Questionnaire showed increased overall treatment satisfaction for parents (n=70), 21.7±6.6 (mean change score±SD), p<0.0001 and teens (13+years) (n=23), 18.7±5.6, p<0.0001. Occurrences of mild or moderate sensor insertion site symptoms were as expected with device use (96 from 42 patients). Three device-related adverse events (AEs), all mild (dry collection, dry flaky skin and redness) were reported by 3 patients. There were no device-related serious AEs.
Conclusion: Use of FreeStyle Libre as a replacement for SMBG by children and adolescents with T1D improved glycaemic control, reduced HbA1c with no change in hypoglycaemia and enhanced treatment satisfaction.

Intermittent scanned glucose (FGM) in pediatrics with typ 1 diabetes: correlation with traditional metabolic control parameters, a multicentre DPV analysis of 476 patients

T. Biester[1], J. Hermann[2], B. Heidtmann[3], B. Rami-Merhar[4], U. Ermer[5], J. Wolf[6], M. Freff[7], B. Karges[8], D. Agena[9], T. Danne[1], R. Holl[2], DPV Study Group;
[1]Diabetes-Center for Children and Adolescents, auf der Bult, Hannover, [2]Institute for Epidemiology und Medical Biometry, University Ulm, Ulm, [3]Catholic Children's Hospital Wilhelmstift, Hamburg, Germany, [4]Department of Pediatrics, Medical University, Vienna, Austria, [5]Pediatric Department, St. Elisabeth Clinic, Neuburg/Donau, [6]Pediatric Department, St.-Vincenz Hospital, Paderborn, [7]Princess Margaret Clinics for Children, Darmstadt, [8]Pediatric Department, Bethlehem Health Center, Stolberg, [9]Pediatric Practice, Hildesheim, Germany.

Background and aims: The method of flash glucose monitoring (FGM) is a novel alternative to finger-prick blood glucose measurements (SMBG).Current FGM devices provide actual glucose values, trend arrows and a retrospective continuous curve of interstitial glucose during the last 8 hours. Combining anonymized profiles with registry data allows real-world analysis of the impact of this new technology in pediatric patients, an age-group characterized by instable glucose values.
Materials and methods: The DPV-Register ("Diabetes-Patienten-Verlaufsdokumentation"),a longitudinal surveillance of patients in Austria, Switzerland, Luxemburg and Germany since 1995, has implemented a method to upload glucose profiles from real-time CGM and FGM devices.In this cross-sectional analysis, FGM data are compared to traditional parameters of glycemic control. Until March 20 2017, we documented flash glucose profiles from 476 patients with T1DM (74,517 total days, 134.9 days per patient). Median age of patients was 12.1 years (Q1-Q3: 8.8 - 14.9),duration of Diabetes 3.4 years, 54.0 % male, 67.2 % with insulin pump therapy (CSII)
Results: Median glucose value was 176.5 mg/dl (9.8 mmol/L). Time in range: 50.9% of individual glucose values were in-between 70 and 180 mg/dl (3.9 and 10 mmol/L), 2.2% <54, 6.2 % < 70, 42.9 % > 180 (<3.0, <3.9, >10). In 20.9 % of the documented time, interval glucose was > 250 mg/dl (> 13.9 mmol/L),in 3.1 % of the time even above 400 mg/dl (22.2 mmol/L).The estimated HbA1c from these profiles was 7.8%, the corresponding median from blood based measurement 7.1 % (Spearman-correlation: r=0.66). n=320 of these patients were on insulin pump therapy, n=156 had MDI. Median Glucose was similar in patients with CSII or MDI (176mg/dl - 9.8 mmol/L vs. 179 mg/dl - 9.9 mmol/L p=0.92 ; Time in Range 50.7% vs. 51.3%, p=0.87). During adolescence (age >= 12 years, n= 245) FGM profiles demonstrated significantly worse glucose control: median glucose 183.4 versus 171.6 mg/dL, time-in-range 47.2 % versus 54.6%.No significant differences between boys and girls were present.On weekends, median glucose values were slightly higher than during weekdays: 179 vs. 176 mg/dl (9.9 vs. 9.7 mmol/L), p<0.001; time-in-range 50.6% versus 51.2 %, p<0.001).
Conclusion: Intermittent continuous measurement of tissue glucose allows a more in-depth analysis of glycemic control and variability.Subgroup analysis revealed clear differences between age-groups, as well as according to treatment modality.Correlation to measured HbA1c seems to be lower compared to adult patients, probably reflecting the lower stability of metabolic control in pediatric patients.Real-world data will help to determine the value of FGM/CGM profiles to improve clinical and patient related outcomes in pediatric diabetology.

Prediction quality of glucose trend indicators in current tissue glucose monitoring systems for use in therapeutic decisions

S. Pleus, U. Kamecke, M. Link, A. Westhoff, C. Haug, G. Freckmann; Institut für Diabetes-Technologie Forschungs- und Entwicklungsgesellschaft mbH an der Universität Ulm, Ulm, Germany.

Background and aims: Tissue glucose monitoring systems (TGMS) typically show glucose curves in addition to current glucose readings, and they often indicate glucose trends (e.g., trend arrows). When using TGMS for diabetes therapy, therapeutic decisions may not only be based on glucose readings alone, but also on glucose curves and trend indicators. In this investigation, the quality of trend indicators of 2 TGMS Dexcom® G5® (DG5) and FreeStyle Libre (FSL) was assessed in 2 different ways.
Materials and methods: Over a span of 14 days, each of 20 patients wore 2 sensors of each TGMS in parallel. Because DG5 is indicated for 7 days wear time, it was routinely replaced after approx. 7 days. On 3 separate occasions, patients visited the study site for 48 h each. On average, 115 blood glucose (BG) measurements were performed per visit with a FreeStyle Freedom Lite system. In parallel to each BG measurement, trend indicators of all TGMS were recorded. DG5 and FSL showed 7 and 5 different trend categories, respectively. On average, a difference of 1 trend category equals to a rate-of-change difference of more than 1 mg/dl/min. In analysis A, the trend displayed by the TGMS was compared to the trend calculated from the continuously stored, linearly interpolated TGMS values over a 15-minute interval. DG5 and FSL stored values every 5 and 15 min, respectively. In analysis B, the trend displayed by the TGMS was compared to the trend calculated from BG measurements with approx. 1 BG measurement per hour. In both analyses, glucose rate of change (based on TGMS or BG values) was calculated and converted to trend indicators according to the respective TGMS labeling.
Results: In analysis A, the displayed trend did match the trend calculated from TGMS values in 63.2%/62.1% (DG5/FSL) of cases. Trends indicating non-stable glucose were mostly overestimating rate of change compared to the calculated trend: When the displayed trend was negative, the indicated rate of change was mostly more rapidly decreasing than the calculated rate of change, whereas when the displayed trend was positive, the indicated rate of change was mostly more rapidly increasing than the calculated rate of change. A difference of at least 2 trend categories was found in 9.5%/8.4% (DG5/FSL) of cases. In analysis B, the displayed trend did match the trend calculated from BG values in 61.1%/58.5% (DG5/FSL) of cases. Again, trends indicating non-stable glucose were mostly overestimating calculated rate of change. A difference of at least 2 trend categories was found in 11.4%/12.5% (DG5/FSL) of cases (see Figure).
Conclusion: More than a third of displayed trend indicators in this study were found to be different from the trend calculated from TGMS or BG values, and slightly more than 10% of trend indicators differed from the calculated BG trend by at least 2 categories. When therapeutic decisions are based on TGMS readings, it should be kept in mind that displayed trends may differ from actual glucose changes.

Increase in continuous glucose monitoring among adults with type 1 diabetes: international comparison from the T1D Exchange and the DPV initiative

K. Miller[1], J. Hermann[2], D. Maahs[3], I. Schütz-Fuhrmann[4], D. DeSalvo[5], R. Holl[2];
[1]Jaeb Center for Health Research, Tampa, USA, [2]University of Ulm, ZIBMT, Institute of Epidemiology and Medical Biometry, Ulm, Germany, [3]Stanford University, Stanford, USA, [4]Hospital Hietzing, Vienna, Austria, [5]Baylor College of Medicine, Houston, USA.

Background and aims: In previous analyses, only a small minority of adults with T1D in the T1DX and DPV registries were using continuous glucose monitoring (CGM). In the past five years, new generations of CGM have shown considerable improvements in accuracy and usability. In this analysis we assessed increase in CGM use over the past 5 years, and compared glycemic control (HbA1c %) among current CGM users and non-users by insulin delivery status (pump or injection) in the US T1DX and Germany/Austria DPV registries.

Materials and methods: Registry data from 15,831 adult patients (age ≥ 18 years) with diabetes duration ≥ 1 year and registry updates from January 1, 2016 to December 31, 2016 (8090 participants from 72 T1DX sites, and 7741 participants from 365 DPV sites) were compared with data collected from both registries on 19,225 participants between September 1, 2010 to August 1, 2012 for T1DX (N=10,956) and between January 1, 2011 to December 31, 2011 for DPV (N=8269). CGM use (including both real-time and intermittent scanning CGM) and most recent HbA1c at each data collection time point were obtained from clinic medical records.

Results: Frequency of CGM use among T1D adults increased from 9% in 2011 to 11% in 2016 in DPV and from 11% in 2010-2012 to 26% in 2016 for T1DX. Increase in CGM use was observed across all age groups for T1DX but only in the young adult (18-<26 years) age group for DPV (Table). In 2016 CGM use was higher among insulin pump users in T1DX vs. DPV (35% vs. 12%, P<0.001) but similar among injection users (12% vs. 10%, P=0.01). For DPV mean HbA1c was lower among Pump+CGM (N=350, HbA1c 7.7%) users compared with injection+ CGM (N=460, HbA1c 8.1%, P=0.009), pump only (N=2538, HbA1c 8.0%, P=0.008) and injection only (N=4032, HbA1c 8.0%, P=0.002) users. For T1DX mean HbA1c in 2016 was lower among both injection+CGM (N=333, HbA1c 7.8%) and Pump+CGM (N=1616, HbA1c 7.6%) users compared with pump only (N=2944, HbA1c 8.1%, P<0.001) and injection only (N=2448, HbA1c 8.6%, P<0.001) users.

Conclusion: CGM use has increased dramatically among adults with T1D in T1DX over the past few years likely due to improved CGM performance but less so in DPV with the exception of the young adult age group. CGM use was associated with improved glycemic control in both pump and injection users for T1DX but only in pump users for DPV. The differences in CGM uptake and glycemic control among CGM users between the two countries may be reflective of differences in registry populations, availability of devices, provider beliefs, diabetes education and CGM training practices and insurance coverage.

Glycaemic outcomes in subjects with and without prior CGM experience, in the MiniMed™ 670G system pivotal trial

S.W. Lee[1], S.K. Garg[2], B.W. Bode[3], J. Ilany[4], S.A. Weinzimer[5], R. Brazg[6], T.S. Bailey[7], R.M. Bergenstal[8], B.A. Buckingham[9], R.H. Slover[2], S.M. Anderson[10], J. Shin[11], X. Chen[11], T.L. Cordero[1], F.R. Kaufman[1];

[1]Clinical Research and Medical Affairs, Medtronic, Northridge, [2]Barbara Davis Center for Diabetes, Aurora, [3]Atlanta Diabetes Associates, Atlanta, USA, [4]Institute of Endocrinology, Sheba Medical Center, Tel Hashomer, Israel, [5]Yale University School of Medicine, New Haven, [6]Rainier Clinical Research Center, Renton, [7]AMCR Institute, Escondido, [8]Park Nicollet Clinic-International Diabetes Center, Minneapolis, [9]Pediatric Endocrinology, Stanford University, Stanford, [10]University of Virginia, Charlottesville, [11]Clinical Research Data, Medtronic, Northridge, USA.

Background and aims: At-home use of the MiniMed 670G hybrid closed-loop system by 124 adolescents and adults, for 3 months, reduced HbA1c and increased overall percentage of sensor glucose (SG) values in target range (71-180 mg/dL), compared to a 2-week baseline run-in phase. Per protocol, both the run-in and study phases required use of the system's continuous glucose monitoring (CGM) feature. Given complexities associated with CGM onboarding, glycemic outcomes of subjects with and without prior CGM experience were evaluated.

Materials and methods: Study subjects (adolescents: n=30, aged 14-21 years and adults: n=94, aged 22-75 years) had T1D for ≥2 years, HbA1c <10%, and used insulin pump therapy for >6 months with or without CGM experience. Exploratory analyses between the run-in and study phases for subjects with previous CGM experience (Prior CGM) and those without previous CGM experience (No Prior CGM) were conducted. Outcomes included: HbA1c, the percent of overall SG values across ranges (≤50 mg/dL, ≤70 mg/dL, 71-180 mg/dL, >180mg/dL and >300mg/dL) and within-day variability of SG values (SD and CV).

Results: From run-in to study phase for adolescents, mean HbA1c fell from 7.5±1.0% to 7.0±0.6% and from 8.0±0.6% to 7.1±0.6% for Prior CGM (n=16) and No Prior CGM (n=14), respectively. The mean percent of in-target SG values increased from 62.2±11.8% to 68.6±8.8% and 58.4±9.8% to 65.5±7.5% for Prior CGM and No Prior CGM, respectively (Table). For adults, HbA1c dropped from 7.3±0.9% to 6.9±0.7% and 7.3±0.8 to 6.7±0.4 for Prior CGM (n=62) and No Prior CGM (n=31), respectively. The percent of in-target SG values increased from 68.1±12.5% to 73.6±8.9% and 70.1±10.7% to 74.2±7.6%, respectively. Comparisons of entire study phase SG values across ranges and within-day variability of SG values, between cohort Prior CGM and No Prior CGM groups, revealed no significant differences (Table, p-values). The change in HbA1c between Prior CGM and No Prior CGM groups also did not differ (adolescents: p=0.1953, adults: p=0.4052, Wilcoxon rank-sum test).

Conclusion: Use of the MiniMed 670G System, at home, improved HbA1c and in-target SG values regardless of study participant prior CGM experience. These findings suggest that the system may benefit current CGM, as well as CGM-naive, users.

Impact of continuous glucose monitoring (CGM) on hypoglycaemia in type 1 diabetes adults on multiple daily insulin injections (MDI)

A.F. Ólafsdóttir[1,2], W. Polonsky[3], J. Bolinder[4], I.B. Hirsch[5], T. Heise[6], H. Wedel[7], S. Dahlqvist[1], M. Lind[1,2];
[1]NU hospital Group, Uddevalla, Sweden, [2]University of Gothenburg, Gothenburg, Sweden, [3]University of California, San Diego, USA, [4]Karolinska Institute, Stockholm, Sweden, [5]University of Washington, Washington, USA, [6]Profil, Neuss, Germany, [7]University of Gothenburg, Gothenburgh, Sweden.

Background and aims: Conventional intensive insulin therapy helps decrease HbA1c but with increased risk of hypoglycaemia. Recent studies show that CGM can decrease HbA1c for persons treated with MDI but how this affects hypoglycaemia is not fully understood. The aim of this study was to evaluate the impact of CGM on hypoglycaemia in persons with type 1 diabetes (T1D) treated with MDI and evaluate hypoglycaemic confidence.
Materials and methods: Evaluations were performed from the GOLD study, an open-label multicentre cross-over randomized trial (n=161) over 69 weeks comparing CGM to self-measurement of blood glucose (SMBG) in persons with T1D treated with MDI. Masked CGM and the Hypoglycaemic Confidence Scale (HCS) were used for evaluations.
Results: Mean age was 43.7 years, 45.3% were female, mean HbA1c was 70mmol/mol and was reduced by 5mmol/mol (p<0.001) more by CGM than SMBG. The hypoglycaemia levels used were <3mmol/L and <3.9mmol/L. The mean time spent in nocturnal hypoglycaemia (00-05:59) for SMBG was 8.9 min (95% CI 6.3-11.5 min) and 19.2 min (95% CI 15.1-24.2 min) respectively. For CGM the mean was 3.1 min (95% CI 1.9-4.2 min) and 10.2 min (95% CI 7.9-12.5 min) respectively. For daytime hypoglycaemia (06:00-23:59) the corresponding values for SMBG were 18 min (95% CI 14.3-21.9 min) and 48.8 min (95% CI 41.3-56.4 min). For daytime hypoglycaemia with CGM the corresponding values were 8.2 min (95% CI 5.8-10.6 min) and 29.5 min (95% CI 23.5-35.4 min) respectively. All differences were significant at significance level, p< 0.001. The improvement on time spent in hypoglycaemia disappeared when CGM was not used (figure 1). The total HCS score improved significantly from 3.27 to 3.40 (p<0.001) during CGM treatment and when analysed separately 4 out of the 9 HCS items improved significantly: staying safe from serious problems with hypoglycaemia when in social situation (p = 0.016), confidence in catching and responding in time to hypoglycaemia (p = 0.0033), avoiding serious problems due to hypoglycaemia (p = 0.002), and continue to do the things you really want despite the hypoglycaemia risk (p = 0.022).
Conclusion: CGM reduces time spent in nocturnal and daytime hypoglycaemia in T1D adults on MDI. CGM also increases confidence in avoiding hypoglycaemia and problems related to them.

CGM combined with either MDI or CSII is superior to standalone MDI or CSII in type 1 diabetes: 2 years of follow-up in the COMISAIR study

J. Šoupal[1], L. Petruželková[2], M. Flekač[1], M. Daňková[1], A. Hásková[1], M. Matoulek[1], O. Mikeš[1], T. Pelcl[1], J. Škrha[1], Š. Svačina[1], M. Prázný[1];
[1]3rd Department of Internal Medicine, 1st Faculty of Medicine, Charles University, [2]Department of Paediatrics, 2nd Faculty of Medicine, Charles University in Prague, Prague, Czech Republic.

Background and aims: To compare different treatment modalities for patients with type 1 diabetes (T1D) based on one of real-time continuous glucose monitoring (RT-CGM) or self-monitoring of blood glucose (SMBG) in combination with one of multiple daily injections (MDIs) or continuous subcutaneous insulin infusion (CSII).
Materials and methods: In this prospective, real-life study, 65 patients with T1D were followed up for 2 years. Of these, 27 started to use RT-CGM; within this CGM group, 15 subjects started sensor augmented pump (SAP) therapy and the remaining 12 continued with MDIs (MDIs + RT-CGM). A second group of 20 patients initiated CSII without RT-CGM, while a third group of 18 subjects continued on MDIs and SMBG. At the baseline, all subjects were monitored by blinded CGM and underwent a structured 4-day training program. In addition, those groups of patients without RT-CGM were monitored for a week by blinded CGM every 3 months and again at the end of the study. The main endpoints were reduction of HbA_{1c}, glycemic variability (GV), and incidence of hypoglycemia.
Results: After 2 years, the baseline mean HbA_{1c} in the CGM group (8.3%) decreased to 7.1% (p<0.0001); both CGM subgroups, SAP and MDIs + RT-CGM, showed comparable improvement. In contrast with the CGM group, at the end of the study no significant reduction of HbA_{1c} was seen either in the MDIs or CSII groups. Improvement of HbA1c in the CGM group was superior to MDIs (p=0.002) and CSII (p=0.002). Importantly, the superiority of a CGM strategy in comparison with CSII alone held not just for SAP, but also for MDIs +RT-CGM; the MDIs + RT-CGM vs CSII comparison favoured the former by -0.86% (95% CI, -1.5% to -0.22%; p<0.01). GV was also lowered both in the CGM (p<0.0001) and CSII (p<0.05) groups. Reduced incidence of hypoglycemia was observed only with CGM (8%±4% vs. 6%±3%; p< 0.01).
Conclusion: To the best of our knowledge, this is the first prospective, 2-year real-life study simultaneously comparing four different treatment strategies based on different combinations of insulin delivery and monitoring systems. In our study, both CGM modalities, SAP and MDIs + RT-CGM, provided significant and comparable decrease of HbA1c with concurrent reduction of hypoglycemia. This improvement was greater than that seen with CSII. The combination of RT-CGM and MDIs can be a suitable alternative to SAP for some patients.

Flash glucose monitoring in over 50,000 users: a favourable relationship between frequency of testing and glycaemic measures

R.A. Ajjan[1], Y. Xu[2], G. Hayter[2], T. Dunn[2];
[1]Leeds Institute of Cardiovascular and Metabolic Medicine, Leeds University, Leeds, UK, [2]Abbott Diabetes Care, Alameda, USA.

Background and aims: Optimising glycaemic control in diabetes involves a combination of reducing high glucose levels while avoiding hypoglycaemia. Our aim was to assess the use of flash glucose monitoring (FreeStyle Libre®) in real life clinical practice across European countries. In particular, glucose testing frequency and relationship with glycemic parameters was analysed together with regional differences in exposure to hyper and hypoglycaemia.
Materials and methods: When flash glucose readers are connected to an internet ready PC, 90-day memory of the device is de-identified and uploaded onto a database after user's consent. For analysis, sensors were required to have at least 120 hours of operation, and all sensors were grouped per reader, resulting in 50,831 readers with 279,446 sensors (86.4 million monitoring hours by 63.8 million scans). Six regions were identified, five countries having the highest device use (Germany, Spain, France, UK and Italy), and a sixth "region" grouped all remaining. Scan rate per reader was determined and twenty equally-sized rank-ordered groups, categorized by scan frequency, were evaluated. Glucose scan frequency was analysed together with relationship to glycaemic markers in each of these regions.
Results: Average scan frequency was 16.3/day [median (IQR) of 14 (10-20)] but this varied significantly across regions. Highest scan frequency was found in the UK at 18.0 [15 (11-23)] while individuals in France showed the lowest scan rate at 13.6 [12 (8-17); p<0.001]. All countries demonstrated strong correlations between frequency of glucose scans and glycaemic markers. Time spent in hyperglycemia (>10 mmol/l) was reduced from (mean±SD) 10.5±5 to 5.9±5 hours/day (p<0.001) in lowest compared with highest frequency scanning groups, while time in hypoglycaemia (<3.1 mmol/l) was reduced from 43±60 to 26±47 minutes/day (p<0.001). However, hypoglycaemic exposure showed regional differences with individuals in France spending the longest time in hypoglycaemia 58±65 to 40±62 minutes/day in lowest and highest frequency scanning groups, respectively, whereas patients from Italy spent the least time in hypoglycaemia 33±59 and 20±35 minutes/day in the lowest and highest frequency scanning groups. Increased scan frequency was also associated with longer time spent in range (defined as 3.9-10.0 mmol/l) and lower estimated HbA1c.
Conclusion: In real-world clinical practice, frequency of glucose testing with the flash monitoring system is high across countries, although regional differences were observed. Increased scan frequency is universally associated with reduced time spent in both hyper and hypoglycaemia but total exposure to low glucose levels showed differences between countries. These findings have implications for the use of flash glucose monitoring to improve glycaemia, whereas the documented regional differences warrant further research.

Type 1 diabetes at high altitude: performance of medical devices

T. Klupa[1], B. Matejko[1], M. Wróbel[2], A. Gawrecki[3], J. Hohendorff[1], T. Benbenek-Klupa[4], M. Malecki[1], D. Zozulińska-Ziółkiewicz[3];
[1]Department of Metabolic Diseases, Jagiellonian University, Kraków, [2]Clinical Department of Internal Diseases and Diabetology, Silesian Center for Heart Diseases, Zabrze, [3]Department of Internal Medicine and Diabetology, University of Medical Sciences, Poznań, [4]Diabway, Kraków, Poland.

Background and aims: High altitude trekking can expose people to extreme environmental conditions, like low temperatures and hypobaric hypoxia. Such extreme conditions make it more difficult for people with type 1 diabetes mellitus (T1DM) to achieve glycemic control. While frequent blood glucose monitoring is imperative in these cases, it remains unclear whether altitude impacts blood glucose meter accuracy. In this observational study, we examined the performance of various insulin pumps at high altitude, including continuous glucose monitoring (CGM) systems and a new flash glucose monitoring (FGM) system (FreeStyle Libre).
Materials and methods: All 19 patients with T1DM included in this study participated in trekking Damavand Mountain (Iran) to an altitude of 5671 meters above sea level. The mean age of the patients was 32.5 years, with a mean body mass index (BMI) of 23.8 kg/m^2, and a mean HbA_{1c} level of 6.6%.
Results: Statistical analysis showed a difference in blood glucose values obtained using the different glucose monitoring systems at day 1 (mean BGM values vs. mean FGM values, 137 vs. 169 mg/dl, p=0.0000), day 2 (mean CGM values vs. mean FGM values, 163 vs. 219 mg/dl, p=0.0014; and mean BGM vs. mean FGM values, 181 vs. 219 mg/dl, p=0.02), and day 3 (mean CGM values vs. mean FGM values, 202 vs. 264 mg/dl, p=0.0035; and BGM vs. FGM, 187 vs. 218 mg/dl, p=0.0000). The SmartGuard technology of insulin pump Minimed 640G (used by 6 patients during expedition) was activated on average 3.3 times per patient per day. We found that, without extreme weather conditions, high altitude trekking is safe for insulin pumps and CGM/FGM systems and causes no clinically significant problems. All pump models worked well without any disruption, and no cases of diabetes decompensation or severe hypoglycemia occurred.
Conclusion: To conclude, despite the risks, healthy, physically fit and experienced individuals with type 1 diabetes can be encouraged to participate in mountain trekking activities and attain their summit goals. Modern personal insulin pumps and continuous glucose monitoring systems appear to work properly even at high altitudes at least in the absence of extreme winter conditions.

Table 1. Glucose values during the three expedition days obtained via the different glucose monitoring methods.

	Mean BGM values ± SD [mg/dl]	Mean CGM values ± SD [mg/dl]	Mean FGM values ± SD [mg/dl]	Number of blood glucose measurements per day ± SD [mg/dl]

Positive clinical outcome of Belgian reimbursement of real-time continuous glucose monitoring for type 1 diabetes patients on insulin pump therapy

S. Charleer[1], C. De Block[2], R. Radermecker[3], E. Weber[4], C. Vercammen[5], L. Crenier[6], Y. Taes[7], F. Nobels[8], B. Keymeulen[9], C. Mathieu[10], P. Gillard[10], The RESCUE investigators;
[1]KU Leuven, Leuven, [2]University Hospital Antwerp, Antwerp, [3]CHU Liege-University of Liege, Liege, [4]Clinique du Sud Luxembourg, Arlon, [5]Imelda Hospital, Bonheiden, [6]Université Libre de Bruxelles-Hôpital Erasme, Brussels, [7]AZ Sint-Jan, Bruges, [8]OLV Hospital Aalst, Aalst, [9]University Hospital Brussels, Brussels, [10]University Hospital Leuven, Leuven, Belgium.

Background and aims: Improving glycemic control, while reducing hypoglycemia, has been achieved in randomized controlled trials evaluating real-time continuous glucose monitoring (RT-CGM) in patients with type 1 diabetes (T1D). However, studies investigating real-life use of RT-CGM are sparse, even though they are of major interest to healthcare providers. This study evaluates the impact of RT-CGM reimbursement on glycemic control and quality of life of patients with T1D treated with continuous subcutaneous insulin infusion (CSII) therapy, followed in one of 17 high volume diabetes centers.
Materials and methods: Over a period of 12 months, the observational RESCUE trial analyzes the impact on predefined clinical outcome parameters of a Belgian RT-CGM reimbursement system in patients with T1D on CSII. Data were collected during standardized clinical follow-up and from questionnaires (SF-36, Problem Areas In Diabetes-Short Form, Hypoglycemia Fear Survey-II) between September 2014 and December 2016. The primary endpoint was defined as evolution of HbA1c from baseline to 12 months. Secondary outcome measures included evolution from baseline to 12 months of hypoglycemic events, quality of life and hospitalization rate for severe hypoglycemia and ketoacidosis. Data are reported as median (interquartile range) unless otherwise stated.
Results: 515 adult patients entered the study of which 421 (82%) used RT-CGM for at least 12 months and 52 (10%) terminated RT-CGM earlier, mainly because of alarm fatigue. The majority of patients used Medtronic sensors (75%), mostly with low glucose suspend features (74%), while others used Dexcom (24%) or Abbott Navigator (1%) sensors. Patients were 41 years (32 - 51) old, 59% female, had diabetes for 21 years (14 - 30) and 47% had complete or partial hypoglycemia unawareness. HbA1c at baseline was 7.5% (7.1 - 8.2) (58 mmol/mol [54 - 66]) and decreased to 7.3% (6.8 - 7.9) (56 mmol/mol [51 - 63]) at 12 months (P<0.001). Patients in the highest HbA1c quartile dropped from 8.7% (72 mmol/mol) to 8.0% (64 mmol/mol) at 12 months (P<0.001), with simultaneous reduction of 26% (-5 - 49) in glucose values < 70 mg/dL (3.9 mmol/L) (P<0.001). For patients in the lowest HbA1c quartile, hypoglycemic glucose values also dropped by 36% (11 - 56) at 12 months (P<0.001), while maintaining an unchanged HbA1c level. Quality of life improved significantly (P<0.001) in all but two sub measures of SF-36 (bodily pain and vitality). One year before reimbursement, 16% of patients were admitted to the hospital for severe hypoglycemic or ketoacidosis episodes in contrast to 3% (P<0.001) the year after, corresponding to a decrease in hospitalization days from 54 to 19 days per 100 patient-years.
Conclusion: Reimbursement of RT-CGM in patients with T1D on CSII results in lower HbA1c and decreased risk of hypoglycemia under real-life conditions and leads to fewer diabetes-related hospitalizations and improvement in quality of life.

PS 053 Hypoglycaemia: identifying people at increased risk

720

Impact of genetic polymorphism in the beta-2-receptor gene on the risk of severe hypoglycaemia in patients with type 1 diabetes

K.Z. Rokamp[1], N.V. Olsen[2], L. Færch[3], P.L. Kristensen[3], B. Thorsteinsson[3], U. Pedersen-Bjergaard[3];
[1]Rigshospitalet-Glostrup, Glostrup, [2]Department of Neuroanaesthesia, Rigshospitalet, Copenhagen, [3]Department of Cardiology, Nephrology and Endocrinology, Nordsjællands Hospital, Hillerød, Denmark.

Background and aims: The frequency of severe hypoglycaemia in T1 diabetes is not equally distributed and a fraction of the patients tends to have recurrent severe hypoglycaemia which makes a genetic influence probable. A potential candidate is the beta-2-receptor gene (ADRB2) that has several common polymorphisms and of which the Arg^{16} allele is associated with agonist-mediated down-regulation. This could be of importance for attenuation of symptoms, counter regulation and promotion of severe hypoglycaemia after repeated hypoglycaemia in patients with T1 diabetes.
Materials and methods: A cohort of 314 patients with T1 diabetes was recruited in an outpatient clinic. Severe hypoglycaemic events were reported retrospectively in a validated questionnaire. The patients were further characterized by diabetes history, degree of hypoglycaemia awareness (Clarke, Gold, and Hillerød methods), C-peptide status, haemoglobin A1c (HbA1c), and determination of ADRB2 genotype.
Results: The ADRB2 Gly16Arg genotype distribution was in Hardy-Weinberg equilibrium and was similar to the distribution in the general population. There was no association between genotype and degree of awareness. There was a significant difference in rate of severe hypoglycaemia between all genotypes (p=0.011) and patients homozygous for the Arg^{16} genotype (AA, n=60) had a relative rate of severe hypoglycaemia of 2.19 (95% CI 1.31 - 3.64) compared to patients homozygotes for the Gly^{16} genotype (GG, n=117) (p=0.003). In patients with impaired awareness the difference was even more pronounced with a relative rate of severe hypoglycaemia of 3.18 (95% CI 1.67 - 6.04) in patients with the AA genotype (p<0.0001). The difference was not explained by other risk factors (HbA1c, diabetes duration, C-peptide).
Conclusion: Genetic polymorphism in the beta-2-receptor gene is associated with risk of severe hypoglycaemia in patients with T1 diabetes, especially in those with impaired hypoglycaemia awareness.
Disclosure: **K.Z. Rokamp:** None.

721

Hypoglycaemia awareness and the risk of severe hypoglycaemia in the global HAT study of 27,585 patients from 24 countries with type 1 and type 2 diabetes

U. Pedersen-Bjergaard[1], R. Aronson[2], H. Gydesen[3], J. Barner Lekdorf[3], K. Khunti[4];
[1]Dept. Cardiology, Nephrology and Endocrinology, Nordsjællands Hospital Hillerød, Hillerød, Denmark, [2]LMC Diabetes and Endocrinology, Toronto, Canada, [3]Novo Nordisk A/S, Søborg, Denmark, [4]University of Leicester, Leicester, UK.

Background and aims: Impaired awareness of hypoglycaemia (IAH) is an important predictor for severe hypoglycaemia, particularly in type 1 diabetes (T1D). IAH and its effects are largely unknown outside Europe and North America. The global Hypoglycaemia Assessment Tool (HAT) study aimed to assess hypoglycaemia incidence and awareness in patients with T1D and type 2 diabetes (T2D) in Northern Europe, Canada, Eastern Europe, the Middle East, Latin America, South East (SE) Asia and Russia.
Materials and methods: Hypoglycaemia awareness was assessed at baseline using a validated method based on the question: 'Do you have

symptoms when you have a low sugar level?'. The answer 'always' implied normal awareness, 'usually' impaired awareness, 'occasionally' and 'never' unawareness. Severe hypoglycaemia was reported in 6-month retrospective and 1-month prospective periods.

Results: In T1D 45% declared normal awareness, 39% impaired awareness and 17% unawareness. People with unawareness had the highest estimated annual incidence rates (IRs) for severe hypoglycaemia both retrospectively and prospectively (Table). Patients with unawareness were older (47.6 years), had longer diabetes duration (21.3 years), and lower HbA_{1c} (62.3 mmol/mol) than those with awareness. Regionally, in T1D, the association between severe hypoglycaemia and IAH was most pronounced in Eastern Europe (retrospective IRs: always 1.36; usually 1.71; occasionally 2.18; never 3.08), but an inverse association was uniquely observed in SE Asia (retrospective IRs: always 2.90; usually 1.92; occasionally 0.91; never 0.27). In T2D, 45% reported normal awareness, 30% impaired awareness and 25% unawareness. Slightly lower IRs for severe hypoglycaemia were observed with reduced awareness particularly in the retrospective period (Table). In contrast to T1D, patients with unawareness were younger (60.6 years) with a shorter duration of diabetes (12.9 years) and insulin use (5.2 years) and had higher HbA_{1c} (65.1 mmol/mol) than those with awareness. In T2D, an inverse association of that seen in T1D was observed in all regions apart from Russia, where there was no association.

Conclusion: The HAT study shows the expected prevalence of hypoglycaemia unawareness and its association with increased risk of severe hypoglycaemia in T1D in some but not all parts of the world. In T2D, an unexpected higher prevalence of unawareness was found and an inverse association with severe hypoglycaemia. Further research is needed in order to explore factors associated with awareness across regions and why contrasting associations occur in T2D.

Table. Severe hypoglycemia in the overall population reported in retrospective and prospective periods.

Period	Hypoglycaemia Awareness	T1D		T2D	
		N (%)	IR	N (%)	IR
All regions retrospective (6 months)	Normal	3501 (23.4)	1.87	6713 (19.8)	1.30
	Impaired	2990 (26.7)	2.00	4592 (22.1)	1.21
	Unawareness	1296 (77.1)	3.40	3972 (23.1)	0.66
All regions prospective (4 weeks)	Normal	3097 (13.0)	4.30	6284 (9.7)	2.90
	Impaired	2631 (14.8)	4.79	4394 (12.2)	3.04
	Unawareness	1170 (42.2)	6.81	3972 (12.9)	2.48

Impaired awareness of hypoglycaemia and severe hypoglycaemia impact on executive functions, hypoglycaemic symptoms, quality of life and distress in type 1 diabetes adults

E. Sepúlveda[1], D. Carvalho[2], D. Seixas[3], S.A. Amiel[4], S.G. Vicente[1];
[1]Faculty of Psychology and Educational Sciences, University of Porto, [2]Department of Endocrinology, Diabetes and Metabolism, São João Hospital Centre, Porto, [3]Institute for Biomedical Imaging and Life Sciences, University of Coimbra, Coimbra, Portugal, [4]Diabetes Research Group, King's College London, London, UK.

Background and aims: Impaired awareness of hypoglycaemia (IAH) increases risk of severe hypoglycaemia (SH) 6-fold in adults with type 1 diabetes (T1D). We hypothesised that IAH and SH may be associated with executive dysfunction, increased distress, and reduced quality of life (QoL).

Materials and methods: We recruited 85 adults with T1D. Hypoglycaemia awareness status was determined using the 1-item Gold Score (GS) and the 8-item Clarke score (CS), with ≥4 = IAH for each. SH was evaluated over two different time frames (6 and 12 months) by 2 questions (3 and 4, respectively) in the CS. Participants also completed the Edinburgh Hypoglycaemia Scale (assessing autonomic, neuroglycopenic, and nonspecific hypoglycaemic symptoms); the Montreal Cognitive Assessment (MoCA, global cognition: visuospatial abilities, executive functions, language, delayed recall, and orientation); the INECO Frontal Screening (IFS, executive functions: inhibition and set shifting, abstraction, and working memory); the Diabetes Health Profile (DHP, QoL: barriers to activity [BA], psychological distress [PD], and disinhibited eating [DE]); and the Hospital Anxiety and Depression Scale (HADS). Mann-Whitney U test was used to compare mean ranks of groups: those with intact awareness of hypoglycaemia (AH) *vs* IAH; SH *vs* noSH; SH&AH *vs* noSH&AH.

Results: Participants' mean±SD age and diabetes duration were 38.4±12.5 and 19.1±11.7 years, respectively; 54.1% were male; 31.8% had IAH by GS and 16.5% by CS. 86% of IAH patients by CS *vs* only 41% with IAH by GS had had SH in the past 6 months (CS question 3), with 50% *vs* 19% reporting seizure, or parenteral therapy for SH in the last 12 months (CS question 4). IAH patients by CS had significantly ($p<0.05$) lower performance on MoCA executive functions domain, higher neuroglycopenic symptoms when hypoglycaemic, more BA, and depression than AH patients by CS. No differences were found between IAH and AH assessed by GS. Furthermore, patients with SH in the past 6 months had significantly worse performance on MoCA executive functions domain, and higher neuroglycopenic symptoms, BA, psychological distress, anxiety and depression than those with noSH. Patients with SH in the past year had worse performance on MoCA language domain, and higher neuroglycopenic symptoms and higher depression scores than noSH patients (all $p<0.05$). SH&AH patients had higher BA and depression than those with noSH&AH. Also, SH&AH had worse performance on MoCA executive functions domain ($p=.004$), and motor series ($p=.034$), conflicting instructions ($p=.009$) and Go-No-Go ($p=.007$) IFS subtests, tending to show poorer performance on IFS total scores ($p=.058$).

Conclusion: Adults with T1D and either IAH or SH show evidence of impaired executive functions, depression, neuroglycopenic symptoms when hypoglycaemic, and higher BA. The evidence for impaired executive functioning (programming, interference sensitivity, inhibitory control), higher depression and BA related to SH, even in people with intact awareness, suggest that SH may be necessary for these dysfunctions. The contribution of IAH on executive dysfunction needs to be further explored.

Unhelpful cognitions about hypoglycaemia in adults with type 1 diabetes

A. Cook[1], N. de Zoyza[1], E. Smith[1], M. Rickels[2], S. Dubose[3], M. Wu[3], J. Speight[4], S. Amiel[1];
[1]King's College, London, London, UK, [2]University of Pennsylvania, Philadelphia, [3]JAEB Centre for Health Reserach, Tampa, USA, [4]Deakin University, Melbourne, Australia.

Background and aims: Severe hypoglycaemia (SH) is a barrier to optimising glycaemic control and continues to affect a significant proportion of people with Type 1 Diabetes (T1D). Growing evidence suggests that cognitive factors play a role in the ability to avoid SH. We explored these using the Attitudes to Awareness Questionnaire (A2A) in a cross sectional survey of the US T1D Exchange Clinic Registry adult population. The A2A was developed from qualitative research into hypoglycaemia beliefs in hypoglycaemia-prone adults with T1D in the UK.

Materials and methods: The A2A was sent to 6200 adults in the T1D Exchange Clinic Registry. Each of the 14 A2A questionnaire items (rated

on a likert scale) relates to an unhelpful belief about hypoglycaemia. The structure of the A2A was examined using exploratory factor analysis with eigenvalues >1.0 and factor loadings >0.3 used in interpretation. Responses were compared between those with and without impaired awareness of hypoglycaemia (IAH) and those with and without SH.
Results: 1978 responses were received (response rate 32%) from participants, mean age 40±16 yrs, 62% female, T1D duration 23±14yrs, HbA1c 7.8±1.4%; 62% female, 37% had IAH; 14% recurrent SH (≥2 episodes of SH in past year). Of those with IAH, 25% had recurrent SH. Data supported the use of factor analysis (Kaiser-Meyer-Olkin = 0.785, Bartlett's test of sphericity χ^2 (91) 3399.71 p<0.001). A forced 3-factor analysis generated 3 strong factors, explaining 40.1% of the variance. Parallel analysis confirmed the retention of 3 factors. The first factor (eigenvalue: 3.12, Cronbach's α=0.64) explained 22.3% of the variance in responses and comprised 5 items relating to minimising concern about negative effects of SH. It was labelled Minimising Hypoglycaemia. The second factor (eigenvalue: 1.31, α=0.49) explained 9.4% of the variance and comprised 5 items describing cognitions relating to excessive emphasis on avoiding high blood glucose. It was labelled Hyperglycaemia Prioritised. The third factor (eigenvalue: 1.17, α=0.51) explained 8.4% of the variance and contained 4 items. Its theme was a lack of concern about hypoglycaemia in the absence of symptoms and was labelled Asymptomatic Hypoglycaemia Normalised. Differences in prevalence of factors were found by awareness status and frequency of SH. Those with IAH minimised concern about hypoglycaemia less (p<0.001) and prioritised avoiding hyperglycaemia more (p=0.002) than those with intact awareness. Those with recurrent SH minimised concern about hypoglycaemia less (p<0.001) and normalised asymptomatic hypoglycaemia more (p=0.019) than those without recurrent SH.
Conclusion: This study identified 3 distinct unhelpful beliefs which appear to present a barrier to reducing hypoglycaemia risk. Prevalence of the beliefs varied with awareness status and frequency of hypoglycaemia. These problematic beliefs may have utility to identify people at high risk of recurrent SH and could represent areas to address in supporting those at risk to protect themselves from SH.

Under-reported hypoglycaemia: detection of burden and clinical interventions in a real-life setting using text mining and electronic health records

P.M. Paldánius[1], G. Petratos[2], G. Bader[1];
[1]Novartis Pharma AG, Basel, Switzerland, [2]HITEKS Solutions Inc, New York, USA.

Background and aims: Appropriate glycaemic control is a foundation of type 2 diabetes (T2DM) management while presence of treatment-induced hypoglycaemic episodes (HEs) and anxiety linked to or fear of HEs may limit proper use of therapies targeting to reduce the risk of progressive vascular complications. Detection of subclinical and potentially under-reported HEs in patients with T2DM is challenging in the absence of frequent blood glucose monitoring or patient but also, physician awareness. We explored the real-world burden of HEs, the rate of subclinical HEs and presence of symptoms indicative of potentially undiagnosed HEs, and clinical interventions using computerised electronic health records (EHRs).
Materials and methods: A convenience population of 347,348 patients from the Northeast states of U.S., and associated 2 million longitudinal records from year 2010 to 2013 with clinical documentation and structured data from the EHRs were used. An analytics funnel for comparison of subgroup combinations of HEs was created using standard database query and natural language processing techniques of 20 pre-defined descriptive signs or symptoms and 14 projected, different physician intervention options related to HE management. The difference in action taken and presence of pre-defined symptoms was assessed between those with and without documented HEs.
Results: The EHR population comprised of 7.8% (n=27,175) patients with a diagnosis of T2DM of those, 5.6% (n=1,522) had documented hypoglycaemia: 91.8% with symptoms and, of those, 84.8% led to an intervention. Yet, out of 25,653 subjects with no documented hypoglycaemia, 80.8% reported at least one symptom of potentially under-reported HEs and, of those, 65.7% had a documented intervention. Subjects with potentially under-reported HEs had a mean age of 61.8 years and multiple comorbidities: 19.8% had renal impairment, 38.8% a history of acute myocardial infarction, and approximately 20.0% had congestive heart failure or hypertension. The subjects were mostly treated with insulin (43.8%), biguanides (metformin) (25.7%) or sulphonylurea (23.6%). Pre-defined potential indicators of HEs such as chills, confusion, tachycardia, dizziness, hunger, sleepiness, blurred vision, numbness, headache, weakness, lack of coordination and seizure were documented more often among those with a documented HE. These symptoms of HEs also more often lead to a therapy switch (OR=1.6; 95% CI: 1.4, 2.0), change in dose or frequency adjustment (OR=2.3; 95% CI: 1.9, 2.7), a consultation (OR=1.6; 95% CI: 1.4, 1.8), or a referral to a diabetes educator (OR=2.2; 95% CI: 1.3, 3.6).
Conclusion: In our real-world dataset, the prevalence of confirmed HEs among the patients with T2DM was around 5-6%. Pre-defined symptoms of HEs lead more often to an intervention when the HE had been well-documented while the same symptoms frequently occur in patients with comorbidity- or therapy-related established risk factors for HEs. Providers with modern and well-supported EHR systems worldwide have potential for proactive detection, testing and documentation for HEs. Quality surveillance of the patient records can alert providers and also include suggestions for an intervention in cases where symptoms occur which are indicative of HEs.

HbA_{1c} and occurrence of severe hypoglycaemias in patients with type 1 diabetes. Results from the disease management programmes in North Rhine-Westphalia, Germany

B.K. Hagen, S. Groos, J. Kretschmann, C. Macare, A. Weber;
Disease Management Programmes, Central Research Institute for Ambulatory Health Care in Germany, Cologne, Germany.

Background and aims: To prevent the incidence and progression of complications caused by diabetes is one of the central aims in the therapy of type-1-diabetes, so a tight glycaemic control is intended. But tight glycaemic control can increase the risk for severe hypoglycaemias. Therefore the association between HbA1c and the occurrence of severe hypoglycaemias was analysed within a population of patients inscribed in disease management programmes (DMP) for type-1-diabetes.
Materials and methods: All analyses are based on documentations of a total of 44 995 patients with type-1-diabetes who were participating in 2014 in the DMPs in the German federal state of North Rhine-Westphalia. In a subgroup of 41 924 patients documentation with regard to the incidence of severe hypoglycaemias was available. Stratified by age and sex HbA1c values and frequencies of severe hypoglycaemias, i.e. cases when patients needed external help and / or an intravenous glucose injection, are presented. Predictors for the incidence of severe hypoglycaemias were estimated by logistic regression analysis (odds ratios, OR, and 95-percent confidence intervals, CI 95%, are given).
Results: In 48.4% of the patients HbA1c is <= 7.5% (58.5 mmol/mol) and in 23.4% of the patients HbA1c is > 8.5% (69.4 mmol/mol). In the time period from early adolescence until approximately the age of 30 low HbA1c levels are reached seldom. From the age of c. 50 yrs. female patients show higher HbA1c levels than male patients. In 2014 severe hypoglycaemias are documented in n = 1.601 (3.8%) of the patients, most frequently in the n = 8 356 patients > 60 yrs. (n = 389, 4.7%). Prevalence

of severe hypoglycaemias is associated with the HbA1c level in 2013 (<= 7.5% = 4.9%; > 10% / 85.8 mmol/mol = 2.9%). Previous severe hypoglycaemias are the most significant predictor of severe hypoglycaemias in 2014 (OR = 10.6; 95-%-CI = 9.3-12.0). As well risk for severe hypoglycaemias increases when diabetic complications (OR = 1.4; 95-%-CI = 1.3-1.6) or cardiovascular comorbidities are documented (OR = 1.2; 95-%-CI = 1.0-1.4). Risk of severe hypoglycaemias decreases when the HbA1c level in 2013 was > 8.5% (OR = 0.6, 95-%-CI = 0.5-0.8) or in case of a body-mass-index >= 30 kg/sqm (OR = 0.8; 95-%-CI = 0.7-0.9).

Conclusion: Approximately half of the patients with type-1-diabetes reach HbA1c levels recommended by clinical guidelines. Nevertheless in around 4% of these patients severe hypoglycaemias are documented in 2014. The strong association found between the previous and the current incidence of severe hypoglycaemias confirms results which have been published earlier by other authors.

Disclosure: **B.K. Hagen:** None.

Can CGM discriminate between type 1 diabetes patients with and without severe hypoglycaemia. Results of the baseline assessment from the HypoDe study

L. Heinemann[1], G. Freckmann[2], G. Faber-Heinemann[1], D. Ehrmann[3], N. Hermanns[3];

[1]Science-Consulting in Diabetes GmbH, Düsseldorf, [2]Institut für Diabetes-Technologie Forschungs- und Entwicklungsgesellschaft mbH an der Universität Ulm, Ulm, [3]Forschungsinstitut der Diabetes-Akademie Bad Mergentheim (FIDAM), Bad Mergentheim, Germany.

Background and aims: Patients with type 1 diabetes on a multiple daily insulin injections (MDI) regimen and hypoglycaemia issues were eligible for the HypoDE study. Hypoglycaemia issues were defined as having suffered a severe hypoglycaemic (SH) episode (third party assistance for recovery needed) during the past 12 months or having reduced hypoglycaemia awareness (unawareness-score ≥4). We analysed whether CGM enables identification of patients which reported at least one episode of SH or which reported reduced hypoglycaemia awareness without SH.

Materials and methods: 149 patients (age 46.5±11.9 yrs, 40.3% female, HbA1c 7.5±1.0%, diabetes duration 21.3±11.9 yrs) were included and randomised to this RCT. Participants wore blinded CGM (DexCom Gen 4) for 28 days and completed the Hypoglycaemia Awareness Questionnaire (HAQ). From these, 90 patients reported at least one episode of SH and 59 reported reduced hypoglycaemia awareness without SH.

Results: Patients wore blinded CGM during 26.9±2.1 days. Patients with SH spent longer time (minutes per day) in the low glucose ranges in comparison to those without SH (≤70 mg/dl: 130.5±98.9 vs. 72.4±56.1 min per day, p<.001; ≤55 mg/dl: 59.4±60.0 vs. 27.3 ±26.5 min per day, p<.001; ≤40 mg/dl: 13.5±25.8vs. 6.7±9.3 min per day, p=.001). However, they spend less time in the hyperglycaemic range (≥180 mg/dl: 441.0±220.8 vs. 568.0±244.4 min per day, p=.001). The number of hypoglycaemic events ≤55 mg/dl was also higher in the SH group than in the group without SH (14.5±11.8 vs. 8.1±7.8 events per 28 days, p<.001). The area under the Receiver Operating Characteristics (ROC) curves of different low glucose ranges or number of hypoglycaemic events ≤55 mg/dl was different from chance assignments (≤70 mg/dl: ROC 0.68 (95% CI 0.60 to 0.77, p<.001); ≤55 mg/dl: ROC 0.68 (0.60 to 0.77, p<.001); number of events ≤55 mg/dl: ROC 0.67 (0.58 to 0.76, p<.001)). Time in range (>70 to <180 mg/dl) does not enable identification of patients with type 1 diabetes and SH in the past (ROC 0.59 (0.49 to 0.69, p=.062)) significantly better than chance.

Conclusion: Time spend in low glucose range during CGM assessment or number of hypoglycaemic events ≤55 mg/dl can discriminate between patients with type 1 diabetes and previous occurrences of SH respectively hypoglycaemia unawareness without occurrence of SH. For the identification of patients with SH events, duration of low glucose values or number of low glucose events appears to be more important than time spent in euglycaemic range. The potential of CGM to identify patients with and without SH is not fully exhausted, since different targets might be applicable to both groups. In patients with SH prevention of re-occurrence of SH should be the primary aim (secondary prevention), whereas in patients without SH, but with hypoglycaemia unawareness the primary prevention of SH should be the primary objective.

Day-to-day variability of fasting self-measured plasma glucose correlates with risk of hypoglycaemia in adults with type 1 and type 2 diabetes

T.S. Bailey[1], A. Bhargava[2], J.H. De Vries[3], G. Gerety[4], J. Gumprecht[5], W. Lane[6], C.H. Wysham[7], B.A. Bak[8], E. Hachmann-Nielsen[9], A. Philis-Tsimikas[10];

[1]AMCR Institute, Escondido, [2]Iowa Diabetes and Endocrinology Research Center, Des Moines, USA, [3]University of Amsterdam, Amsterdam, Netherlands, [4]Albany Medical Center, Albany, USA, [5]Medical University of Silesia, Zabrze, Poland, [6]Mountain Diabetes and Endocrine Center, Asheville, [7]Rockwood Clinic, Spokane, USA, [8]Novo Nordisk A/S, Søborg, Denmark, [9]Novo Nordisk A/S, Frederiksberg, Denmark, [10]Scripps Whittier Diabetes Institute, San Diego, USA.

Background and aims: The relationship between hypoglycaemia and day-to-day variability of glycaemic control has not yet been well established. This *post hoc* analysis aimed to investigate the correlation between the day-to-day variability of fasting self-measured plasma glucose (SMPG) and hypoglycaemia in patients with type 1 (T1D) and type 2 diabetes (T2D).

Materials and methods: A *post hoc* analysis was performed correlating day-to-day variability of fasting SMPG with hypoglycaemia in two double-blind, treat-to-target, crossover trials that compared insulin degludec once daily (OD) with insulin glargine U100 OD in adults with T1D (SWITCH 1, n=501) or insulin-experienced adults with T2D (SWITCH 2, n=721). Available pre-breakfast SMPG measurements were used to determine a weekly variance for each patient, using the log SMPG values to allow for relative comparisons. For each patient and treatment, the geometric mean of the weekly variance was calculated and these values were categorised into low, medium and high tertiles, as a measure for day-to-day variability. The effect of having low or high variability compared with medium variability was analysed in relation to overall symptomatic (severe or blood glucose [<3.1 mmol/L (56 mg/dL)] confirmed), nocturnal symptomatic (00:01-05:59, both inclusive), and severe (requiring third-party assistance and confirmed by a blinded adjudication committee) hypoglycaemia.

Results: Day-to-day SMPG variability was a significant predictor for the risk of overall and nocturnal hypoglycaemia in T1D and T2D, and severe hypoglycaemia in T1D (Table).

Conclusion: In conclusion, day-to-day glycaemic variability is associated with a risk of hypoglycaemia.

Table. Effect of fasting SMPG variability on hypoglycaemia in SWITCH 1 and 2: low and high tertiles compared with medium tertile

Within-day variability based on 9-point profiles correlates with risk of overall and nocturnal hypoglycaemia in adults with type 1 and type 2 diabetes

G. Gerety[1], T.S. Bailey[2], A. Bhargava[3], J.H. De Vries[4], J. Gumprecht[5], W. Lane[6], C.H. Wysham[7], B.A. Bak[8], C.T. Hansen[8], A. Philis-Tsimikas[9]; [1]Albany Medical Center, Albany, [2]AMCR Institute, Escondido, [3]Iowa Diabetes and Endocrinology Research Center, Des Moines, USA, [4]University of Amsterdam, Amsterdam, Netherlands, [5]Medical University of Silesia, Zabrze, Poland, [6]Mountain Diabetes and Endocrine Center, Asheville, [7]Rockwood Clinic, Spokane, USA, [8]Novo Nordisk A/S, Søborg, Denmark, [9]Scripps Health Whittier Diabetes Institute, San Diego, USA.

Background and aims: Higher glycaemic variability has previously been linked to an increased risk of hypoglycaemia. This *post hoc* analysis investigated the correlation between clinical within-day glycaemic variability, based on 9-point profiles, and hypoglycaemia in patients with type 1 (T1D) and type 2 diabetes (T2D).
Materials and methods: The correlation between within-day variability, based on 9-point profiles, and hypoglycaemia was investigated as a *post hoc* analysis in two double-blind, treat-to-target, crossover trials comparing insulin degludec once daily (OD) with insulin glargine U100 OD in adults with T1D (SWITCH 1, n=501) or insulin-experienced adults with T2D (SWITCH 2, n=721). Within-day glycaemic variability was calculated as the relative fluctuation of the 9-point profile, defined through the integrated absolute distance from the mean. Variabilities were subsequently categorised into low, medium and high tertiles based on the geometric mean of the two 9-point profiles available per patient and treatment. Hypoglycaemia was defined as overall symptomatic (severe or blood glucose [<3.1 mmol/L (56 mg/dL)] confirmed), nocturnal symptomatic (00:01-05:59, both inclusive) and severe (requiring third-party assistance and confirmed by a blinded adjudication committee) events.
Results: Within-day variability was a significant predictor for the risk of overall and nocturnal hypoglycaemia in patients with T1D or T2D (Table). However, no correlation was found for severe hypoglycaemia in this dataset.
Conclusion: In conclusion, within-day glycaemic variability is associated with a risk of overall and nocturnal hypoglycaemia.

Decreased glucose intestinal absorption lowers 2 hour postprandial glycaemia after gastric bypass

V. Raverdy, H. Verkindt, R. Caiazzo, F. Pattou;
Translational Research in Diabetes, Lille University, INSERM, CHU Lille, Lille, France.

Background and aims: Postprandial hypoglycemia is a frequent concern after Roux-en-Y gastric bypass (RYGB). This condition occurs generally 2 hours after a meal. It is favored by postoperative weight loss in patients with high preoperative beta cell function. However, it is rarely observed after ajustable gastric banding (AGB). The aim of the study was to determine the specific mechanisms responsible for lowering two hour postprandial blood glucose after RYGB.
Materials and methods: We enrolled in a parallel arm, observational study, 109 patients undergoing RYGB (n=89) or AGB (n=20). All patients were submitted to a standardized mixed meal test (MMT) prior to, and again 3, 12, or 60 months after surgery. We measured glucose, insulin, and glucagon like peptide-1 (GLP-1) postprandial profiles during 3 hours after the mixed meal, as well as intestinal glucose absorption (D-xylose test), and calculated validated indices of insulin sensitivity (Matsuda index), and postprandial beta cell function (Insulinogenic index).
Results: The shape of postprandial blood glucose curve remained unchanged after AGB. After RYGB an early rise at 30 minutes was followed by a rapid fall beyond 60 minutes. When adjusted to fasting level, 2 hour postprandial blood glucose was significantly lower after RYGB than after AGB, independent of BMI, insulin sensitivity, and beta cell function (linear mixed model, $p < 0.0001$). Two hour postprandial blood glucose was significantly associated with lower intestinal glucose absorption (area under the curve of D-xylose), independent of BMI, insulin sensitivity, beta cell function, and GLP1 response (linear mixed model, $p < 0.01$).
Conclusion: Two hour postprandial blood glucose decreases after RYGB in close relation with intestinal glucose absorption, independent of BMI, insulin sensitivity, beta cell function, and GLP1 response.

PS 054 Hypoglycaemia: treatment and consequences

730

High one year mortality rate following admissions with severe hypoglycaemia to the hospital: Which group of patients is most at risk?

M.M. Teh, S.Y. Goh, Y.M. Bee, E. Chan, A. Tan, X.H. Xin, L.C. Ang, W.M. Heng, W.Y. Lim;
Department of Endocrinology, Singapore General Hospital, Singapore, Singapore.

Background and aims: Intensification of glycaemic control in diabetes patients increases the risk of severe hypoglycaemia. Hence, hypoglycaemia is recognised as a barrier to attaining good diabetes control. Severe hypoglycaemia is associated with increase mortality but there is a lack of evidence to link hypoglycaemia and mortality directly. Self - reporting of severe hypoglycaemia is associated with increased mortality at least in the medium term of 5 years. However, much less is known about the 1 year short term mortality rate following hospital admissions with severe hypoglycaemia.
The aims of the study are: 1.To ascertain the 1 year short term mortality rate following admission with severe hypoglycaemia to an acute tertiary care hospital. 2.To determine the factors which influence the 1 year mortality rate.
Materials and methods: Clinical, biochemical and 1 year mortality data from diabetes patients who were admitted with severe hypoglycaemia in the year of 2014 were extracted from the institutional medical record. Comparison of the patients' characteristics was made between the patients who survived a year following admission with those who did not survive a year following admission. Logistic regression was used to determine the risk of death within 1 year which is expressed as odd ratio and 95% confidence interval (CI).
Results: Three hundreds and eleven patients (185F: 126M) had been admitted with severe hypoglycaemia and the mean capillary blood glucose on admission was 2.3±0.7 mmol/l. Mean age, glycated haemoglobin and Charlson Comorbidity index (CCI) of the cohort were 70.7 ±11.2 year old, 6.9±1.4% and 4.5±2.1 respectively. Seventy patients or 22.5% of the cohort died within a year of admission. Those who deceased were older (69.2±11.0 vs 75.3±11.0 year old, $p<0.05$) with higher CCI (4.1 ±1.9vs6.0±2.3, $p<0.05$) and longer length of stay (5.0±7.4vs 10.0±14.5 days, $p<0.05$). However, there was no significant difference in glycated haemoglobin level between the 2 groups (7.0±1.4vs 6.7±1.6%, $p>0.05$). The patients who deceased within a year of admission also had lower albumin count on admission (36.2±5.4vs 30.3±6.8G/L, $p<0.05$). Age, length of stay and CCI were associated with increased in 1 year mortality risk with odd ratio of 1.06 (95% CI: 1.03 -1.09, p =0.01), 1.05 (95% CI: 1.02-1.08, p=0.01) and 1.57 (95% CI: 1.34-1.83, $p<0.001$) respectively.
Conclusion: Alarmingly high 1 year mortality rate of 22.5% following admissions with severe hypoglycaemia. Older diabetes patients with more comorbidities and longer length of stay were at increased risk of dying within a year of admission with severe hypoglycaemia. The degree of glycaemic control did not influence the 1 year mortality rate significantly. There was insufficient evidence in the current data set to draw the definitive link between hypoglycaemia and the cause of death. The high 1 year mortality rate also highlighted the vulnerabilities of certain individuals to adverse outcomes. Hence, admission with severe hypoglycaemia has important prognostic implications. Admission with severe hypoglycaemia offers the window of opportunity for healthcare professionals to intervene by comprehensively addressing the issue of hypoglycaemia and other health issues especially in the high risk group of patients.

Psychological impact of severe hypoglycaemia on fear of hypoglycaemia and diabetes-related distress: baseline assessment in participants of the HypoDe study

D. Ehrmann[1], N. Hermanns[1], L. Heinemann[2], G. Faber-Heinemann[2], G. Freckmann[3];
[1]Research Institute Diabetes Academy Mergentheim (FIDAM), Bad Mergentheim, [2]Science-Consulting in Diabetes GmbH, Düsseldorf, [3]Institut für Diabetes-Technologie Forschungs- und Entwicklungsgesellschaft mbH an der Universität Ulm, Ulm, Germany.

Background and aims: Patients with type 1 diabetes on a multiple daily insulin injections (MDI) regimen were eligible to participate in the HypoDE study if they reported reduced hypoglycaemia awareness (unawareness-score ≥4) or the occurrence of severe hypoglycaemia (SH) in the past 12 months. We analysed the psychological profile of participants who had experienced at least one episode of SH (third party assistance for recovery) vs. participants with hypoglycaemia unawareness, but without a recent SH episode.
Materials and methods: Blinded CGM recordings (DexCom Gen 4; 28 days) of 149 study participants (age 46.5±11.9 yrs, 40.3% female, HbA1c 7.5±1.0%, diabetes duration 21.3±11.9 yrs) which had completed the Hypoglycaemia Awareness Questionnaire (HAQ), the Hypoglycaemia Fear Survey (HFS) and the Diabetes Distress Scale (DDS) were analysed.
Results: Participants who experienced SH and participants without SH did not differ in age (46.1±11.5 vs. 47.2±12.5 yrs, p=.578), diabetes duration (22.6±13.9 vs. 19.1±13.7 yrs, p=.126) or gender (female 42.2% vs. 37.3%, p=.551). Patients who experienced SH had a lower HbA1c (7.2±1.0% vs. 7.8±0.9%, p<.001) and a lower HAQ score (4.6±0.6 vs. 5.0±1.4, p=.018) compared to the group of patients without SH. Patients with SH also spent more time in the hypoglycaemic range (≤70mg/dl: 131±99 vs. 72±55 min per day, p<.01) and less time in the hyperglycaemic range (≥180 mg/dl: 441 ±221 vs. 568±244 min per day, p=.001) during the baseline blinded CGM phase. These participants also reported more worries about hypoglycaemia (34.6±14.4 vs. 29.2±15.2, p=.030) and more avoidance behaviour towards low glucose values (22.2±9.1 vs. 18.7±8.3, p=.020) than participants without SH. Overall, diabetes distress was higher in subjects with SH (2.7±0.8 vs. 2.3±0.7, p=.003) than in patients without SH. Participants with SH also reported more feelings of powerlessness (3.3±1.2 vs. 2.8±1.1, p=.010), more hypoglycaemia-related distress (3.9±1.2 vs. 3.3±1.2, p=.007), more social problems in public (2.2±1.1 vs. 1.8±0.9, p=.045), more family arguments (2.7±1.1 vs. 2.1±1.1, p=.003) and physician-related distress (1.4 ±0.7 vs. 1.2±0.4, p=.014) as well as eating-relating distress (2.7±1.2 vs. 2.3±1.1, p=.025). Overall diabetes-related distress and negative family arguments showed significant correlations with duration of hypoglycaemic episodes (r=.19, p=.022 respectively r=.20, p=.012).
Conclusion: Occurrence of SH affects many areas of living with diabetes. The psychological impact of SH was strongest with regard to family arguments and the overall distress levels. Avoidance of hypoglycaemic glucose values was also more prominent in participants with SH. Diabetes distress and family arguments was not only correlated with occurrence of SH but also with the duration of low glucose values. Besides the reduction of biochemical and clinical hypoglycaemia, also hypoglycaemia-related distress should be addressed in this specific group of patients with diabetes.

Association of hypoglycaemia with insulin titration and body weight in people with type 2 diabetes commencing insulin glargine 100 U/ml and achieving different HbA_{1c} levels

B.M. Frier[1], W. Landgraf[2], M. Zhang[3], G.B. Bolli[4], D.R. Owens[5], P.D. Home[6];

[1]The Queen's Medical Research Institute, University of Edinburgh, Edinburgh, UK, [2]Sanofi Germany, Frankfurt, Germany, [3]Sanofi US, Bridgewater, USA, [4]University of Perugia School of Medicine, Perugia, Italy, [5]Swansea University, Swansea, [6]Newcastle University, Newcastle upon Tyne, UK.

Background and aims: To assess the relationship between hypoglycaemia frequency, insulin dose titration, and body weight in people with type 2 diabetes (T2D) commencing Gla-100 at bedtime in combination with oral agents, and achieving different HbA_{1c} levels at Week 24.
Materials and methods: Standardized patient-level data were pooled from 16 treat-to-target randomized controlled trials (≥24 week duration, fasting plasma glucose [FPG] target <5.5 mmol/l). Glycaemic and hypoglycaemia outcomes were assessed descriptively to Week 24, stratified according to endpoint HbA_{1c} (<7.0, 7.0-8.0, >8.0%) and number of episodes (0, 1-3, ≥4) of confirmed hypoglycaemia (PG <3.9 mmol/l).
Results: Overall, 3,415 participants (54% male) were included. Baseline characteristics in the <7.0, 7.0-8.0, and >8.0% HbA_1 categories were (mean ± SD): age 58 ± 9, 58 ± 10, and 57 ± 10 years; disease duration 8.1 ± 5.6, 9.4 ± 6.5 and 10.0 ± 6.7 years; BMI 30.8 ± 5.0, 30.5 ± 5.4 and 29.9 ± 5.4 kg/m^2; C-peptide level 1.16 ± 0.55, 1.13 ± 0.57, and 1.16 ± 0.77 nmol/l, respectively. More participants (46%) achieved endpoint HbA_{1c} <7.0% than 7.0-8.0% (37%) or >8.0% (17%) and more people achieved FPG target (≤ 5.5 mmol/l) in the <7.0% group (44%) vs other groups (30% and 22%) despite similar reductions in FPG (−4.1 ± 0.1 mmol/l) from baseline to Week 24. HbA_{1c} response was lower in the >8.0% group (−0.5%) vs other groups (−2.0 and −1.4%), associated with longer diabetes duration, higher baseline FPG and HbA_{1c}. In the <7.0% group, more people (54%) had anytime hypoglycaemia (PG <3.9 mmol/l), had the lowest mean final Gla-100 dose (0.42 U/kg vs 0.44 U/kg and 0.51 U/kg, respectively), and the smallest dose increment (0.27 U/kg vs 0.28 U/kg and 0.32 U/kg, respectively). FPG change was greater in patients with ≥4 hypoglycaemia events vs those with no hypoglycaemia events in the <7.0% group (−4.5 vs −4.1 mmol/l) and the >8.0% group (−5.7 vs −3.5 mmol/l). Hypoglycaemia was associated with lower baseline C-peptide levels and lower final Gla-100 dose across all HbA_{1c} groups in people experiencing hypoglycaemia (**Table**). Weight gain was more pronounced in people with increasing numbers of hypoglycaemia events and with higher endpoint HbA_{1c} (1.1 ± 4.1 kg, 2.0 ± 3.5 kg, 2.4 ± 3.5 kg) in those with no hypoglycaemia vs 1.8 ± 3.7 kg, 2.5 ± 3.0 kg, and 3.7 ± 3.8 kg in those with ≥4 hypoglycaemia events and HbA_{1c} <7.0, 7.0-8.0, and >8.0%, respectively).
Conclusion: This pooled analysis of people with T2D confirms that baseline HbA_{1c} and FPG levels are important predictors for achieving HbA_{1c} <7.0%. Hypoglycaemia apparently has little or no influence on HbA_{1c} achievement and is mainly associated with insulin dose titration and weight gain over the first 6 months after beginning Gla-100 therapy.

Table. Clinical outcomes in people with type 2 diabetes starting Gla-100, stratified by endpoint HbA_{1c} range

		<7.0% n=1,584	7.0–8.0% n=1,262	>8.0% n=569
Hypoglycaemia[a]	no events (% people)	46	53	65
	1–3 events (% people)	30	26	20
	≥4 events (% people)	24	21	15
	event rate (events/person-year)	6.5 (0.3)	5.3 (0.3)	4.4 (0.5)
Hypoglycaemia[a] no events	C-peptide baseline (nmol/l)	1.22 (0.62)	1.20 (0.55)	1.28 (0.86)
	FPG week 24 (mmol/l)	6.0 (1.4)	6.8 (1.8)	8.3 (3.1)
	Gla-100 dose Week 24 (U/kg)	0.45 (0.24)	0.46 (0.24)	0.56 (0.31)
≥4 events	C-peptide baseline (nmol/l)	1.08 (0.54)	1.00 (0.48)	0.75 (0.38)
	FPG Week 24 (mmol/l)	5.9 (1.7)	6.2 (1.9)	6.3 (1.9)
	Gla-100 dose Week 24 (U/kg)	0.37 (0.20)	0.39 (0.23)	0.41 (0.21)

Recurrent insulin-induced hypoglycaemia leads to weight gain in association with increased adiposity and reduced basal metabolic rate

A.D. McNeilly, J.R. Gallagher, R.J. McCri;
Division of Molecular and Clinical Sciences, University of Dundee, Dundee, UK.

Background and aims: Intensification of insulin therapy in type 1 diabetes is associated with significant weight gain. This study examined the hypothesis that recurrent hypoglycaemia (RH) might contribute, at least in part, to this phenomenon. This hypothesis was tested in rodents subjected to RH or control injections over 12 weeks.
Materials and methods: Male C57BL6J mice (n=12/group) received either RH (1mu/g insulin i.p.; 3 per week for 12 weeks to achieve glucose of approx.3.0mmol/l) or Vehicle (Saline i.p. in equivalent volume). Body composition and energy homeostasis were assessed using EchoMRI and CLAMS system respectively. Transcript abundance was assessed using Taqman real time PCR. Data are expressed as mean±SEM.
Results: RH animals were significantly heavier and had increased fat mass compared to Control animals (8.49±0.64 v 16.56±1.38% body weight) despite comparable food intake (4.83±0.81 v 4.89±0.44 g/mouse/24hr). Energy expenditure was significantly lower at baseline in RH animals (0.414±0.006 v 0.218±0.004 kcal/min) and was associated with a decrease in the respiratory exchange ratio (RER; 0.98±0.01 v. 0.96 ±0.01). There was no difference in locomotor activity. These changes were associated with the suppression of genes involved in thermogenesis, mitochondrial energetics and lipolysis within the brown adipose tissue.
Conclusion: Consistent with our hypothesis, RH leads to increased accumulation of fat stores which is associated reduced energy expenditure and RER. These results suggest that RH induces a state of hypometabolism that may contribute to weight gain observed with intensification of insulin therapy in Type 1 diabetes

Fear of hypoglycaemia was not associated with glycaemic variability in patients with type 1 diabetes: the VARDIA study

S. Hadjadj[1], E. Gand[1], L. Chaillous[2], S. Dubois[3], F. Bonnet[4], G. Fradet[5], I. Delcourt Crespin[5], V. Kerlan[6], D. Gouet[7], C. Perlemoine[8], P.-H. Ducluzeau[9], M. Pichelin[10], S. Ragot[11], P.-J. Saulnier[11], B. Cariou[10];
[1]Endocrinology -Diabetology, CHU Poitiers, Poitiers, [2]Endocrinology - Diabetology, CHU NANTES, Nantes, [3]Endocrinology - Diabetology, CHU Angers, Angers, [4]Endocrinology - Diabetology, CHU Rennes, Rennes, [5]Endocrinology -Diabetology, CH La Roche/Yon, La Roche/Yon, [6]Endocrinology -Diabetology, CHU Brest, Brest, [7]Endocrinology -Diabetology, CH La Rochelle, La Rochelle, [8]Endocrinology - Diabetology, CH Lorient, Lorient, [9]Endocrinology - Diabetology, CHU Tours, Tours, [10]CIC 1413, CHU Nantes, Nantes, [11]CIC 1402, CHU Poitiers, Poitiers, France.

Background and aims: In type 1 diabetes (T1D), treatment efficacy is limited by unpredictability of blood glucose results and glycemic variability. This unpredictability strongly and negatively impacts patients' appreciation of their disease. Fear of Hypoglycemia (FOH) remains associated with significant issues for managing insulin treatment. The main goal of our study was to assess the relationship between glycemic variability and FOH in patients with T1D in an observational cross-sectional study performed in 9 centers from Western France.
Materials and methods: Main recruitment criteria were the following: men or women with T1D diagnosed for ≥ 5 years, aged 18 - 75 years, on stable insulin therapy (type of insulin and number of injections/pump) for ≥ 3 months, no severe renal failure (eGFR ≥ 30 ml/min/1.73 m^2) and no acute condition possibly leading to unusual glycemic

variability.Glycemic variability was determined using the coefficient of variation of three 7-point self-monitoring blood glucose (SMBG) profile determined in 2 weeks: 3 pre-meal /3 post-prandial/ 1 night (4:00) determinations. FOH was assessed using the validated French version of the Hypoglycemia Fear Survey-II (HFS-II) questionnaire.
Results: A total of 571 patients were recruited, with 527 fulfilling all recruitment criteria. Among them, 393 returned their SMBG profiles: 55% women, 55% on insulin pump, mean age 48 ± 12 years, mean diabetes duration of 26±13 years, HbA1c of 7.5±1.0 % and 12% with severe hypoglycemia (requiring assistance from another person) in the previous 6 months. HFS-II score was 34±18. SMBG glycemic variability was not significantly different between patients treated with continuous subcutaneous insulin infusion and multiple daily injections (39.3±9.4 and 40.9±10.1 % respectively).SMBG variability did not significantly correlate with HFS-II score (R= 0.022; *P*=0.69), and was not associated with the presence or absence of long-term complications (retinopathy, nephropathy and cardiovascular disease). HFS-II score was not different according to the distribution of quintiles of SMBG variability.The SMBG variability did not differ between patients with or without history of severe hypoglycemic episode in the previous 6 months (42±11 vs. 40 ±9 *P*=0.12), but HFS-II score was higher in patients with history of severe hypoglycemia: 39±20 vs. 33±18; *P*=0.03, respectively regarding anxiety (18±13 vs. 23±15; *P*=0.02), but not behavior (15±8 vs. 16±8; *P*=0.263).
Conclusion: FOH determined using the HFS-II questionnaire was not associated with SMBG variability in patients with T1D, but was associated with the occurrence of severe hypoglycemia in the previous 6 months.

A pilot study of mini-dose glucagon for treatment of non-severe hypoglycaemia in adults with type 1 diabetes

M. Haymod[1], S. DuBose[2], M. Rickels[3], H. Wolpert[4], V. Shah[5], J. Sherr[6], R. Weinstock[7], S. Agarwal[3], A. Verdejo[2], M. Cummins[8], B. Newswanger[8], R. Beck[2];
[1]Baylor College of Medicine, Houston, [2]Jaeb Center for Health Research, Tampa, [3]University of Pennsylvania Perelman School of Medicine, Philadelphia, [4]Joslin Diabetes Center, Boston, [5]Barbara Davis Center for Diabetes, University of Colorado, Aurora, [6]Yale School of Medicine, New Haven, [7]SUNY Upstate Medical University, Syracuse, [8]Xeris Pharmaceuticals, Austin, USA.

Background and aims: The objective of this analysis is to evaluate the use of low-dose glucagon to treat mild hypoglycemia in ambulatory adults with type 1 diabetes.
Materials and methods: Twenty adults with type 1 diabetes using an insulin pump and continuous glucose monitor (CGM) and experiencing frequent mild hypoglycemia participated in a crossover trial (two 3-week periods) comparing non-aqueous mini-dose glucagon (MDG) (150 μg, Xeris Pharmaceuticals, Inc.) versus oral glucose tablets (TABS) (16 g) to treat hypoglycemia (blood glucose [BG] 40-69 mg/dL). BG meter measurements were made prior to treatment and again 15 and 30 minutes post-treatment. Successful treatment was defined as BG ≥50 mg/dL 15 minutes and ≥70 mg/dL 30 minutes after intervention. Two authors, blinded to treatment arm, independently judged the outcome of each event as a clinical success or failure.
Results: Sixteen participants (mean age 39 years, 75% female, mean diabetes duration 23 years, mean HbA1c 7.2%) had 118 analyzable events with initial BG 50-69 mg/dL. Successful treatment criteria were met for 58 (94%) of 62 events during the MDG period and 53 (95%) of 56 events during the TABS period (adjusted p=0.99). Clinical assessments of success for these events were 97% and 96%, respectively. CGM-measured time 70-180 mg/dL data did not differ between treatment groups during the 2 hours post-events but TABS resulted in higher maximum glucose (116 vs 102 mg/dL; p=0.01) over the first hour.
Conclusion: Small doses of glucagon can successfully treat mild-to-moderate hypoglycemia and may be a useful alternative to treatment with oral carbohydrate.

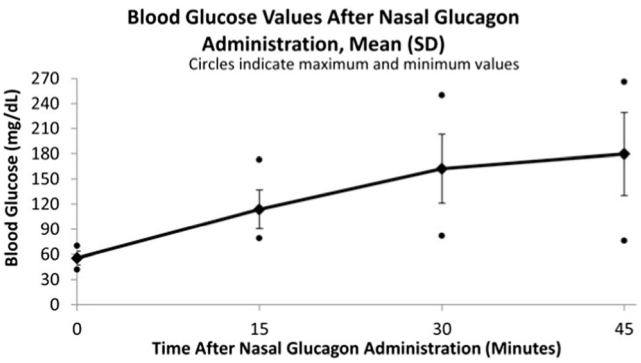
Nasal glucagon for the treatment of moderate to severe hypoglycaemia episodes in children and adolescents with type 1 diabetes in home or school settings

C.B. Guzman[1], L. Deeb[2], H. Dulude[3], M. Zhang[4], S. Zhang[5], B.J. Reiner[6], C.A. Piché[3];
[1]Lilly Diabetes, Eli Lilly and Company, Indianapolis, [2]Pediatric Endocrine Office, Tallahassee, USA, [3]Locemia Solutions, Montreal, [4]Eli Lilly Canada Inc., Toronto, Canada, [5]Eli Lilly and Company, Indianapolis, [6]Pediatric Endocrine Office, Baltimore, USA.

Background and aims: This multicenter, open-label study evaluated NG for effectiveness and ease of use in treating moderate or severe hypoglycemia episodes in patients with T1D, age 4 to <18 years.
Materials and methods: Patients and caregivers were taught how to use NG. During naturally occurring symptomatic episodes of moderate or severe hypoglycemia in real-world settings, caregivers administered 3 mg NG and measured blood glucose (BG) over time. Adverse events (AEs), recovery of symptoms, and ease of use were solicited by questionnaires.
Results: Fourteen patients, who experienced 33 moderate hypoglycemia episodes with neuroglycopenic symptoms and a BG ≤70 mg/dL, were included in the efficacy and main safety analyses. The mean number of episodes per pt was 2.4 (range 1-4). In all episodes, patients returned to normal status within 30 minutes after NG dose. No calls to 911 (emergency medical services) were needed. Mean baseline BG was 56 (range 42-70) mg/dL. Within 15 minutes after NG dose, mean BG rose to 114 (range 79-173) mg/dL, and continued to rise (figure). No serious AEs occurred. For most episodes (61%), caregivers administered NG in <30 seconds; in all cases administration took <2 minutes. Caregivers were satisfied or very satisfied with NG after most episodes (91%).
Conclusion: NG raised BG and resolved symptoms in all reported episodes of hypoglycemia among children and adolescents with T1D. The majority of caregivers were highly satisfied with NG. Data suggest NG is a viable alternative to currently available injectable recombinant glucagons.



Mean blood glucose at time 0 was 56 mg/dL

A pilot study in adults with type 1 diabetes to examine the efficacy of stable non-aqueous liquid glucagon for treatment of severe hypoglycaemia

M. Christiansen[1], M. Cummins[2], S. Prestrelski[2], L. Shi[3], P. Strange[3,2];
[1]Diablo Clinical Research, Walnut Creek, [2]Xeris Pharmaceuticals, Austin, [3]Integrated Medical Development, Princeton Junction, USA.

Background and aims: Severe hypoglycemia remains a significant problem in patients with diabetes. Currently approved rescue products are based on lyophilized formulations which require reconstitution at time of use, complicating administration in emergency situations. A premixed, ready-to-use, non-aqueous liquid glucagon formulation in a prefilled syringe and auto-injector is in development. This glucagon formulation is expected to be stable for at least 24 months at room temperature. A pilot study was conducted in adults with type 1 diabetes mellitus (T1DM) to explore whether subcutaneously injected non-aqueous glucagon (0.5 or 1 mg) could rescue subjects from insulin-induced hypoglycemia.
Materials and methods: On treatment days subjects arrived at the clinic following an overnight fast and were given IV insulin to induce moderate hypoglycemia with plasma glucose concentration < 2.8 mmol/l. After a 5-minute wait and a confirmatory plasma glucose < 2.8 mmol/l, subjects were given a subcutaneous injection of non-aqueous liquid glucagon in the upper arm. The product was stored in a vial for approximately 18 months at controlled room temperature before it was used in the study. Plasma glucose was assessed every 15 minutes via glucometer (YSI Life Sciences) during the hypoglycemia induction phase. Once plasma glucose was < 2.8 mmol/l, glucose was assessed every 5 minutes until 90 minutes post-treatment. At the same time points during the induction phase and through 30 minutes post-treatment, subjects completed a hypoglycemia symptom questionnaire. Pharmacodynamic characteristics of plasma glucose were assessed with particular attention to time to reach > 3.9 mmol/l. Subjects with return of plasma glucose to > 3.9 mmol/l by 30 minutes post-dosing were considered a primary (objective) responder. Secondary efficacy endpoints included hypoglycemia symptom relief as assessed based on aggregate scores for 4 autonomic and 4 neuroglycopenic symptoms. Safety endpoints included: incidence/severity of adverse events, clinically significant out-of-range vital signs, and tolerability.
Results: Across 7 adult subjects and 13 hypoglycemia induction procedures, IV insulin resulted in a mean plasma glucose of 2.5 ± 0.18 mmol/l just prior to treatment. For the 1 mg dose, 7/7 subjects achieved primary response with plasma glucose > 3.9 mmol/l in a mean time of 11.9 minutes (range: 8.1 to 15.9 minutes). For the 0.5 mg dose, 6/6 subjects achieved plasma glucose > 3.9 mmol/l in a mean time of 14.4 minutes (range: 9.5 to 19.7 minutes). Symptomatic relief began within 5 minutes of dosing, and all subjects experienced complete resolution of hypoglycemia symptoms in a median time of 20 minutes (range 10-30). Overall, no significant safety concerns were noted in this pilot study. For the 1 mg dose, 3/7 subjects reported a total of 8 mostly mild treatment-emergent adverse events, including 3 cases of nausea/vomiting.
Conclusion: The results of this study provide support for Phase 3 clinical development of this room-temperature stable non-aqueous liquid glucagon in a ready-to-use auto-injector as a rescue treatment for severe hypoglycemia.
Clinical Trial Registration Number: NCT02423980

Dasiglucagon, a novel soluble glucagon analogue, successfully restores blood glucose levels after hypoglycaemia in people with type 1 diabetes

T. Heise[1], B. Væver Bysted[2], U. Mouritzen[2], U. Hövelmann[1], D. Lamers[1], D. Vega Møller[2];
[1]Profil, Neuss, Germany, [2]Zealand Pharma A/S, Glostrup, Denmark.

Background and aims: Currently available glucagon formulations for rescue treatment of severe hypoglycaemia need to be reconstituted before use which delays its use and may lead to underutilization.
Materials and methods: In this single centre, randomised, double-blind trial we investigated the pharmacodynamic (PD) and pharmacokinetic (PK) characteristics of dasiglucagon (DASI), a novel stable soluble glucagon analogue, in comparison to GlucaGen® (GLUCA). Fifty-eight patients with type 1 diabetes received subcutaneous injections of 0.1, 0.3, 0.6 or 1 mg DASI or 0.5 or 1 mg GLUCA after induction of hypoglycaemia (55 mg/dl) through intravenous insulin infusion.
Results: DASI demonstrated a dose-dependent and rapid increase in PK reaching maximum levels at ~35 min with a half-life of ~0.5 hours. DASI rapidly increased plasma glucose (PG) by ≥20 mg/dl (9-14 min) and to PG≥70 mg/dl (within 6-10 min), similar to GLUCA (table). All patients on DASI reached these endpoints within 30 min (predefined success criteria). Both treatments were well tolerated. Nausea was the most frequent adverse event occurring at a similar rate of 44-56% patients.
Conclusion: DASI was well tolerated and showed similar early PD response to GLUCA at equivalent doses suggesting they have comparable clinical effects. Dasiglucagon may be an effective and reliable emergency treatment for severe hypoglycaemia in a ready-to-use pen.

Table 1

	Dasiglucagon*				GlucaGen®	
Dose	0.1 mg	0.3 mg	0.6 mg	1.0 mg	0.5 mg	1.0 mg

Nasal glucagon for the treatment of moderate-to-severe hypoglycaemic episodes in real-world settings in adults with type 1 diabetes

E.R. Seaquist[1], H. Dulude[2], M.X. Zhang[3], E. Rampakakis[4], R. Rabasa-Lhoret[5], G.M. Tsoukas[6], J.R. Conway[7], S.J. Weisnagel[8], G. Gerety[9], V. Woo[10], S. Zhang[3], D. Carballo[2], M. Triest[2], C.A. Piché[2], C.B. Guzman[3];
[1]University of Minnesota, Minneapolis, USA, [2]Locemia Solutions, Montreal, Canada, [3]Eli Lilly and Company, Indianapolis, USA, [4]JSS Medical Research, Montreal, [5]Montreal Clinical Research Institute, Montreal, [6]McGill University Health Centre, Montreal, [7]Canadian Centre for Research on Diabetes, Ontario, [8]CHU de Québec-Université Laval, Montreal, Canada, [9]Albany Medical Center, New York, USA, [10]University of Manitoba, Winnipeg, Canada.

Background and aims: This study evaluated nasal glucagon (NG) for efficacy and ease-of-use in moderate or severe hypoglycaemic episodes (HEs) in real-world settings in adult patients (pts) with type 1 diabetes (T1D).
Materials and methods: Pts and caregivers (CGs) were taught to administer NG 3 mg for symptomatic HE and to assess for return to normal status over time. In addition, Pt/CG-reported HE symptoms, blood glucose (BG), adverse events (AEs), and ease-of-use were evaluated through questionnaire.
Results: In the efficacy population (EP) 69 pts experienced a total of 157 HEs (mean [SD], 2.3 [1.77] events/pt). In 96.2% of HEs, pts met the primary objective, return to normal status within 30 minutes. There were 6 HEs in which the recovery did not occur within 30 minutes. In 5 of these 6 events, pts recovered within 30 to 45 minutes and in 4 events, BG was ≥3.9 mmol/L at 30 minutes. Mean BG at HE onset was 2.7 (range 1.2 to 4.1) mmol/L and rose to 6.3 (range: 2.4 to 14.8) mmol/L by 30 minutes and continued to rise with progressive time. No emergency service calls were made. Twelve severe HEs in 7 pts were observed in the EP. All severe HEs resolved; and pts awoke or returned to normal status within 15 minutes. NG administration time was <30 seconds for most HEs (70.4%) and was <2 minutes in nearly all (97.7%) HEs. The safety population included 74 pts who had a total of 179 HEs. At least 1 AE was experienced by 87.8% of pts, with the most common being nasal irritation (82.4%) and headache (54.1%). Most AEs during HEs lasted ≤1 hour (59.5%) and were of mild or moderate severity. There were no serious drug-related AEs, and CGs were satisfied or very satisfied with NG after most HEs (82.7%).
Conclusion: NG showed real-world effectiveness when administered to treat moderate or severe HE in pts with T1D. For most HEs (96.2%), pts recovered within 30 minutes and there were no emergency calls. The majority of CGs were satisfied with NG. NG is a potential alternative to currently available injectable recombinant glucagon.

Glycaemic index, extended bolusing and diabetes education in insulin pump therapy

S.K. Rilstone[1], N. Oliver[2];
[1]Department of Nutrition and Dietetics, Imperial College Healthcare NHS Trust, [2]Imperial College, London, UK.

Background and aims: Advice given to insulin pump users on how to manage slowly digested food is varied. There is no published evidence on whether educating patients on glycaemic index, extended bolusing and super bolusing can affect glycaemic control, quality of life or treatment satisfaction. The aim of this study was to evaluate the clinical and psychosocial efficacy of a clinical education programme on rates of digestion and bolusing.
Materials and methods: The literature on glycaemic index, extended bolusing and superbolusing was reviewed and consolidated to produce a three hour, interactive education session aiming to enable effective self-management. At baseline, participants undertook one week of blinded continuous glucose monitoring (CGM) and kept a food diary. During this period participants were provided with two test meals: a low GI meal (pizza with extra cheese) and a high GI meal (white bread with jam). Participants were asked to bolus in whatever way they would usually for these foods. Participants completed validated "Problem Areas in Diabetes" (PAID) and "Diabetes Quality of Life" (DQOL) questionnaires and blood samples were taken to measure HbA1c. The participants then attended the education programme. Four weeks after attending the educational intervention, the CGM and test meals week were repeated. 8 and 12 weeks after the intervention, participants underwent another week of CGM. At the end of week 12, HbA1c, DQOL and PAID were repeated. Glucose AUC were calculated at 1 hour, 2 hours, 4 hours and 8 hours after the test meals. Time spent in hyperglycemia and hypoglycaemia were calculated.
Results: Eleven participants were recruited (mean age 42.3 (SD 12.8) years, mean baseline HbA1c 57.3 (SD 10.0) mmol/mol, duration of diabetes 19.5 (SD 9.9) years). HbA1c did not change over the treatment period, nor did quality of life assessed by DQOL and PAID. %time spent in hypoglycaemia (<3.9mmo/L and <3.3mmol/L) fell at week 12 compared to baseline from 5.8 (IQR 2.1-8.3)% to 4.3(IQR 2.1-5.4)%, p=0.013, for <3.9mmol/L, and from 2.9 (IQR 1.2-3.9)% to 1.6 (IQR 0.7-2.4)%, p=0.029, for <3.3mmol/L. Area under the curve for glucose following test meals did not differ significantly following education except for in the first two hours after the high GI meal (pre course 83.1 (0.23-88.9), post course 5.38 (-16.2- 50.8).
Conclusion: An education programme to support type 1 diabetes self-management using extended and super boluses does not impact on overall glucose or quality of life but does reduce exposure to hypoglycaemia in this pilot study suggesting further work is warranted.

The smartphone application "Pregnant with Diabetes" communicates antenatal health information and reaches pregnant women with diabetes and those planning pregnancy

E.R. Mathiesen[1,2], S.K. Nørgaard[1,2], V. Ladefoged[1], C. Barfred[1], H.M. Juul[1], A.L. Secher[1,2], L. Ringholm[3], P. Damm[1,4];
[1]Center for Pregnant Women with Diabetes, Rigshospitaltet, Copenhagen, [2]Department of Endocrinology, Rigshospitalet, Copenhagen, [3]Steno Diabetes Center Copenhagen, Gentofte, [4]Department of Obstetrics, Rigshopitalet, Copenhagen, Denmark.

Background and aims: To evaluate the awareness and use of the smartphone application "Pregnant with Diabetes" locally, nationally and internationally.
Materials and methods: In 2013, a teamwork between a patient and the staff at The Center for Pregnant Women with Diabetes, Rigshospitalet, succeeded in developing the smartphone application (app) "Pregnant with Diabetes". The app communicates clinically important antenatal health information to women with diabetes, based on recommendations from our center. To obtain local data, women with type 1 or type 2 diabetes completed an anonymous, structured questionnaire at first antenatal visit in early pregnancy, at our center. National and international data on numbers of downloads were obtained from Google Play, App Store and Google analytics.
Results: Among 139 pregnant women with diabetes (96 with type 1 diabetes, 43 with type 2 diabetes), 99% had a smartphone and 75% had downloaded the app, whereof 48% had obtained information from the app before pregnancy. For women with type 1 diabetes, the topics reported of greatest interest in the app were "blood glucose", "the fetus", and "insulin dose", and for type 2 diabetes; "diet and carbohydrates", "blood glucose" and "what is diabetes". In December 2016, the app had been downloaded 3,810 times in Denmark and 21,640 times in 177 different countries worldwide. Internationally, the topics of greatest interest were "diet and carbohydrates", "blood glucose" and "possible complications".
Conclusion: Easily accessible patient information, via app technology, reaches the patients and may contribute to improved pregnancy planning and outcome in women with diabetes - locally, nationally and internationally.

Close reading and creative writing in a group care intervention to manage type 2 diabetes: a randomised trial

F.S. Rosário[1], D. Almeida[2], I. Correia[1], S. Oliveira[1], L. Narciso[1], A. Rodrigues[1], S. Barrocas[3], J. Oliveira[4], J.F. Raposo[1], L. Lima[3];
[1]Associação Protectora Diabéticos de Portugal, [2]Faculdade de Letras, Universidade de Lisboa, [3]ISCTE- Instituto Universitário de Lisboa, [4]Universidade Lusófona, Lisbon, Portugal.

Background and aims: The use of group dynamics for patients with diabetes is a recognized practice with positive outcomes in terms of metabolic control, quality of life parameters and knowledge acquisition about the condition. This study attempts to determine if the same group dynamic strategies using narrative and reading produce the same positive outcomes.
Materials and methods: A total of 49 patients with type 2 Diabetes, aged < 85 years old, with a follow-up in our outpatient clinic for at least 6 months and > 6 years of formal education were randomized to two different Group Care Dynamics. One group, with 17 patients, designed 'control group', was presented with a classical structured educational approach of six monthly sessions where different issues of diabetes management were discussed (chronic disease, nutrition, exercise, complications, self-management, and diabetic foot). Another group, with 32 patients, designed 'intervention group', subdivided in 2 similar subgroups, was presented with six monthly sessions with close reading and creative writing using literary narratives that parallel the issues focused in the control group. Participants were evaluated before the first session and after the third session. Two final evaluation will be performed at the sixt session and one month later. Patient evaluation includes anthropometrical measures (weight, fat mass, waist circumference), A1c and specific questionnaires about quality of life, locus of control, empathy and group satisfaction (respectively DQOL, SF36, DSLOC, JSPE, GSS).
Results: We present the baseline results and the interim analysis at the third session. The entire sample had an initial BMI of 29,16 (SD-4,67) and A1c of 7,51% (SD- 1,13). The two groups were very similar either in the physical and in the psychological variables at baseline. An interim analysis at the moment of the second evaluation was performed on a sample of 39 patients. The intervention group showed a significant reduction of HbA1c of 0,35% (initial: 7,55% (DP-1,13) vs. 7,20% (DP-1,06); p<0,001 while the control group maintained the A1c (initial: 7,44 %(DP-1,23) vs 7,42% (DP-1,49).
Conclusion: To our knowledge this is the first randomized trial designed to evaluate a Group Care intervention to manage type 2 diabetes using close reading and creative writing. At the interim analysis, a significant reduction of A1c was observed in the intervention group. The final appraisal of all the anthropometric and biochemical variables as well of the psychological domains will be made after the 6th month session.

Assessment of inpatient diabetes education throughout an structured questionnaire applied by a team for diabetes education (TED)

T.B.M. Cardim, M.T. Yamamoto, G. Daher, T.L. Santos, C.R. Laselva, F.N. Camargo, R.S. Ribeiro;
Diabetes Program, Albert Einstein Hospital, São Paulo, Brazil.

Background and aims: To describe the work and methodology for the implementation of a team for diabetes education in hospital settings and to test the efficiency of patient education using a adapted questionnaire based on American Association of Diabetes Educators.
Materials and methods: In August 2014, a project of diabetes education inspired by STAR Practical Diabetology Course was started, a questionnaire was adapted from American Association of Diabetes Educators to evaluate patient's knowledge. Eight professionals (6 nurses and 2 nutritional therapists) were selected, trained and designated to dedicate three hours weekly exclusively to diabetes education in collaboration with TED. From November 2014 to December 2014, the assigned professionals were trained in weekly sessions and initiated educational activities in January 2015.
Results: From January 2015 to January 2017, we included 474 patients; they were educated during hospitalization and were considered in this analysis. The questionnaire evaluated the perceived importance of DM care and the knowlwdge about DM, nutrition, physical activity, glycemic control and medications. For those on insulin, there were questions concerning administration and storage, glucose monitoring, response to hypo/hyperglycemia and foot care. Each item was scored form 0 (no knowledge) to 10 (full knowledge). The same questionnaire was applied as a pretest and after the educational process as a posttest. On average, age was 66+17 yrs and time of diagnosis was 16+2 yrs and 172 patients were on insulin. The average number of sessions were 1,9 (range 1-8). Previous A1c were available for 322 patients on the average: 8,1%. From all the patients 48 unaware of the diagnosis of DM and 55 with admissions primarily related to diabetes (15 ketoacidosis). Some of these patients did not agree or were not able to respond to the pretest (242). 175 (37%) answered the pretest and were reevaluated by the posttest. The major reasons for no reevaluation were discharge during weekend or without notification.
Conclusion: Using TED, we were able to develop a methodology to better assess the knowledge and skill of diabetic patients and to improve the education for complex patients By performing a structured evaluation, we documented an improvement in diabetes knowledge of hospitalized patients. Besides every patient has some knowledge of the disease, after the education guided by the question form, all patients increase their grades for each subject.

Family dialogue tools: how can healthcare professionals facilitate mutual involvement in families dealing with type 2 diabetes

D. Grabowski[1], K. Olesen[1], M.R. Reino[1], T. Andersen[2];
[1]Diabetes Management Research, Steno Diabetes Center Copenhagen, Gentofte, [2]Danish Diabetes Association, Copenhagen, Denmark.

Background and aims: Family involvement plays a key role in management of type 2 diabetes. Self-management interventions rarely target family dynamics or family education and support. Through an extensive design based research process including needs assessment, ideation, prototype-testing and feasibility study we have developed dialogue tools designed to generate mutual family involvement in daily family life with type 2 diabetes. To implement the tools in healthcare practice we have trained 70 diabetes educators in how to use the tools.
Materials and methods: 126 family members from 54 families participating in family education sessions filled in the Family functioning and change questionnaire before the session and then again 3-4 weeks after the session. 40 of these families were randomly chosen to take part in semi-structured family interviews that took place in their home. The combined data were analysed using radical hermeneutics.
Results: The analysis disclosed that the families were affected in 5 primary areas: 1) Knowledge: Many families found it easier to share knowledge and search for common knowledge after they had worked with the tools. Before working with the tools the relatives often felt that they lacked knowledge about the disease and how to support. Families often felt more involved in each other's life after the education session, 2) Communication: Before the sessions most families found it difficult to balance communication about type 2 diabetes. Some families do not talk about it at all and others talk too much about it. Many families seemed to find it easier to find that balance after working with the tools, 3) Roles: Accepting the role as a person with type 2 diabetes as well as the role as a relative to a person with type 2 diabetes is difficult. The dialogue generated by the tools make it easier to understand the new roles and to relate existing role structures to life with type 2 diabetes, 4) Everyday life: Most families do not want type 2 diabetes to dominate life and therefore try to maintain a perceived normality. After working with the tools families found it easier to accept type 2 diabetes in their lives and did not feel the need to create difficult practices designed to ignore the disease, 5) Support: Before the session many relatives found it difficult to be supportive without being controlling. Many families had experienced conflicts about support that had resulted in the relatives completely opting out of supporting and thereby significantly reducing mutual involvement. After working with the tools several families reported that they had gained a common understanding of each other's needs and worries and that this made it significantly easier to support each other in appropriate ways.
Conclusion: The family dialogue tools provide healthcare professionals with a novel approach to facilitate mutual involvement in families. The study shows that the tools manage to generate communication and dialogue in the families and that significant problem areas in daily life are positively affected.

Barriers to uptake of education by adults with type 1 diabetes: the BUDiE study

S. Harris[1], H. Mulnier[2], S.A. Amiel[1];
[1]Diabetes Research Group, King's College London, [2]Florence Nightingale Faculty of Nursing and Midwifery, King's College London, London, UK.

Background and aims: Structured diabetes education transfers clinical knowledge to empower people to self-manage their long-term condition. Type 1 diabetes requires multiple daily decisions about self-management to maintain glycaemic control and avoid complications. However, attendance at high-quality courses run by the National Health Service (NHS) is poor. We explored reasons for poor attendance rates in an adult population in south London, UK.
Materials and methods: There were three parts to this mixed-methods study using exploratory sequential design with quantitative dominance. Adults with, or providing care for people with, type 1 diabetes, in two London boroughs were included. In part 1, we compared education course attenders with non-attenders as recorded in an NHS service-use database. In part 2, a survey of adults with type 1 diabetes and semi-structured interviews were done, and a provider survey conducted. Focus groups were conducted in part 3. Analysis included exploratory regression models, thematic analysis of interviews, and quantisising data using a mixed methods matrix.
Results: In part 1, 303 (27%) of 1121 adults had attended courses. In univariate analysis, non-attendance was significantly associated with older age, male gender and greater social deprivation. In part 2 (n=496, 34% response rate), there were 233 non-attenders (47%), 59 (31%) of whom had not heard of the course. Univariate analysis corroborated part 1 findings, with significant differences (all $p<0{\cdot}05$) in attendance according to employment status, ethnic origin, and other socioeconomic factors. Exploratory regression analysis identified four key variables associated with attendance: a positive health-care professional message (odds ratio for positive *vs* negative message 2·77, 95% CI 1·54-5·01; p=0·001), female sex (0·56, 0·36-0·86, p=0·009), educational attainment (university *vs* secondary school 0·49, 0·3-0·81; p=0·005), and glycaemic control (glycated haemoglobin <7·5% (<58 mmol/mol) *vs* 7·5-8·9% (58-75 mmol/mol): 1·83, 1·06-3·14; p=0·03). Four typologies were identified and labelled according to individuals' coping strategies: "go-getters" (high educational attainment, high thirst for knowledge, and internal locus of control leading to self-education and perceived low benefit from the course); "not yetters" (long-standing diagnosis, previous or current judgmental relationships, unable to prioritise attendance); "trodden downers" (low numeracy, low self-worth, nervousness of taking control); and "diabetes downers" (denial of diabetes or avoidant behaviour making it difficult to self-manage). These typologies were integrated with the patient survey to quantify barriers. In part 3 (five focus groups) potential solutions were proposed, such as modular or blended learning options and taster sessions for both healthcare professionals and patients.
Conclusion: Social determinants of health such as educational attainment and gender influence attendance at structured education, but health-care professional attitude to courses is key. Identifying and quantifying typologies on the basis of psychological constructs supports recommendations for service redesign— for example; patient champions, motivational interviewing, and clear clinical pathways integrating education courses.

Changing HbA_{1c} units: a hindarance, not a help to patients

J. Elliott[1], J. Carlton[2], D. Rowen[2], J. Brazier[2];
[1]Oncology and Metabolism, University of Sheffield, [2]School of Health and Related Research (ScHARR), University of Sheffield, Sheffield, UK.

Background and aims: Patient knowledge of HbA1c has been reported as being associated with better glycaemic outcomes. However, despite opposition from some clinicians, in 2009 the way in which HbA1c was reported altered, and for 2 years from June 2009 to May 2011 HbA1c units were dual reported, before % was phased out. In this study we aimed to assess patient knowledge of HbA1c either in terms of mmol/mol or %, to determine how well this change has been received from a patient perspective

Materials and methods: The study was undertaken using data collected as part of the Health and Self-Management in Diabetes (HASMiD) project. This project aims to develop a Patient Reported Outcome Measure to determine the utility of self-management in people with diabetes in the UK, in both patients with type 1 diabetes (T1DM) and type 2 diabetes (T2DM). As part of this we conducted a survey, Oct '16 to Jan '17, and two of the questions related to knowledge of HbA1c, "What is your current HbA1c, either in mmol/mol or %?" and "What do you think is the ideal number for HbA1c? Please choose a number for either mmol/mol or %". Ethics approval for this research was provided by the Coventry and Warwick Research Ethics Committee, 16/WM/0345PR. The demographics of the 2973 total cohort, 835 with T1DM, and 2088 with T2DM were 53.4; 67.4; 47.8 %female, mean+SD: age 56.3+/-15.9; 42.6+/-16.0; 61.8+/-12.1 years, and duration of diabetes 12.0+/-10.8; 20.1+/-14.3; 8.8+/-6.8 years respectively. Statistical significance was determined using paired Student's t-tests for continuous data and Chi-squared tests for categorical data, where a p value of <0.05 was considered to be statistically significant.

Results: Only 41.9% (1247) of participants said they knew their current HbA1c, and this was more common in those with T1DM as opposed to T2DM, 59.8% vs 34.9%, p<0.00001. Participants self-reported a plausible HbA1c more often in mmol/mol vs %, 60% vs 40% respectively. The new units, mmol/mol, were more often adopted in those with T2DM, as opposed to T1DM, 62.6% vs 55.7%, p=0.004. In comparison, knowledge of the ideal target HbA1c was less for the new units of mmol/mol, as opposed to %, 79.8% vs 85.5% respectively. Whilst knowledge of the ideal HbA1c in mmol/mol was consistent across both types of diabetes, 79.9% and 79.8% for T1DM and T2DM, more T1DM patients correctly re-called the target HbA1c in % units, 100% vs 74.9%. In terms of duration of diabetes, those diagnosed since 2011, the new units (mmol/mol), were equally adopted in those with T1DM, as opposed to T2DM, 71.4% vs 66.0%, p=0.15, but patients with T1DM were less able to reliably recall the correct mmol/mol target, than those with T2DM, 81.0 vs 70.9% respectively.

Conclusion: Patient recall of their HbA1c is poor, and understanding of target HbA1cs is sub-optimal for those using either mmol/mol or still using the old units of %. There were differences in knowledge, patients with T1DM were more likely to be able to recall their HbA1c. Whilst the newer units are more often used, especially amongst those diagnosed since the change in units, patient understanding of the ideal target is less reliable than for those still using % for HbA1c. Therefore this study highlights a significant gap in patient knowledge that ought to be addressed in order to try to improve glycaemic outcomes in the UK.

Glycaemic control and associated factors in a population of children and adolescents living with type 1 diabetes in Cameroon

C.D.D. Djonou[1], M.Y. Dehayem[1], A. Tankeu[1], S. Choukem[2], E. Sobngwi[1], J. Mbanya[1];
[1]Internal Medecine and Specialities, Faculty of Medecine and Biomedical Sciences, Yaounde, [2]Internal Medecine and Specialities, Faculty of Medecine, Buea, Cameroon.

Background and aims: Free access to insulin in the context of Changing Diabetes in Children (CDiC) program has improved glycemic control in children living with type 1 diabetes in Cameroon. Despite this improvement, glycemic control is still largely insufficient

Materials and methods: We carried out a cross-sectional study on a 5-month period in a group of children living with type 1 diabetes and provided free of charge management in seven different centers of diabetic children's care pertaining to the CDiC program. HbA1c was used to assess glycemic control. For each participant, the last value of HbA1c on a period of 6 months was considered. The analyzed parameters were related to sociodemographic data, history of diabetes, patients knowledge about diabetes, self monitoring of blood glucose level and dietary adherence. Good glycemic control was defined as the achievement of specific HbA1c targets according to age as defined by ADA. Logistic regression analysis was used to identify factors associated with glycemic control. Data was analyzed using SPSS 19.0 and STATA 9

Results: A total of 95 children and adolescents (50 boys) were included in our study. The mean age was 16±3 year with a greater proportion of the study population being aged from 13 to 19 years (85/95). The mean diabetes duration was 4.1± 2.9 (1-14 years). The mean insulin dose per day was 0.79±0.32 U/kg and 68.1% of the study population received 3 or more insulin injections a day. The mean HbA1c was 9.5%±2.8 and only 29.5% of the participants met their glycemic targets. Participants with a level of at least upper secondary education had a better glycemic control ($\chi2$=5.59; p=0.018). Conventional insulin regimen was associated with achievement of HbA1c targets ($\chi2$=16.8; p<0.001). Leaving with both parents was associated with a better glycemic control but this association was not statistically significant ($\chi2$=3.44; p=0.063). Glycemic control seems to be inversely correlated to diabetes duration, but this was not significant ($\chi2$= 1.49; p=0.475). In multivariate analysis, only the conventional insulin regimen was associated with achieving glycemic targets (OR=0.15; p=0.018). That may be explained by the residual secretion of insulin in those with shorter duration of diabetes (the majority of patients with conventional insulin regimen), but also by the less frequent blood glucose monitoring observed in this study

Conclusion: Despite free access to care, only 29.5% of participants achieve their glycemic targets. Conventional insulin regimen has been identified as a determinant of good glycemic control

Real-world clinical and economic outcomes of liraglutide among patients with type 2 diabetes at high risk of cardiovascular events, Canadian perspective

N. Kragh[1], J. Hornberger[2], Q. Li[3], T. Feroz[4];
[1]Novo Nordisk A/S, Søborg, Denmark, [2]Cedar Associates, Menlo Park; Stanford University School of Medicine, Stanford, [3]Cedar Associates, Menlo Park, USA, [4]Novo Nordisk Canada, Mississauga, Canada.

Background and aims: Diabetes affects 3.5 million Canadians, or 9.2% of the population. The prevalence is rising mostly due to an aging population. Annual direct healthcare costs for diabetes are $3-4 billion, with much of it spent on managing macro- and microvascular complications. The Liraglutide Effect and Action in Diabetes Evaluation of cardiovascular outcome Results (LEADER) trial reported a 13% risk reduction in time to first cardiovascular event with liraglutide 1.8 mg compared to placebo (both added to standard of care [SOC]) among subjects with type 2 diabetes mellitus at high cardiovascular risk over 3.5-5 years.
Materials and methods: A state-transition analysis estimated the effects of adding liraglutide or placebo to SOC on clinical and economic outcomes over 25 years from a Canadian public payer perspective. The analysis represented multivariate causal relationships among patient demographics, disease characteristics, management pathways, and endpoints. Endpoint-rate equations for complications were derived from LEADER findings. Price and quality-of-life vectors were from published literature. A 5% annual discount rate was applied to health benefits and costs accrued in the simulation. Univariate and multivariate sensitivity analyses were conducted to assess robustness of the outcomes.
Results: Liraglutide was associated with longer overall survival and quality-adjusted survival compared to placebo (0.75 and 0.46 years, respectively). Cumulative rates for all macrovascular events and nephropathy were lower with liraglutide. The drug/administration costs of liraglutide were partly offset by lower costs to manage complications. The incremental cost-effectiveness ratio per quality-adjusted year gained was $12,808. The sensitivity analyses confirmed the robustness of the findings across a large range of input values, including the hazard ratios for complications.
Conclusion: Adding liraglutide to SOC improves survival and is cost-effective from a Canadian public payer perspective.

Low income predicts cardiovascular event risk independently from the presence of type 2 diabetes and pre-existing coronary artery disease

R. Saely[1], A. Vonbank[2], C.H. Saely[2], C. Lins[3], D. Zanolin[3], A. Leiherer[3], A. Schuler[2], A. Muendlein[3], A. Mader[1], P. Schwerzler[1], H. Drexel[4];
[1]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [2]Academic Teaching Hospital Feldkirch, Feldkirch, [3]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, Austria, [4]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: A low socioeconomic status has been associated with an increased cardiovascular event risk. Whether low income predicts cardiovascular event risk independently from the presence of type 2 diabetes (T2DM) and pre-existing coronary artery disease (CAD) is not known and is addressed in the present study.
Materials and methods: We assessed the annual net income through a standardized questionnaire in a consecutive series of 389 patients referred to coronary angiography for the evaluation of established or suspected stable coronary artery disease (CAD). Prospectively, we recorded cardiovascular events over a mean follow-up period of 8.0±3.7 years.
Results: Annual net income was <€20.000 in 58%, €20.000-35.000 in 33.1% and >€35.000 in 8.9% of our patients. It was significantly lower in women (<€20.000 in 70.4%, €20.000-35.000 in 25.6%, >€35.000 in 4.0 %) than in men (<€20.000 in 53.0%, €20.000-35.000 in 36.1%, >€35.000 in 10.9%; p<0.001) but did not differ significantly between patients with T2DM (n=109) and nondiabetic subjects (p=0.237) nor between patients with CAD (n=225) and those who did not have CAD at angiography (p=0.995). During follow-up, the incidence of cardiovascular events significantly increased with decreasing income: it was 62.4%, 32.4%, and 5.3 % in patients with net incomes of <€20.000, €20.000-35.000 and >€35.000, respectively; p=0.042). Annual net income significantly predicted the incidence of cardiovascular events both univariately (HR 0.77 [0.60-0.98]; p=0.037) and after adjustment for age, gender, smoking, LDL cholesterol, HDL cholesterol, hypertension, BMI, waist circumference, T2DM and angiographically determined baseline CAD (HR 0.68 [0.51-0,92]; p=0.011).
Conclusion: We conclude that a low net income predicts cardiovascular event risk independently from the presence of T2DM and pre-existing coronary artery disease.

Costs and patient outcomes associated with adherence to basal insulin therapy for people with type 2 diabetes

M. Perez-Nieves[1], K.S. Boye[1], J. Kiljanski[1], D. Cao[1], M.J. Lage[2];
[1]Eli Lilly and Company, Indianapolis, [2]HealthMetrics Outcomes Research, Bonita Springs, USA.

Background and aims: Studies have suggested that people with type 2 diabetes (T2D) experience improved outcomes when they take their medication as prescribed. However, there is little evidence specifically focusing on adherence to basal insulin therapy or examining the effects of such adherence over an extended time horizon. The goal of this research is to compare costs, resource utilisation, and complications between adherent and non-adherent patients over the 3 year period post initiation on basal insulin therapy.
Materials and methods: US based Truven Health MarketScan® Research Databases from 2011 through 2015 were utilised. Adults age 18 or older identified with T2D who initiated therapy on basal insulin in 2012 were included. Patients were excluded if they were pregnant at any time during the 3 years post-period, if they filled their index basal insulin prescription via mail order, or if they were not continuously insured from 1 year prior through 3 years post initiation on basal insulin. Instrumental variables were used to control for selection bias and general linear models with a gamma distribution and log link were used to examine costs, while logistic and negative binomial regressions were used to examine resource utiliz\sation and acute complications. Adherence was measured by the proportion of days covered (PDC) and patients were considered adherent if they achieved a PDC threshold of 80%. Analyses controlled for patient characteristics, pre-period comorbidities, general health, medication use, visits to specialists, and number of A1c laboratory tests ordered.
Results: There were 21,363 individuals who fit the study criteria. Over the 3 year post-period, patients who initiated therapy on basal insulin and were adherent to such therapy (33.7% of patients) had significantly higher diabetes-related drug costs. However, adherence was also associated with significantly lower diabetes-related outpatient, acute care, and total diabetes-related costs. Results for all-cause costs fit the same general pattern. Patients initiating basal insulin who were adherent had significantly higher all-cause drug costs ($22,267 v $21,030; P<0.0001) and lower total costs ($73,687 v $78,778; P<0.0001). Patients initiating basal insulin who were adherent also had significantly fewer all-cause and diabetes-related hospitalisations and ER visits and were significantly less

likely to be diagnosed with an acute complication (Odds Ratio = 0.766; 95% Confidence Interval 0.713 - 0.823).
Conclusion: Results of this study illustrate that despite higher drug costs, there are both disease specific and all-cause cost offsets and improved patient outcomes associated with adherence to basal insulin therapy for people with T2D. These results suggest that it is important for healthcare providers and payers to create interventions and to work with their patients to improve adherence to basal insulin therapy.

Three Year Outcomes	Non-Adherent PDC < 80% (N=14,149)		Adherent PDC ≥ 80% (N=7,214)		P Value
	Mean	Std Dev	Mean	Std Dev	
Diabetes-Related Outpatient Costs	$6,759	$3,795	$6,319	$3,518	<0.0001
Diabetes-Related Acute Care Costs	$9,789	$6,946	$8,290	$5,709	<0.0001
Diabetes-Related Drug Costs	$10,316	$3,769	$11,898	$4,163	<0.0001
Diabetes-Related Total Costs	$26,800	$9,953	$26,488	$9,176	0.0027
Number of Diabetes-Related Hospitalisations	0.64	0.58	0.53	0.45	<0.0001

Ethnic and socioeconomic disparities in type 2 diabetes care: a trend analysis

W. Hinton[1], A.P. McGovern[1], S. Calderara[2], N. Munro[1], M. Whyte[1], S. de Lusignan[1];
[1]Department of Clinical and Experimental Medicine, University of Surrey, Guildford, UK, [2]Eli Lilly and Company, Geneva, Switzerland.

Background and aims: The prevalence of type 2 diabetes (T2D) is more common in people of lower socioeconomic status (SES) and those of Black and Asian ethnic groups, who are also more likely to experience complications. It is unclear if disparities in diabetes management contribute to complication rates. We analysed the monitoring of diabetes and complications in England to identify possible disparities in healthcare provision.
Materials and methods: We performed a retrospective cohort analysis using a primary care sentinel network in England (Royal College of General Practitioners Research and Surveillance Centre). We identified people with T2D diagnosed before 2012 and registered for a five year follow up period (2012 - 2016 inclusive). We analysed the monitoring of HbA1c, blood pressure (BP), estimated glomerular filtration rate (eGFR), retinopathy, and neuropathy annually for the period. We ran logistic regression models to identify factors associated with complete monitoring (annual checks for all five years). Factors included were: age, gender, ethnicity, SES, duration of diabetes, and comorbidities. SES was assessed using a governmental measure: the index of multiple deprivation.
Results: We identified 50,615 adults with T2D registered for the follow up period. The proportion monitored has improved annually for HbA1c (82.6% in 2012 to 92.8% in 2016), eGFR (83.3% in 2012 to 92.4% in 2016), and neuropathy (65.5% in 2012 to 72.1% in 2016). A similar trend was seen for BP (86.0% in 2012 to 92.9% in 2015) except a slight reduction in 2016 (91.3%). The monitoring rates for retinopathy peaked in 2013 (68.6%) and have fallen annually since to 59.3% in 2016. The proportions with complete monitoring over these five years were; HbA1c (69.0%), eGFR (66.1%), BP (71.5%), neuropathy (27.7%), and retinopathy (25.8%). People from Black ethnicity groups were less likely to have complete monitoring for HbA1c, eGFR, retinopathy, and neuropathy; those of Mixed ethnicity less likely for HbA1c, eGFR, and retinopathy; and those of Asian ethnicity were more likely for BP and less likely for retinopathy (Table 1). The people in the most deprived SES quintile were less likely to have complete monitoring in all domains investigated.
Conclusion: Monitoring rates for diabetes complications are high and have broadly improved over the last five years with the exception of retinopathy. People are less likely to have consistent monitoring if they are of Black or Mixed ethnicities, or of lower SES. These differences may exacerbate or otherwise contribute to wider ethnic and socioeconomic disparities in diabetes outcomes and should be urgently addressed.

Healthcare resource utilisation in patients with diabetes and elevated potassium levels, a Danish population based cohort study

E. Palaka[1], R.W. Thomsen[2], S.K. Nicolaisen[2], K. Kim[3], H.T. Sørensen[2];
[1]Global Payer Evidence, AstraZeneca, Cambridge, UK, [2]Department of Clinical Epidemiology, Aarhus University Hospital, Aarhus, Denmark, [3]Medical Evidence, AstraZeneca Nordic-Baltic, Södertälje, Stockholm, Sweden.

Background and aims: The aim was to investigate healthcare resource utilization (HRU) before and after a hyperkalemia event (HK, i.e. elevated potassium (K+) levels) in patients with diabetes in the Danish clinical practice setting.
Materials and methods: We identified 76,942 patients with a first incident record of DM using population-based health databases between 2000 and 2012, covering the entire population of Northern Denmark (1.8 million). Of these patients, 13,530 were identified with incident HK, i.e., a first blood test in primary care or hospital with K+ level >5.0 mmol/L. HRU was estimated based on patient level information on hospital care, general practitioner consultations, and use of prescription drugs, and was compared 6 months before and 6 months after the HK event (event date of HK included). HRU changes were also explored among age-, gender-, and diabetes duration- matched diabetes patients without HK. Results were stratified by age and presence of kidney disease or chronic heart failure.
Results: Among 13,530 patients with diabetes and incident HK, median age was 71 years, 42% were female, and 49% had a history of chronic kidney disease, 19% chronic heart failure, and 71% hypertension. The *Figure* shows that the proportions with any acute hospitalization increased substantially from 6 months before to 6 months after the HK event, most profoundly among younger diabetes patients without kidney disease or heart failure (increase from 23% to 47%). In comparison

patients without HK, risks were lower and more stable throughout the follow-up. In patients with HK, the mean number of acute hospitalization bed days increased from 3.5 before the HK episode to 6.0 after the HK episode (+72% increase). The corresponding bed days for the matched comparison cohort without HK were 1.3 and 1.4. Non-acute hospitalization bed days increased from 1.0 before HK to 1.9 (+84% increase) after HK (comparison cohort 0.5 before and after), whereas ICU treatments increased from 1 in 33 persons to 1 in 5 persons after the HK event. Mean hospital outpatient visits per patient increased from 1.4 before to 1.6 (+16% increase) after the HK event (comparison cohort, 0.8 before and after). Mean number of GP consultations was rather stable at 4.9 before HK and 4.7 after HK (4% decrease) (comparison cohort 4.2 and 4.1). The average number of individual medication prescriptions filled declined from 30 to 23 prescriptions after the HK event (21% decrease) (comparison cohort 24 and 23) potentially related to drug discontinuation, transfer to hospital care, or mortality associated with the HK event.

Conclusion: The burden of hospitalization is greatly increased after an event of HK in patients with diabetes. As hospital admission costs constitute the largest healthcare cost component, societal costs associated with HK are likely to be high.

Diabetes and Opiate Replacement Therapy (ORT): a retrospective cohort study of health care usage and clinical outcomes

H. Druce[1], R. Lowrie[2], C. Ritchie[3], D. Morrison[1], C.A.R. Sainsbury[1], G.C. Jones[1];
[1]Department of Diabetes, Gartnavel General Hospital, [2]Pharmacy and Prescribing Support Unit, West Glasgow Ambulatory Care Centre, [3]Addiction Services, NHS Greater Glasgow and Clyde, Glasgow, UK.

Background and aims: People with problem drug use can have chaotic lives and often have high risk health behaviours. Diabetes is a common comorbidity in this population with significant potential impact of excess complications and mortality. We investigated the hypothesis that people with both diabetes and problem drug use engage less with services and have worse outcomes.

Materials and methods: All adults prescribed methadone or suboxone opiate replacement therapy (ORT) between 2011 and 2016 in our region who also appeared in national diabetes database were included. An age, gender and diabetes duration matched case control cohort was identified without ORT use from national database and a comparative analysis performed.

Results: 393 people (age 41.0 (35.9-46.1), male 64%) on ORT and an equally sized matched cohort were included for analysis. ORT group included 389 people who had been prescribed methadone and 38 who had been prescribed suboxone. People on ORT were offered more diabetes clinic review appointments/year than those not on ORT (0(0-1.13),0(0-0.6)p=0.009). Non-attendance at diabetes clinic and retinal screening (proportion appointments not attended/year) was higher in ORT group versus matched cohort ((median(IQR)0.53 (0.33-0.83)0.17(0-0.5)p<0.001)(0.33 (0-0.8),0 (0 -0.2) p<0.001)). In ORT cohort unscheduled hospital attendance rate/year was higher (0.6(0-1.64), 0(0-0.52), p=<0.001). HbA1c levels showed no significant difference (p=0.47) but number of HbA1c measures/year were lower (1.2(0.4-2.0), 1.6(0.8-2.5), p<0.001). 5-year all cause mortality was increased in ORT cohort (Hazard Ratio = 5.14, p<0.001).

Conclusion: People with diabetes and problem drug use engage less with scheduled diabetes services and have more unscheduled care attendances resulting in potentially significant excess healthcare costs. HbA1c is measured less often, but glycaemic control is similar, in ORT patients compared to diabetes only cohort. The similarity in HbA1c may be secondary to acquisition bias in those who do attend but could also suggest that better control is possible when there is engagement with diabetes services. Mortality in ORT using group is much higher than in patients with diabetes alone. This cohort presents a potential target for enhanced case management facilitated through their regular attendance at ORT treatment and care clinics.

Disclosure: **H. Druce:** None.

Factors influencing non-adherence to diabetes self care activities among diabetic patients in rural Bangladesh

B. Banu[1], L. Ali[2], R. Sauerborn[1], A. Souares[1];
[1]Institute o Public Health, Heidelberg University, Heidelberg, Germany, [2]Bangladesh University of Health Sciences, Dhaka, Bangladesh.

Background and aims: This study was designed to determine the extent of non-adherence to the 7 components of diabetes self care activities including drug, diet, physical exercise, follow-up visit, risk behaviors, blood glucose test and foot care and to identify the influencing factors.

Materials and methods: A cross-sectional study was conducted among 990 diabetics aged between 18-64 years residing in Thakurgaon district of Bangladesh. Data were collected by face to face interview method.

Results: The proportion of non-adherence was found for drug (65.8%), diet (91.8%), physical exercise (70.6%), follow-up visit (82.5%), risk behaviors (50.6%), blood glucose test (82.5%) and foot care (92.1%). Factors which were found to be significantly influencing to the non-adherences of drug were >2 number of rooms (OR=1.591), >10,000 Tk of monthly income (OR=1.353), residing in their own house (OR=8.059) and using electricity (OR=5.342); to dietary non-adherences were education >5 class (OR=2.609), >10000 Tk monthly income (OR=2.740), >2 number of rooms (OR=1.699), negative family history DM (OR=0.619), had complications (OR=1.679); to physical exercise were having diabetes >2 years (OR=0.756), more cost need to come to hospital (OR=0.714), nuclear family (OR=1.480); to follow-up visits and blood glucose test were >10000 Tk monthly income (OR=1.950), age >25 years (OR=0.313), education >5 class (OR=1.448), >2 number of rooms (OR=1.772), negative family history DM (OR=0.719); to tobacco quitting were education >5 class (OR=0.467), >10,000 Tk monthly income (OR=0.630), parity >2 (OR=1.388), nuclear family (OR=1.381), >2 number of rooms (OR=0.768), having >200 decimal of land (OR=0.763), having diabetes >2 years (OR=0.727), negative family history DM (OR=1.486), more distance (OR=1.380) and more time (OR=2.010) to reach hospital; to foot care were education >5 class (OR=3.493), >10,000

Tk monthly income (OR=3.539), parity >2 (OR=0.639), nuclear family (OR=0.114), >2 number of rooms (OR=1.742), negative family history DM (OR=0.508). Reasons for non-adherences to 7 self care activities were also identified.

Conclusion: An alarmingly high proportion of diabetics' are non-adherent to self care management. Major factors for these non-adherences are found under socio-economic and health care services related characteristics. Long term health educational programs including monitoring and reminder system could motivate patients for proper management of diabetes.

Long term sickness absence and diabetes: a Danish register-based longitudinal study with up to 17 years of followup

M.A. Nexo[1], K. Carlsen[2], J. Pedersen[3], T. Watt[4], S.M. Hansen[3], J.B. Bjorner[3,5];
[1]Diabetes Management Research, Steno Diabetes Center Copenhagen, Gentofte, [2]The Danish Working Environment Authority, Copenhagen, [3]Epidemiology, The National Research Center for the Working Environment, Copenhagen, [4]Medical endocrinology, Copenhagen University Hospital, Copenhagen, Denmark, [5]Optum Patient Insights, Lincoln, USA.

Background and aims: The number of individuals with diabetes mellitus within the working age range is expected to rise. Type 1 and type 2 diabetes mellitus (diabetes) can have work related consequences such as decreased productivity, increased risks of sickness absence and early retirement. Sickness absence has been used as a central indicator of work disability, but has mainly been examined by short term spells of sickness absence in studies with limited follow-up time. This study aimed to identify the risk of long term sickness absence (LTSA) in individuals with diabetes within the first year of diagnosis and in subsequent years.

Materials and methods: The study was based on registers with up to 17 years of follow-up. In a working population (n=102,746) individuals with the diagnoses of type 1 or type 2 diabetes (n=3,325: women, n=1,987, men=1,338) and individuals without diabetes (n=99,421: women, n=73,332, men=26,089) were identified by Danish national registries of diagnosis (ICD-10 codes: E10.0-10.9, E11.0-E11.9, E12-E14) and prescribed medicine (ATC codes: A10A, A10B, A10BA02), in the period 1994 to 2011. We estimated the hazard ratios of transitions from work to LTSA (>3 consecutive weeks) in Cox proportional multi-state models with separate estimates for the risk within the first and subsequent years after diagnosis. The underlying time axis for the analyses was age. Analyses were stratified by gender and controlled for immigrant status, highest attained education, marital status, calendar year, and job type. Results were reported in terms of incidence rates (LTSA events per 1,000 person years: PY), hazard rates (HR) with a 95% confidence interval (CI) and relative risks for LTSA in subsequent years compared to the first year after diagnosis.

Results: Within the first year of diagnosis, the incidence rates for persons with diabetes were 126 in women (138 events / 1,091 PY) and 100 in men (78 events / 780 PY) with significantly elevated risks of LTSA (HR=1.60, CI: 1.35-1.91 in women and HR=1.57, CI: 1.24-1.98 in men). In the subsequent years after diagnosis the incidence rates for persons with diabetes were 137 in women (784 events / 5,718 PY) and 132 in men (506 events / 3,821 PY) with significantly elevated risks of LTSA (HR=1.49, CI: 1.36-1.63 in women and HR=1.82 CI: 1.60-2.06 in men). The relative risks of LTSA in subsequent years were 0.93 in women and 1.16 in men.

Conclusion: Women and men with diabetes had elevated risk of LTSA, compared to those without diabetes. After the first year of diagnoses the risk decreased slightly in women and increased slightly in men. Studies of other chronic diseases have found substantial decrease in risk of LTSA after the first year of diagnosis - presumably due to a stabilization of disease with treatment. The absence of such an effect in diabetes may be due to diabetes-related comorbidities or poor treatment adherence. Future studies need to consider the impact of diabetes type, co-morbidities, and treatment adherence on LTSA.

Disclosure: **M.A. Nexo:** None.

Work matters: accounts of the relationship between diabetes and work life in the second Diabetes Attitudes Wishes and Needs (DAWN 2) study

B. Cleal[1], H. Stuckey[2], I. Willaing[1], M. Peyrot[3];
[1]Diabetes Management Research, Steno Diabetes Center Copenhagen, Copenhagen, Denmark, [2]Pennsylvania State University, Harrisburg, [3]Loyala University, Baltimore, USA.

Background and aims: In previous analyses of qualitative data obtained in the second Diabetes Attitudes Wishes and Needs study (DAWN2), discrimination at work was identified as a theme associated with negative psychosocial experiences for people with diabetes (PWD). We undertook a more specific analysis focusing exclusively on how the topic of work was addressed by people with diabetes who participated in DAWN2. The aim was to obtain insight into the range of experiences that PWD have in the context of work.

Materials and methods: The DAWN2 survey of adult PWD contained open-ended items about challenges of, successes with and wishes for improvement in living with diabetes. All responses to these questions provided by participants (1,368 with type 1 diabetes and 7,228 with type 2 diabetes) were reviewed by the first author and all direct and indirect references to work life were extracted for analysis. An emergent coding procedure was undertaken on the basis of the extracted data and all authors contributed to the development of the thematic framework. A coding manual was written describing the themes and sub-themes in detail. Validation of the thematic framework was performed by two independent coders. The coders worked with the text excerpts independently of one another, coding the data in accordance with the themes articulated in the coding manual. The coders' results were then systematically compared to determine the level of agreement between them. Cohen's Kappa statistic was applied as the interrater reliability correlation coefficient. The kappa score represents a measure of the extent to which a specific theme can be considered an accurate and robust expression of the data.

Results: In total, 343 PWD wrote about work, 95 (27.7%) with type 1 diabetes and 248 (72.3%) with type 2 diabetes, of whom 94 took insulin. The 343 PWD commenting on work included 204 men (59.5%) and 139 women (40.5%). Analysis of the data generated five primary themes (and twenty seven sub-themes): Restriction of Work Opportunity: Work Exclusion; Work downgrading; Work termination (voluntary & involuntary): Negative consequences of work restriction. Diabetes impacts upon Work: Hypo/hyperglycemia; Fatigue; Treatment demands; Distress; Complications. Work influences lifestyle/diabetes self-management: Work as cause of diabetes; Healthcare appointments; Medication & monitoring; Diet; Exercise; Glucose Control; Lack of support. Coping strategies and Benefits; Coping; Work as coping; Social support. Diabetes Awareness: Diabetes diagnosis at work; Compromised work ability; Diabetes specific social learning. Discrimination at work remains prevalent in our data e.g. in accounts of exclusion from work. More generally, specific challenges relating to the impact of diabetes upon work, and vice-versa, are clearly articulated. Finally, affirmative psychosocial experiences are identified in strategies for coping and in supportive social relations.

Conclusion: Recognizing the real limitations that diabetes, its treatment and its complications can have on PWD working, our analysis of the qualitative DAWN2 data highlights the importance of the physical and social environment in which work is undertaken. To the extent that these are supportive of the person with diabetes, the degree to which being at work is experienced as burdensome is likely to be diminished.

Disclosure: **B. Cleal:** None.

Socioeconomic status and family status but not race/ethnicity are associated with glycaemic control in children, adolescents and young adults with type 1 diabetes

A. Galler[1], A. Ernert[2], K. Raile[3];
[1]Paediatric Endocrinology and Diabetology, Charité - Universitätsmedizin Berlin, [2]Institute for Biometrics and Clinical Epidemiology, Charité - Universitätsmedizin Berlin, [3]Charité - Universitätsmedizin Berlin, Berlin, Germany.

Background and aims: Aim of the study was to examine associations between socioeconomic status, race/ethnicity, family status, and glycaemic control in children, adolescents and young adults with type 1 diabetes.
Materials and methods: The cross-sectional study included 222 subjects with type 1 diabetes up to the age of 22 years. Data about socioeconomic status, race/ethnicity, and family status were obtained by self-report questionnaires. Clinical data and HbA1c were assessed. Variables were analysed by Man-Whitney-U and Kruskal-Wallis tests, and by multiple regression.
Results: Out of all children, adolescents and young adults with type 1 diabetes (mean age 12.6+/-4.1 years, median HbA1c 8.1%, mean diabetes duration 5.8+/-3.3 years, socioeconomic status: 30% low, 37% moderate, 33% high) 21% lived in a single-parent family and 29% had non-German race/ethnicity. Children, adolescents and young adults from two-parent families had significantly lower HbA1c levels compared to subjects from single-parent families (median HbA1c 7.3% vs 8.0%, p=0.002). Multiple logistic regression analysis revealed that longer diabetes duration (p=0.01), lower socioeconomic status (p=0.006), and single-parent status (p=0.048) but not race/ethnicity (p=0.37) were significantly associated with higher HbA1c levels.
Conclusion: Diabetes duration, socioeconomic status, and family status but not race/ethnicity were associated with glycaemic control in children, adolescents and young adults with type 1 diabetes.

An informed shared decision making programme for patients with type 2 diabetes in primary care: cluster randomised controlled trial

S. Buhse[1], N. Kuniss[2,3], K. Liethmann[1], U.A. Müller[2,3], T. Lehmann[4], I. Mühlhauser[1];
[1]Health Sciences and Education, University of Hamburg, Hamburg, [2]Endocrinology and Metabolic Diseases, University Hospital Jena, [3]Diabetes Centre Thuringia, Jena, Germany, [4]Centre for Clinical Studies, University Hospital Jena, Jena, Germany.

Background and aims: Informed shared decision making (ISDM) is not yet implemented in diabetes care. We have developed and evaluated an ISDM programme (ISDM-P) for patients with type 2 diabetes in a randomised controlled trial (RCT) at a single diabetes centre. Study results have been published. The aim of the present study was to translate the ISDM-P to primary care in Germany.
Materials and methods: We conducted a 6 months cluster RCT with 22 family practices that participated in the German Disease Management Programme (DMP) for type 2 diabetes and employed a medical assistant (MA) with special training in diabetes education. The ISDM-P comprises a 90 minutes group patient teaching session provided by MA, a decision aid booklet for patients, ISDM training modules for MAs and practitioners (GPs), and a patient-held documentation sheet with patient-defined treatment goals to be shared and discussed with the GP. The control group received standard care supplemented by an extract of the German National DMP Guideline for type 2 diabetes. Patients, 40 to 69 years, without diagnosis of ischemic heart disease or stroke were included. Primary endpoint was patients' adherence to antihypertensive or statin therapy by comparing prescriptions and patient-reported uptake after 6 months. Secondary endpoints included informed choice (risk knowledge and achievement of personal treatment goals), realistic expectations, and prioritised treatment goals. Interviews with MAs and GPs focused on the implementation process. The study was registered and a protocol has been published.
Results: Of 363 eligible patients 279 agreed to participate in the cluster RCT, and 268 completed the 6 months follow-up; 11 practices with 151 patients were randomised to ISDM-P (136 patients participated in a total of 35 group teaching sessions), and 11 practices with 128 patients to standard care. Baseline characteristics were comparable; 45% women, mean age 59 years, duration of diabetes 8 years, blood pressure 140/82mmHg, HbA1c 7.0%. At follow-up 218 patients were prescribed antihypertensive drugs and 107 statins. Adherence to antihypertensive drugs and statin intake was similar for both study groups (81.4% vs. 78.9% and 87.9% vs. 95.6%, resp.). More ISDM-P patients made informed choices regarding statin intake (60% vs. 8%; p<0.001), blood pressure control (65% vs. 7%; p<0.001), and glucose control (67% vs. 7%; p<0.001). Realistic expectations were 3/5 correct answers for ISDM-P and 1/5 for controls (mean difference 2 [95% CI 1.7 to 2.7]; p<0.001). Prioritisation of treatment goals differed significantly between groups. Among ISDM-P more patients prioritised blood pressure control rather than HbA1c targets. Matching of treatment goals between patients and GPs was higher for ISDM-P; prioritized goals matched for 89% vs. 57%; p<0.001. GPs stated that the patients were well prepared for decision making. MAs described workload for the ISDM-P as similar as for DMP patient education modules.
Conclusion: The ISDM-P was successfully implemented in the primary care setting. Patients were able to make informed choices. The patient-held documentation sheet ensures that patients and physicians pursue common treatment goals.

Theory based diabetes self-management education with pre-selection of participants: results of a randomised controlled trial with 2.5 years follow-up

R.C. Vos, L. van Heusden, G.E.H. Rutten;
Primary Care, University Medical Center Utrecht, Utrecht, Netherlands.

Background and aims: Many diabetes self-management programs could improve lifestyle and reduce cardiovascular risk, but changes tend to be small and short-lived and programs are not beneficial for all patients. The course Beyond Good Intentions in people with screen-detected type 2 diabetes showed sustained effectiveness after one year. It is a 12 weeks, group-based self-management course with four sessions focusing on sustained change of health behaviour by proactive coping. The aim of the current study was to evaluate the 2.5-year effectiveness of this course on clinical parameters for cardiovascular risk in a group of pre-selected patients with known type 2 diabetes.
Materials and methods: The Eindhoven Long-term Diabetes Education Study (ELDES) study is a parallel randomised controlled trial (1:1) conducted in Dutch primary care. Pre-selection of eligible participants who were most likely to benefit from a diabetes self-management education program was performed; patients were randomised to intervention group or control group. Changes in BMI, weight, systolic blood pressure, fasting glucose, HbA1c, and lipid profile between baseline and 2.5-year follow-up were analysed using ANCOVA, adjusted for baseline values.
Results: 108 participants were included in two separate periods (2015 and 2016) (56 intervention group, 52 control group); the first 48 were available for analysis. BMI and body weight decreased in both groups (intervention BMI from 30.0±5.2 kg/m^2 to 29.6±4.9 kg/m^2; decrease in percentage body weight -1.6%±5.5 and control BMI from 29.8±3.7 kg/m^2 to 28.8±3.4 kg/m^2 and decrease in percentage body weight -3.3%±4.6); no significant group effect (BMI F=1.729, p=0.195; body weight F=1.280, p=0.264). Although non-significant, systolic blood pressure decreased in the intervention group (from 133 ± 13.6 mmHg to 131 ± 16.9 mmHg) and increased in the control group (from 131 ± 12.9 mmHg to 134 ± 15.9 mmHg); no significant group effect (F=1.096, p=0.301). LDL-cholesterol showed a significant group effect in favour of the control group (F=4.869, p=0.032). Other values remained stable and on target over time (table).
Conclusion: Both groups were on target at baseline and during follow-up. Because patients from the first round were at baseline similar to patients from the second round, the results of current analysis are likely to hold true for the total study population. Since Dutch diabetes care is already efficient, no further beneficial effects can be expected from self management programs on biomedical factors. Perhaps the aim of self-management intervention should shift from further reducing cardiovascular risk to improving factors like quality of life and patient satisfaction.

Table – Baseline and 2.5-year follow-up scores

	Intervention group (n=23)		Control group (n=25)		Group effect	
	T0	T1	T0	T1	F	P-value
BMI (kg/m^2)	30.0 ± 5.2	29.6 ± 4.9	29.8 ± 3.7	28.8 ± 3.4†	1.729	0.195

One off structured dietary education can improve diabetes management in Nepal

J. Pradhan[1], S. Rajbhandari[2];
[1]Nutrition Dept, Padma Kanya Campus, Kathmandu, Nepal, [2]Diabetes Dept, Lancashire Teaching Hospital, Chorley, UK.

Background and aims: The prevalence of diabetes is rising in urban Nepal. It is estimated that 20% of adult population have diabetes or pre-diabetes state. The treatment of diabetes is focused mainly on medication there. Diabetes education if at all provided is delivered by doctors in a busy clinic. There is no structured education programme. We wanted to see if one off structured education focusing on nutrition can improve control in newly diagnosed type 2 diabetes.
Materials and methods: Type 2 diabetes subjects (between the age of 30 to 60 years and within one year of diagnosis) who were attending one of the 5 urban clinics in Kathmandu were approached by the investigator. Out of 780 eligible subjects 150 gave written consent. Subjects were randomised to 'Education' or 'Control' group. Education group received one off 90 minutes structured education around dietary guidelines as recommended by WHO. Baseline and six month follow up data were collected from both groups.
Results: Sixty patients were randomised to 'Education' and 90 to 'Control; group. They were similar in age and gender ratio. Mean monthly expenditure was high in 'Education' group than in 'Control' group (€ 9.56 vs € 6.10) at baseline. At 6 months, there was a significant reduction in fasting glucose, 2 hour post prandial glucose and HbA1c in both groups in comparison to baseline. In 'Education' group this difference was significantly lower than the 'Control' group after 6 months. A trend in greater reduction was also seen in post prandial glucose and HbA1c in 'Education' group. There was no change in BMI or waist circumference between both groups at follow up. There was no difference in lipid profile however there was significant improvement in cooking style with Education group using more boiling but less frying. The mean numbers of fruit serving improved from 0.5 to 1.3 servings in the education group at post survey, whereas in control group, the mean declined from 0.4 to 0.3 serving.
Conclusion: This study shows that in resource limited countries, one off structured education can improve diabetes care in the form of low fasting blood glucose. There is a trend for the reduction in HbA1c. This short education programme changed dietary habit in a positive way and the effect lasted 6 months. Further larger scale studies are needed to validate this.

RESULTS

	Education		Control		P value
	Baseline	6 months	Baseline	6 months	
Fasting Glucose mmol	8.6 +/- 2.9	6.6 +/- 1.2	8.0 +/- 1.8	7.0 +/- 1.8	0.005
Post prandial Glucose	11.2 +/- 3.7	8.3 +/- 10.2	11.5 +/- 4.0	9.7 +/- 2.3	0. 06
HbA1c (%)	8.9 +/-2.1	7.8 +/- 1.5	8.7 +/-2.4	8.1 +/- 1.2	0.06
BMI	25.8	25.4	26.4	27	0.275

A diabetes education programme with supervised physical activities: results from 12 years and almost 20.000 attendances

J. Dullius[1], T. Gollo[1], L. Santana[1], L. Ferreira[1], A. Nunes[2], L.Z. Monteiro[3], R. Dantas[4], G. Dantas[4], S. Lemos[4];

[1]Physical Education - Diabetes Education Programme, University of Brasília, [2]Pharmacy School, University of Brasília, [3]Physical Education, University Center of the Federal District (UDF), [4]Diabetes Education Programme, University of Brasília, Brasília, Brazil.

Background and aims: Diabetes education and physical exercise are important parts of the diabetes (DM) treatment. With this in mind, the Doce Desafio Program (DDP) was created in 2001 and with the data collected over the years it was possible to do a preliminary analysis that shows some relevant results.Aim: To describe the profile and the characteristics of those with DM that started with the program.
Materials and methods: DDP is a free diabetes education program in a public university in which classes of health education and supervised physical exercises are performed for people with DM. The meetings (120 min) occur 1-3 times a week. The regular routine is: 1) the capillary blood glucose (BG) and the blood pressure (BP) are measured at the beginning of each class. Diet, the medication and the overall well-being are also assessed; 2) there is a protocol for adjustments (with carbohydrates, insulin or exercise) when necessary. 3) 60 min of supervised physical activities; 4) a health educational activity (30min) taking taught by a multidisciplinary staff; 5) again measures (BG and BP). Data were collected from 2001-2012 (socio-demographic, clinical) from individual files.
Results: 786 people with DM participated with the following characteristics: Age= 4-90 (52+18) years; 63.1% female; 80.9% T2DM; time since DM diagnostic 0-50 (7+8) years; 36% in insulin therapy (IT); 26.5% uses public health system; education: fundamental 21.5%, high school 24.2%, superior 33.7%; attended 1-305 (24+40) classes. Regarding to the age, 7.5% are 4-17 years and 57.1% are >54 years old (23.2% in IT). At admission, 19.3% of T2DM were in insulin therapy (IT)[em1] . Most attendants with T2DM presented hypertension. Attendances frequency): 73.2% people had <25 classes (4076 attendances); 14.8% had 25-50 (4163), 10.1% had 51-170 (7438), and 1.9% (n=15) were present in >170 classes (4109 att. through >3 years). There were 19.782 attendances over 12 years with almost 40000 BG measures. In average, BG measure (in mg/dl) was 181+83 (56 to 579, median 163) before the classes and 144+68 (44 to 492, median 123) after this classes. After 12 classes the values were reduced consistently; in the 24th class the mean BG values were 124+34 (median 118).
Conclusion: Regular and continuous diabetes education and supervised physical activities are possible and can be a good way to the commitment.

Assessment of the efficacy of intensive life style modification programme in overweight (obese) patients with type 2 diabetes

S. Andreeva[1], L. Savelyeva[1], L. Rudina[2], M. Gurkina[3], E. Surkova[1], G. Galstyan[1];
[1]Endocrinology Research Centre, [2]The Russian Presidential Academy of National Economy and Public Administration, [3]Medical Rehabilitation Centre, Moscow, Russian Federation.

Background and aims: To evaluate the efficacy of intensive life style modification program in overweight (obese) patients with Type 2 diabetes mellitus (T2DM) on clinical and metabolic parameters.
Materials and methods: 80 patients with T2DM were recruited (60 - intervention group, 20 - control group). Mean age (intervention group) was 54 years [46; 59.8]; diabetes duration 5 years [2; 10.8]; weight 96.7 kg [88.3; 103.2]; BMI 34.6 kg/m^2 [32; 36.5]; waist circumference 108.5 cm [105; 113]; fasting plasma glucose level 8.0 mmol/l [6.4; 9.9]; HbA_{1c} 6.9% [6.1; 8.2]. The control group was matched to the intervention group by the clinical and demographic characteristics. This program was adapted from Weight Achievement and Intensive Treatment (Why WAIT) a 12-week multidisciplinary program for weight reduction and intensive diabetes management designed and implemented at the Joslin Diabetes Center in Boston since 2005. The main components of the program were structured dietary intervention, individualized exercise intervention, cognitive behavioral intervention, group education and antidiabetic drug adjustment. During 1st phase (3 months) educational sessions were conducted once per week in small groups with team of specialists (dietician, diabetologist, clinical exercise physiologist and psychologist). During 2nd phase (9 months) monitoring was carried out monthly. Anthropometric, clinical and metabolic parameters were measured initially, after 3 and 12 months. Whenever applicable, diabetes medications were changed to ones that have little or no impact on body weight. Thus 21% of patients received metformin as the monotherapy; DPP-4 inhibitors were one of the antidiabetic medications in 55% of patients.
Results: Currently 47 patients of intervention group completed the study. Following parameters decreased: body weight from 97.0 kg [89.5; 103.3] to 88.2 [82.8; 95.1] after 3 months and to 87.0 [83.1; 98.5] after 12 months (p=0,000); BMI from 34.6 kg/m^2 [32.0; 37.0] to 32.1 [29.7; 34.9] and to 32.1 [28.4; 34.5] (p=0,000); waist circumference from 109 cm [105; 113] to 100 [96; 109] and 101 [97; 106] (p=0,000); fasting plasma glucose level from 8.3 mmol/l [6.5; 10.0] to 7.1 [6.2; 8.3] and to 6.4 [5,7; 8.3] (p=0,000); HbA_{1c} from 6.9 % [6.1; 8.1] to 6.2 [5.8; 7.3] and to 6.3 [6.0; 7.1] (p=0,000); triglycerides from 1.9 mmol/l [1.3; 2.7] to 1.6 [1.0; 2.0] and to 1.4 [0.9; 2.2] (p=0,000) after 3 and 12 months, respectively; C-reactive protein from 2.5 mg/L [1.6; 5.2] to 1.9 [0.8; 4.0] (p=0,047); sistolic BP from 130 mm Hg [120; 140] to 120 [120; 135] (p=0,010); diastolic BP from 85 mm Hg [80; 90] to 80 [75; 80] (p=0.000) after 12 months. There were no statistically significant changes in total cholesterol, LDL, HDL after 12 months. At the end of the study in 11 participants weight reduction was 5% and more and in 19 participants 10% and more. In patients on insulin therapy the daily dose of long-acting insulin was reduced from 10% to 50%. In patients on sulfonylurea drugs therapy was stopped in 58.3% while dose reduction by 50% was achieved in 16.7% of patients.
Conclusion: The program demonstrated significant weight and waist circumference reduction accompanied by improvement of metabolic parameters during 12 months as well as beneficial changes in diabetes medications.

Glycaemic control changes after the programme of personalised support for the patients with type 2 diabetes on insulin therapy

A.Y. Mayorov[1,2], O.G. Melnikova[1,2], E.V. Surkova[1], O.G. Motovilin[1];
[1]Diabetes Institution, Endocrinology Research Centre, [2]I.M.Sechenov First Moscow State Medical University, Moscow, Russian Federation.

Background and aims: Patient education and long-term follow-up is regarded as the basis for improving glycemic control. The aim of the study was to assess glycemic control after the program of personalized support for the patients with type 2 diabetes on insulin therapy.
Materials and methods: Study group consisted of 305 patients with type 2 diabetes (68 men/237 women; mean age 61,3±8,4 years) from several regions of the country receiving different regimens of insulin therapy. All subjects were educated by a specially created structured program, which is a part of the project of personalized support of the patients realized by medical centre in cooperation with national public organization of diabetes patients. Unlike existing structured program in “Diabetes Schools” this program, besides 5 standard classes on main topics, includes 3 additional classes organized in 3, 6 and 9 months after the end of the basic course. Educational program included methodological guideline with the material discussed at the classes, “plates”-cards with the images of the food and educational posters. Before participation in the project endocrinologists were trained during a 2-days workshop. During the main course classes (one class a week in groups no more than 10 people, duration 2,5-3 hours) following topics were discussed: basic knowledge about

diabetes, diet, insulin therapy, blood glucose self-monitoring, diabetic complications prevention and treatment. During additional classes (duration 2,5 - 3 hours) individual dynamics of significant metabolic and clinical characteristics were analyzed. The achievement of individual target values was evaluated and the obstacles preventing from the effective control of the disease were discussed during those classes as well. Sustainment training of practical skills in insulin therapy and blood glucose control, insulin therapy regimens and doses of insulin or other medications - all this was done at the additional classes. HbA1c level was evaluated before the start of the educational program, and then in 3, 6 and 9 months after the end of the basic course.

Results: Before the beginning of the educational program the mean level of HbA1c was 8,4 [7,4; 9,3] %, in 3 months after the end of the main educational course the mean level of HbA1c was lowered to 8,0 [7,3; 9,2] % (p<0,001 comparing to the baseline level), in 6 months - to 7,9 [7,1; 9,1] % (p<0,001), in 9 months (around a year after the beginning of participation in the project) - to 7,7 [7,1; 8,6] % (p<0,001). Before the educational program most commonly recommended target level of HbA1c <7,0% was achieved only by 42 (13,8%) patients, and the amount of patients who had HbA1c level higher than maximum allowed target level according to the national guidelines (≥8,0%) was in 182 (59,7%) patients. At the end of the study HbA1c <7,0% was found in 47 (15,4%) patients (NS), and the amount of patients with HbA1c ≥8,0% was lowered to 130 (42,6%) patients (p<0,001).

Conclusion: The program of personalized support for the patients with type 2 diabetes on insulin therapy is the first educational program in the country with a long-term follow-up and personalized support of the patients. This program allows significantly decreasing the amount of patients not reaching the target level of glycemic control.

My diabetes my way: user experiences of an electronic personal health record for diabetes

S.G. Cunningham, B. Allardice, D.J. Wake;
School of Medicine, University of Dundee, Dundee, UK.

Background and aims: My Diabetes My Way (MDMW) is a website containing interactive resources for people with diabetes and their carers. It incorporates an electronic personal health record (ePHR) allowing online access to clinical results and assessments. We aimed to assess user experience and perceived benefits.

Materials and methods: In January 2015, an online evaluation survey was emailed to 3,979 active users of the MDMW ePHR. This questionnaire aimed to capture qualitative and quantitative data using a series or open and closed questions. Patients completed the questionnaire online using Survey Monkey and provided information detailing the impact the system had on their satisfaction and how it enhanced their ability to self-manage.

Results: 1,095 (27.5%) active users completed the survey. Key results: 92.1% - contained all expected features; 87% - serves as reminder of information discussed at consultations; 89.6% - helps make better use of consultation time; 85.2% - don't need to phone doctor for results; 89.1% - system was easy to use; 94.2% - supporting information helped to understand results better; 93.7% - helped find information tailored to own diabetes; 95.9% - graphs helped monitor changes over time; 96.7% - confident the system was secure; 88.2% - helped manage diabetes better; 90.3% - improved knowledge; 89.3% - improved motivation; 89.8% - helps set own goals; 96.4% - system will significantly improve diabetes self-care in Scotland. Feedback: *"Immensely satisfied with the system. Really amazing to see my results online. Real motivator"*;*"I don't have to make appointments to see GP or nurse which is good as I work and don't like taking time off work"*

Conclusion: MDMW is a highly-effective intervention in the pursuit of supported self-management. Patients report enhanced knowledge and understanding of diabetes and improved motivation to make positive changes. MDMW is a key resource to engage patients in order to achieve strategic aims for the diabetes population in Scotland. We are actively pursuing opportunities to extend the service into other parts of the UK, and beyond.

Improved treatment engagement among patients receiving insulin glargine 300 U/ml who enrolled and received live support through the COACH patient support programme

J. Goldman[1], J. Gill[2], T. Horn[3], T. Reid[4], J. Strong[5], W. Polonsky[6];
[1]MCPHS University, Boston, [2]Sanofi US, Inc., Bridgewater, [3]Symphony Health Solutions LLC, Phoenix, [4]Mercy Diabetes Center, Janesville, [5]Ministry Medical Group, Plover, [6]Behavioral Diabetes Institute, San Diego, USA.

Background and aims: The insulin glargine 300 U/ml (Gla-300) COACH Support Program provides support for patients with diabetes initiating Gla-300 by delivering tailored, product-focused educational materials and encouraging lifestyle changes for better glycaemic control. This analysis specifically evaluated the impact of COACH live phone support on treatment engagement.

Materials and methods: Patients who enrolled in COACH received a welcome call from a Guide to identify specific disease/therapy management needs. Ongoing support included contact with the Guide to reinforce healthcare provider recommendations and access to training sessions/digital tools. Patients who filled a first prescription for Gla-300 in April −December 2015 and completed the welcome call were matched to control patients receiving Gla-300 from the Symphony Health Solutions Integrated Dataverse™ prescription claims database, based on demographic attributes (age, gender, geographical location, prior use of insulin/other agents, diabetes type, insulin dose, co-pay, and payer type). Number of refills and days on therapy (days of Gla-300 supply summed for all patients divided by total number of patients) were determined at 6 and 9 months.

Results: The analysis population included 1,724 COACH patients and 1,724 matched controls. The COACH and control cohorts comprised: 52% men, 48% women; 22% aged 18−47 years, 23% 48−55 years, 27% 56−61 years, and 28% >61 years. A total of 99% of patients had used insulin in the 1-year period prior to the welcome call (45% insulin glargine 100 U/ml; 54% another insulin), and 71% had a co-pay of $15 on their first paid Gla-300 prescription claim. More COACH vs control patients had commercial health insurance (42% vs 34 %) and Medicare coverage (12% vs 5%); 43% and 58% COACH and control patients, respectively, received coupons/discount cards or payment aids ($P < 0.0001$ for all). After 6 months, COACH patients refilled their prescription on average 3.2 times vs 2.4 times for control patients; at 9 months, the average number of refills was 4.7 for COACH patients vs 3.6 for control patients ($P < 0.0001$ for both time points). The average number of days on therapy was 102.2 and 151.9 for COACH patients, and 81.5 and 121.6 for control patients, at 6 and 9 months of follow-up, respectively ($P < 0.0001$ for both time points). At 9 months, an increase of 32% and 25% in number of prescription refills and length of therapy, respectively, was observed for the COACH cohort vs control cohort.

Conclusion: Patients who received live phone support through the COACH Support Program were more likely to refill their prescriptions and stay on therapy. Enrolment in programmes with a phone-support component may contribute to improved insulin therapy.

PS 058 Psychological factors affecting outcomes in diabetes

766

The process of adaptation following a diagnosis of type 1 diabetes in adulthood

M. Due-Christensen[1], I. Willaing[2], A. Forbes[1];
[1]Faculty of Nursing and Midwifery, King's College London, London, UK, [2]Health Promotion Research, Steno Diabetes Center Copenhagen, Copenhagen, Denmark.

Background and aims: Little consideration has been given to the experiences of patients following a diagnosis of type 1 diabetes in adulthood, despite the fact that more than half of all cases occur during this time. A diagnosis of type 1 diabetes is a major event and necessitates significant physical and psycho-social adaptation. The adaptive strategies adults engage in following their diagnosis may influence their future risk of diabetes complications and their psycho-social well-being. Therefore, to better understand and attend to the needs of adults at and following their diagnosis, the aims of the study were: Firstly, to explore the experience of being diagnosed with type 1 diabetes in adulthood and secondly, to explore the underlying bio-psycho-social phenomena that influence the process of adaptation when becoming a person with diabetes.
Materials and methods: Thirty participants were recruited from hospitals in Denmark and the UK, sixteen were men. At the first interview the median age of participants were 29 years (range 20-67); the median diabetes duration was 23.5 months (range 3-46) and median HbA1c was 48 mmol/mol (range 55 - 138 mmol/mol). Longitudinal semi-structured interviews were conducted face to face followed by a telephone interview six months later. A narrative approach detailing the themes emerging from the narratives was used for the analysis of the interviews.
Results: From the participants' narratives it was evident that a diagnosis of type 1 diabetes in adulthood is perceived as a major disruption to their daily life. Adapting to a life with diabetes was experienced as a multi-dimensional process occurring over a long period of time. The study identified the following bio-psycho-social phenomena as being influential in the adaptive process: their prior life experiences; their understanding of diabetes; their emotional responses to the diagnosis; the way diabetes is introduced to them and their ongoing interactions with healthcare professionals; the expectations placed on them and those they place upon themselves in relation to their diabetes control and behaviours; their experience of the physical elements of the disease; their perception of the impact diabetes has on their lives; their interactions with others (family, friends and the wider public); their perception of how others view them; and the extent to which they accept diabetes as part of themselves. The findings showed that the healthcare support adults receive following their diagnosis largely focuses on technical skills and disease specific knowledge. Less attention is given to support the accommodation of diabetes in their day-to-day lives.
Conclusion: Following their diagnosis adults engage in a lengthy and multi-faceted process of adapting to a life with type 1 diabetes. Our findings suggest that psycho-social support during this early 'fluid' phase of the disease may be important in preventing the development of harmful emotional responses and behaviours that can negatively impact their risk of complications and reduce their well-being short and long term. Such interventions need to be instigated early from the point of diagnosis, with a focus on developing positive adaptive strategies and thinking styles.

The influence of affective temperaments on the glycaemic control and glucose variability of patients with type 1 diabetes

S. Orbán[1], L. Barkai[1], A. Előry[2], P. Pánczél[1], I. Karádi[1], N. Hosszúfalusi[1], K. Lukács[1];
[1]Semmelweis University 3rd Department of Internal Medicine, [2]Semmelweis University Department of Family Medicine, Budapest, Hungary.

Background and aims: Increased glucose variability (GV) is an important clinical feature of type 1 diabetes mellitus (T1DM) and a dominant component of glycaemic control. Increased GV enhances the hypoglycaemia risk and worsens the quality of life. However, we have limited information about the possible causes of between-patient variation in GV. Affective temperaments (such as depressive, cyclothymic, hyperthymic, irritable and anxious) are genetically determined personality traits which remain unchanged through the life. They influence the emotional reactivity through affecting the level of activity, biorhythms, mood and thinking process. It's proven that affective temperaments show significant correlation with the compliance of patients having chronic diseases. The aim of our study was to examine the influence of affective temperaments on glycaemic control and GV in patients with T1DM.
Materials and methods: 186 T1DM patients on analogue insulin therapy (98 male, mean age 36,61±13,00 years, with 14,90±11,22 years of diabetes duration) completed the TEMPS-A questionnaire, which is a 110-item instrument to measure affective temperaments. The limit for dominant temperaments was determined by adding 2 standard deviations (SD) to the mean score of the population on the subscale. We compared the results with the pattern of affective temperaments of healthy Hungarian population. A one-way between-groups analysis of variance was conducted to explore the effect of affective temperaments on glycaemic control, as measured by actual HbA_{1c} level. Then a one-way between-groups multivariate analysis of variance was performed to investigate the association between temperaments and indicators of GV (MBG: Mean Blood Glucose, SD, MAGE: Mean Amplitude of Glucose Excursion, HBGI: High Blood Glucose Index and LBGI: Low Blood Glucose Index) calculated from a six-day-long continuous glucose monitoring (CGMS) of the patients. Clinical parameters (sex, age, diabetes duration, BMI, C-peptide and specific insulin dose) were used as covariates.
Results: Prevalence (14%) and distribution of dominant temperaments in the T1DM group fitted to the standard population ($p=0.5229$ and $p=0.481$, resp.). The higher score on the depressive and anxious subscale correlated significantly with higher HbA_{1C} values ($p=0.012$ and $p=0.041$, resp.) Statistically significant differences were found in patients with higher scores on the depressive, hyperthymic and anxious subscales on the combined indicators of GV ($p=0.013$; $p=0.031$ and $p<0.001$, resp.). When the results for certain indicators were considered separately, significant associations were perceived between the depressive scale and MBG and MAGE, the hyperthymic scale and LBGI, the anxious scale and MBG, SD and MAGE using a Bonferroni adjusted alpha level of 0.01. All results were independent from the clinical parameters.
Conclusion: To the best of our knowledge, this is the first report to show the direct and independent effect of affective temperaments on metabolic control and GV in patients with T1DM. Our study suggests that higher points on the depressive and irritable scales correlate with significantly worse metabolic state and higher glucose fluctuations, and hyperthym temperament correlates with increased risk for hypoglycaemia.

768

Depression differed by midnight cortisol secretion, alexithymia and anxiety between diabetes types: a cross sectional comparison

E.O. Melin[1], M. Thunander[1], M. Landin-Olsson[1], M. Hillman[1], H.O. Thulesius[2];

[1]Department of Clinical Science, Lund University, Lund, [2]Department of Clinical Science, Lund university, Malmö, Sweden.

Background and aims: Increased prevalence of depression is found in both type 2 diabetes (T2D) and type 1 diabetes (T1D). Melancholia and atypical depression differ by cortisol secretion and clinical features. The aim was to compare between T1D and T2D patients the associations between self-reported depression, self-reported anxiety and alexithymia, midnight salivary cortisol (MSC), and obesity.

Materials and methods: Comparative cross-sectional design. The study was performed in one hospital diabetes outpatient clinic. Participants were T2D patients (n = 24; 31-59 years) and T1D patients (n = 148; 32-59 years). Self-reported depression, anxiety and alexithymia were assessed by Hospital Anxiety and Depression scale and Toronto Alexithymia Scale-20 items. MSC, HbA1c, anthropometrics and data from medical records were collected. Non-parametric tests and multiple logistic regression analysis were performed.

Results: Comparisons of prevalence between diabetes types showed for T2D/T1D: depression 25%/12% (P = 0.10); high MSC (≥9.3 nmol/L) 38%/22% (P = 0.13); alexithymia 25%/13% (P = 0.12); anxiety 38%/35% (P = 0.82). The prevalence of high MSC did not differ between depressed (17%) and non-depressed (44%) T2D patients (P = 0.35), but differed between depressed (53%) and non-depressed (18%) T1D patients (P = 0.003). The alexithymia prevalence differed between depressed (67%) and non-depressed (11%) T2D patients (P = 0.018), and between depressed (47%) and non-depressed (11%) T1D patients (P < 0.001). The anxiety prevalence did not differ between depressed (67%) and non-depressed (28%) T2D patients (P = 0.15), but differed between depressed (76%) and non-depressed T1D patients (30%) (P < 0.001). The obesity prevalence (BMI ≥30 kg/m^2) was for the depressed patients: T2D 80% and T1D 6%. In the T2D patients, depression was associated with alexithymia (AOR 15.0). In the T1D patients, depression was associated with anxiety (AOR 11.0), foot complications (AOR 8.5), HbA1C > 70 mmol/mol (AOR 6.4), and high MSC (≥9.3 nmol/L) (AOR 4.8).

Conclusion: The depressed T2D patients had traits of atypical depression, without associated high MSC (≥9.3 nmol/L) and anxiety, but the association with alexithymia was strong. The depressed T1D patients had traits of melancholia with associated high MSC and anxiety. The obesity prevalence was high in depressed T2D patients and low in depressed T1D patients.

Validation of a shortened 11-item version of the Problem Areas in Diabetes scale to measure distress in adults with type 1 diabetes

P. Mansell[1], N. Stanulewicz[2], D. Hopkins[3], D. Cooke[4], H. Blake[5];
[1]Department of Diabetes and Endocrinology, Nottingham University Hospitals NHS Trust, Nottingham, [2]Department of Psychology, Durham University, Durham, [3]Department of Diabetes, Kings College Hospital, London, [4]School of Health Sciences, University of Surrey, Guildford, [5]School of Health Sciences, University of Nottingham, Nottingham, UK.

Background and aims: There is a need for a brief measure to assess diabetes-related emotional distress in people with type 1 diabetes (T1D) and also responsiveness following interventions aimed at reducing such distress. The 20-item Problem Areas in Diabetes (PAID-20) questionnaire is lengthy for routine use in clinical settings. We analysed PAID data to determine whether a shortened form could be derived without loss of reliability, validity and sensitivity to change in a large cohort of people with T1D.

Materials and methods: Information was extracted from a research database covering 10 UK centres, including PAID data collected before and one year after participants with T1D had attended a DAFNE (Dose Adjustment For Normal Eating) diabetes structured education course. Exploratory factor analysis (EFA) with a principal axis factoring method was conducted on the baseline (pre-intervention) data to determine whether a shorter PAID scale would retain the psychometric properties of the original scale. Confirmatory factor analysis (CFA) was conducted on 1-year post-intervention data to check the reliability of the initial factor solution.

Results: Of 2496 people taking the DAFNE course, baseline PAID-20 data were available for 1772, (mean age 48 (SD 14) years, duration of diabetes 24 (14) years and 51% female). One year follow-up data were complete in 1096 with HbA1c 8.67 (1.54)% (71.3 (16.9) mmol/mol) before and 8.37 (1.46)% (68.0 (15.1) mmol/mol) 12 months after DAFNE (P<0.001) and corresponding PAID-20 scores 27.9 (19.6) and 20.2 (17.4) (P<0.001). We successively removed from PAID-20: a) one question with a factor loading less than 0.50, b) 5 questions with mean scores below 1.0 (indicating floor effects) to create PAID-14 and finally, c) the 3 questions with the lowest reliability (convergence with both PAID-14 and PAID-20 < 0.65) to formulate an 11-item PAID. PAID-11 has high internal (Cronbach's α = .96) and test-retest (r = .61) reliability. For the post-DAFNE confirmatory analysis, the same 11 questions in PAID showed the highest factor loadings. The area under the curve analysis showed the optimal cut-off score for detecting significant diabetes related distress (equivalent to PAID-20 score of 33) was 16.5 in PAID-11. For the 1034 participants with complete, paired data, the PAID-11 score fell from 14.1 (10.1) at baseline to 11.0 (9.1) after DAFNE (P<0.001).

Conclusion: There is apparent redundancy in the PAID-20 questionnaire as applied to people with T1DM as an 11-item version of the questionnaire can be used without loss of sensitivity or specificity, and shows a similar responsiveness to change after an intervention. The PAID-11 questionnaire therefore appears suitable both to determine diabetes related distress in people with T1D and responsiveness to a relevant intervention. Its relative brevity may enhance its usefulness in everyday clinical practice.

Vision related quality of life and locus of control in type 1 diabetes. A multicentre observational study

M. Trento[1], S. Merlo[1], O. Durando[1], P. Fornengo[1], S. Bertello[2], S. Oleandri[2], G. Picca[3], C. Donati[4], F. Bandello[5], R. Lattanzio[5], E. Aragona[5], L. Scoccianti[6], R. Perilli[7], S. Casati[8], L. Charrier[9], F. Cavallo[9], M. Porta[1];
[1]Department of Medical Sciences, University of Turin, Turin, [2]Service of Endocrinology and Diabetology, Azienda Ospedaliera, Cuneo, [3]Service of Endocrinology., Azienda Ospedaliera Universitaria, Foggia, [4]Eye and Pathophysiological Clinic, Azienda Ospedaliera Universitaria Careggi, Florence, [5]Department of Ophthalmology, Scientific Institute San Raffaele, University Vita-Salute, Milan, [6]Diabetic Retinopathy Centre and Laser Treatment, Institute of Ophthalmology, Parma, [7]Department of Social Ophthalmology, Azienda Ospedaliera Universitaria, Pescara, [8]Department of Neurosciences and Biomedicine, Azienda Ospedaliera Universitaria, Verona, [9]Department of Public Health and Paediatric Sciences, University of Turin, Turin, Italy.

Background and aims: Vision plays an important role in the ability of people to process information from their environment and to participate in everyday activities. Diabetic Retinopathy (DR) is considered to remain asymptomatic until it reaches its late stages. However, subtle changes in vision related quality of life (QoL) may occur even in mild DR and their perception may be related to a patient's locus of control (LoC) of his/her disease. To evaluate vision-related QoL and LoC in patients with Type 1 Diabetes and different stages of DR.

Materials and methods: The 25-item National Eye Institute Visual Functioning (NEI VFQ-25) and Locus of Control (LoC) questionnaires were self-administered to 258 patients between January 2014 and March 2017 in 9 DR screening centres. The NEI VFQ-25 explores 12 dimensions**:** General Health (GH), General Vision (GV), Ocular Pain (OP), Near Activities (NA), Distance Activities (DA), Visual Specific Social Functioning (VSSF), Mental Health (VSMH), Role Difficulties (VSRD), Dependency (VSD), Driving (D), Colour Vision (CV) and Peripheral Vision (PV). The LoC questionnaire includes 18 items assessing 3 areas: Internal Control of disease, the role of Chance and trust in Others (family members, health operators). Data on socio-anagraphic variables and presence of DR, cataract and previous laser treatment (LT) were collected.
Results: Patients included 124 women and 134 men aged 42.0±12.4 years and with 28.0±12.4 disease duration. DR was absent (n=74), mild-moderate (n=75), severe (n=96) and laser treated (n=13). DR severity was directly associated with disease duration (p<0.001) and measuring blood glucose less than 4 times a day (p=0.013). Smoking showed a trend to protect from DR. The patients with no DR had better scores for GH (p=0.0008), GV (p=0.0007), CV (p=0.045) and PV (p=0.0001) than those with mild and more severe DR. There were no differences in any of the LoC areas.
Conclusion: Even in mild asymptomatic stages, DR is associated with impaired perception of vision related quality of life, with specific reference to general health, general vision, colour vision and peripheral vision, independently of personality traits explored by the LoC tool. The possible protective effect of smoking confirms previous reports and requires further investigation

771

Non-disclosure of type 2 diabetes at work among Danish employees
O. Kasper[1], B. Cleal[1], T. Skinner[2,1], I. Willaing[1];
[1]Diabetes Management Research, Steno Diabetes Center Copenhagen, Gentofte, Denmark, [2]School of Psychological and Clinical Sciences, Charles Darwin University, Darwin, Australia.

Background and aims: Increasing retirement age in many OECD countries, in addition to increasing prevalence of type 2 diabetes in younger people, is expected to result in a substantial increase of people with type 2 diabetes in the labour force. In many jobs, disclosure of diabetes at the work place is necessary for optimal self-management during work hours, whereas non-disclosure may lead to impaired self-management behaviours, such as adverse eating, inexpedient consumption of medication, or not taking necessary breaks. We explored which factors were associated with disclosing diabetes at work among Danish workers with type 2 diabetes.
Materials and methods: In total 705 people with type 2 diabetes successfully completed a questionnaire including work and diabetes related questions. Three logistic regressions were modelled to estimate the associations between the included factors and likelihood of disclosure to employer and colleagues. Associations were expressed by odds ratios and 95% confidence intervals. The models were adjusted for background characteristics, socio-economic factors, life-style factors, diabetes duration, diabetes treatment, and work-related factors.
Results: Almost a quarter of the participants (23%) had not disclosed their diabetes to employer and colleagues, whilst (13%) of the participants had not disclosed their diabetes to at least one colleague. In the adjusted logistic regression analysis, workers with, long diabetes duration, and use of diabetes medication, particular injections, were more likely to disclose their diabetes to their employer. People who reported receiving respect from their superiors were also more likely to disclose their diabetes. Likewise, participants who considered it an employer responsibility to provide flexible work conditions for people with chronic illness were more likely to disclose their diabetes. In contrast, people with the highest educational level were less likely to disclose their diabetes. Adjustment for covariates in the analyses slightly modified the estimates.
Conclusion: Workplace factors rather than individual factors seemed associated with disclosure. Future prospective studies should focus on reasons for concealing type 2 diabetes at work and impact of disclosure on diabetes self-management and work environment.

Table: Results from adjusted logistic regressions.
Associations between background characteristics and disclosure of type 2 diabetes. N = 705

Characteristic:	Model 1 Odds ratio (95 % CI)	Model 2 Odds ratio (95 % CI)
Age (year, continuous)	1.02 (0.99-1.04)	1.02 (0.99-1.05)
Gender (male)	0.85 (0.58-1.24)	0.76 (0.51-1.13)

People with type 1 diabetes and psychosis have a markedly increased risk of hospitalisation for acute diabetes complications
J. Petit, K. Goueslard, J. Cottenet, J.-C. Chauvet-Gelinier, B. Bouillet, B. Verges, C. Quantin;
Diabetologie, CHU du Bocage, Dijon, France.

Background and aims: The management of type 1 diabetes in people with psychosis is complex, and acute diabetes complications, such as ketoacidosis or hypoglycaemia, which require hospitalization, are probably more common than in people with type 1 diabetes without psychiatric diseases. However, little information is available on the effects of psychotic disorders on acute complications among patients with type 1 diabetes. The aim of our study was to examine the relationship between a history of hospitalization with a diagnosis of psychosis and acute diabetes complications for patients with type 1 diabetes.
Materials and methods: The principle of this population-based retrospective cohort study was to examine hospital data for all patients hospitalized in France for type 1 diabetes, from 2009 to 2012. In the medico-administrative database, people under 35 years with type 1 diabetes were identified from the codes E10 to E14 as the main, related or associated diagnoses. Then, two groups were formed: on the one hand, people with previous hospitalization with a diagnosis of psychosis (codes F2) over the two years before the index hospitalization; on the other hand, people with no hospitalization with a diagnosis of psychosis, over the two years before or after the index hospitalization, until 2015. Epidemiological follow-up was conducted at one and three years. It focused on hospitalization for acute diabetes complications (hypoglycaemia, hyperglycaemia, coma, ketoacidosis) and suicide attempts, but also on hospital mortality.
Results: From 2009 to 2012, 65,684 patients were hospitalized for type 1 diabetes complications. Among these, 350 had a previous hospitalization for psychosis: these patients were older (28.35 vs 20.99 years) and there were more men (67.71% vs 50.13%, p<.0001). At three years, patients with a history of psychosis were more frequently hospitalized for hypoglycaemia (p=0.002), hyperglycaemia (p=0.0003), coma (p=0.0003), ketoacidosis (p=0.02), all acute complications (p=0.001), or suicide attempts (p<.0001) and hospital mortality was higher (p=0.001). After adjustment for age and gender, the logistic regression showed that a history of hospitalization for psychosis for patients with type 1 diabetes was associated with an increased risk of all acute complications (hypoglycaemia, hyperglycaemia, ketoacidosis) (adjusted Odds-Ratio (aOR)=1.98 [1.47-2.66]), death (aOR=3.62 [1.92-6.82]), and suicide

attempts (aOR=12.38 [8.68-17.66]). Similar results were found for the follow-up at one year.

Conclusion: This nationwide population-based study showed that a history of hospitalization for psychosis in patients with type 1 diabetes was significantly associated with an increase in hospitalizations for acute diabetes complications and suicide attempts, and in in-hospital mortality. These results may be related to a lack of compliance with insulin therapy, self-aggressive behaviour, and social isolation. These results must encourage diabetologists to develop specific multidisciplinary health education actions for people with type 1 diabetes and psychiatric disorders in collaboration with psychiatric departments. A history of hospitalization for psychosis must be considered a warning sign for the risk of acute diabetes complications.

Disclosure: **J. Petit:** None.

Endline assessment of patients' knowledge, attitudes, and practices on diabetes and tuberculosis comorbidities in South Africa

R. Matji[1], B. Mbambo[1], N. Kak[2], S. Mechiche[3], J. Zingwari[1], M. Germe[3], A. Surette[2], H. Jassim alMossawi[2];
[1]Aquity Innovations, Pretoria, South Africa, [2]University Research Co., LLC, Chevy Chase, USA, [3]Sanofi, Paris, France.

Background and aims: Rates of DM are quickly increasing in high TB burden countries such as South Africa (SA). In most of these countries, service delivery for DM and TB are vertical, and therefore patients at risk of or with both diseases do not receive integrated care. In 2011, SA initiated the Integrated Chronic Disease Model to integrate clinical services and respond to the growing burden of chronic diseases in the country. This follow-up survey was administered to assess changes in patients' knowledge and behaviors regarding TB and DM services, since implementation of a series of educational, advocacy and capacity building interventions at patient, provider, and facility levels in three provinces in SA.

Materials and methods: A cross-sectional Knowledge, Attitudes, and Practices (KAP) survey was conducted among 395 and 420 patients attending TB and DM service sites respectively, in 22 public health facilities across three provinces in SA that were involved in the baseline (BL) survey (results reported elsewhere). Patients completed a structured questionnaire around patient's knowledge, beliefs, health-seeking behaviors and experience of TB and DM public health services in SA in December 2016.

Results: Survey participant characteristics and demographic profiles were similar at BL and endline (EL). Among patients with DM, 81% were female; while only 39% were women with TB. Similar to the BL results, most of the survey patients listed clinic as their main source of health information (over 80% of the study population). The survey revealed improvements in patient exposure to health education, counselling and screening for comorbidities (TB for DM patients and DM for TB patients). Compared to BL, TB testing among DM patients increased from 37% to 57% ($p<.01$) while DM testing among TB patients increased from 55% to 67% ($p<.01$). Counselling on comorbidities was also higher in both groups: counselling was higher by 41% for TB patients ($p<.01$) and by 59% for DM patients ($p<.00$). Exposure to health education doubled for DM patients from 22% at BL to 45% at EL ($p<.01$). Among TB patients, exposure to health education was higher by 71% ($p<.01$) from BL to EL. Patients with DM demonstrated good basic knowledge of how to maintain their health. At EL, the proportion of DM patients with knowledge on the importance of regular exercise, attending regular checkups, and taking medication as prescribed was higher compared to BL (+52%, +18%, and + 45%, respectively, $p<.01$; $<.01$; 0.02). However, the proportion of DM patients who understood the risk of developing complications if they did not regularly take medication as prescribed was lower, from 17% at BL to 9% at EL ($p<.01$). The proportion of DM patients knowing the link between DM and TB was also higher compared to BL. There was a high level of general knowledge about TB among both patient groups, but little understanding on the importance of treating co-morbidities.

Conclusion: While much research has been done in SA on patient KAP towards TB and HIV, and to a lesser extent towards DM, this is the first study of patient understanding of TB-DM comorbidity and experience of counselling, screening, and testing for both diseases at the facility level. Implementation of integrated care from educational, advocacy and capacity building interventions may contribute to provide overall quality care to patients with both diseases.

INITIAL combination therapy with vildagliptin/metformin in drug-naive Asian type 2 diabetes patients: influence of age, BMI and co-morbidities in a real world setting

R.C. Mirasol[1], M.F. Pathan[2], M. Chawla[3], T.H. Kim[4], K. Cooke[5], P. Hours-Zesiger[5], A. Shete[5];
[1]St. Luke's Medical Center, Quezon City, Philippines, [2]BIRDEM Hospital, Dhaka, Bangladesh, [3]LINA Diabetes Care Centre, Mumbai, India, [4]Seoul Medical Center, Seoul, Republic of Korea, [5]Novartis Pharma AG, Basel, Switzerland.

Background and aims: Individualising diabetes therapy is imperative to address the multi-factorial impact of the disease. Advancing age, overweight/obesity, hypertension, and elevated lipids are identified risk factors for cardiovascular (CV) disease and are useful considerations for making treatment decisions. We assessed these characteristics in the multinational INITIAL study.
Materials and methods: **I**nitial combi**N**ation therapy with vildagliptin/metformin **I**n drug-naïve **T**2DM patients **I**n a re**A**l **L**ife study was a 24-week, non-interventional, prospective study conducted across four Asian countries. Drug-naïve patients with documented HbA1c >7.5% (>8.0% in India) were prescribed vildagliptin/metformin (vilda/met) combination therapy within four weeks of study entry according to local label. The primary endpoint was change in HbA1c from baseline to week 24. Key secondary endpoints were safety, achievement of HbA1c ≤7.0%, and change in HbA1c by subgroups: age, BMI, associated co-morbidities.
Results: Out of 532 enrolled patients, 457 (85.9%) completed the study. Study population was relatively young with mean age 49.6±11.27 years (>90% patients were aged <65 years), mean HbA1c 9.3±1.57%, diabetes duration 0.8±2.47 years, and BMI 26.7±4.50 kg/m^2. At baseline, patients presented with hypertension (30.4%), dyslipidaemia (31.4%), obesity (17.9% or 38.7% using 30.0 or 27.5 kg/m^2 cut-off, respectively), and diabetes family history (28.4%). Overall, vilda/met therapy was associated with significant (p<0.001) reduction in HbA1c from baseline both at weeks 12 (−1.6 ±1.59%) and 24 (−1.9±1.70%) (Table). At week 24, body weight reduced by −1.1±2.62 kg and 39.6% patients achieved HbA1c ≤7.0%. Clinically meaningful and generally consistent HbA1c reductions were also seen across various sub-groups: age ≥65 years, −1.9% and <65 years, −1.8%; baseline BMI categories: obese vs. non-obese by Asian cut-off −1.7% vs. −2.0%; associated co-morbidities: no co-morbidity −1.6%, hypertension −1.8%, and dyslipidaemia −2.0%). The vilda/met initial combination was well tolerated in this population with adverse events reported in 48 (9.0%) patients.
Conclusion: We believe the INITIAL study complements the relatively limited evidence available assessing initial combination therapy in drug-naïve Asian patients with type 2 diabetes mellitus. Patients included in the study were relatively young, with high baseline HbA1c and often associated with CV risk factors. Vildagliptin/metformin was associated with early and statistically significant HbA1c reductions from baseline. Clinically meaningful and generally consistent HbA1c reductions were also observed, regardless of baseline age, BMI, or associated co-morbidity (i.e. hypertension, dyslipidaemia).

Table. Clinical parameters of the study population by visit: INITIAL study (full analysis set)

Clinically significant change in albumin creatinine ratio with saxagliptin: a post hoc analysis from the SAVOR-TIMI 53 trial

O. Mosenzon[1], B.M. Scirica[2], A. Rozenberg[1], I. Yanuv[1], A. Cahn[1], I. KyungAh[2], Y. Gurmu[3], B. Hirshberg[4], C. Stahre[5], D.L. Bhatt[2], I. Raz[1];
[1]The Diabetes Unit, Hadassah Hebrew University Medical Center, Jerusalem, Israel, [2]TIMI Study Group, Brigham and Women's Hospital, Harvard Medical School, Boston, [3]TIMI Study Group, Brigham and Women's Hospital, Boston, [4]Medimmune, Gaithersburg, USA, [5]AstraZeneca R&D, Mölndal, Sweden.

Background and aims: A 30% decrease in Albumin Creatinine ratio (ACR) is considered a clinically significant improvement. It is associated with improved renal and possibly also cardiovascular outcomes. We tested whether saxagliptin is associated with ≥30% change in ACR.
Materials and methods: The SAVOR-TIMI 53 trial randomized 7,501 (45.5%) patients with ACR<15 mg/g, 2,197 (13.3%) patients with 15≤ACR<30 mg/g, 4,426 (26.8%) patients with micro-albuminuria (30≤ACR<300 mg/g) and 1,638 (9.9%) patients with macro-albuminuria (ACR ≥300 mg/g) to treatment with saxagliptin versus placebo. Median follow-up was 2.1 years and ACR was measured at baseline, 1-year, 2-year and end of the trial (EOT) time-points.
Results: At the EOT, there were more patients with ≥30% decrease in ACR in the saxagliptin arm versus placebo (38% vs. 33.8% respectively, p<0.001). Additionally, there were less patients with ≥30% increase in ACR in the saxagliptin arm versus placebo (39.5% vs. 44%, p<0.001). Both of these differences between the saxagliptin and placebo arms were also observed at different categories of ACR at baseline (table).
Conclusion: In a large population of patients with type 2 diabetes and increased cardiovascular risk, saxagliptin was associated with higher incidence of clinically significant improvement in ACR.

No major impact seen with sitagliptin on rates of cardiovascular death or hospitalisation for heart failure following myocardial infarction during TECOS

M.A. Nauck[1], K.S. Pieper[2], Y. Lokhnygina[2], D.K. McGuire[3], E.D. Peterson[2], R.R. Holman[4], for the TECOS Study Group;
[1]Division of Diabetology, Medical Department I, St. Josef Hospital, Ruhr University Bochum, Bochum, Germany, [2]Duke Clinical Research Institute, Durham, [3]University of Texas Southwestern Medical Center, Dallas, USA, [4]Diabetes Trials Unit, University of Oxford, Oxford, UK.

Background and aims: Dipeptidyl peptidase-4 inhibitors (DPP-4i) reduce myocardial infarction (MI) size in animal models, but the clinical relevance of these observations remains unknown.
Materials and methods: TECOS randomized 14,671 participants with type 2 diabetes (T2D) and atherosclerotic cardiovascular disease to sitagliptin or placebo therapy in addition to usual care. For all participants, time to a primary composite endpoint of cardiovascular death or hospitalisation for heart failure (hHF), and the two components separately, were analysed by Cox proportional hazards models left-censored at the time of the MI (without and with adjustment for potential confounders).
Results: During the trial 616 participants had an MI (300 and 316 allocated to sitagliptin and placebo, respectively); 102 (17%) subsequently died, including 81 (13%) with cardiovascular death; and 57 (9%) experienced hHF. At the time the MI occurred, 253 (41%) participants were taking a DPP-4i and 362 (59%) were not. Those with an MI during the trial generally had similar characteristics to those without but were more likely to be male (77.9% *vs.* 70.4%, p<0.0001), more often had pre-existing coronary artery disease (89.4% *vs.* 73.4%), previous MI (57.8% *vs.* 42.0%, both p<0.0001) or hHF (21.4% *vs.* 17.9%, p=0.024). Metformin treatment was reported less frequently (75. 5% *vs.* 81.8%), whilst insulin treatment was reported more frequently (32.5% *vs.* 22.8%, both p<0.0001). Drugs to treat cardiovascular conditions were used significantly more frequently in MI patients. Intention-to-treat analyses for the primary composite endpoint yielded non-significant hazard ratios of 1.17 (95% CI 0.82-1.67, p=0.38, unadjusted) and 1.22 (0.84-1.77, p=0.29, adjusted), with similar results for the two components (see Figure). As-treated analyses also yielded non-significant hazard ratios of 0.79 (0.55-1.14, p=0.21, unadjusted) and 0.82 (0.56-1.20, p=0.30 adjusted), mainly driven by a reduced hazard for cardiovascular death (0.65 [0.41-1.03], p=0.07 unadjusted; 0.61 [0.28-0.99], p=0.05 adjusted), with no obvious change in the risk of hHF.
Conclusion: These data do not provide conclusive evidence regarding the hypothesis that DPP-4i therapy ameliorates the consequences of MI in patients with T2D.

Association between race and glycaemic response to sitagliptin: insights from TECOS

T.M.E. Davis[1], H. Mulder[2], Y. Lokhnygina[2], E. Standl[3], E.D. Peterson[2], R.R. Holman[4], for the TECOS Study Group;
[1]School of Medicine, University of Western Australia, Fremantle, Australia, [2]Duke Clinical Research Institute, Durham, USA, [3]Munich Diabetes Research Institute, Munich, Germany, [4]Diabetes Trials Unit, Oxford University, Oxford, UK.

Background and aims: Evidence from pooled small-scale efficacy studies suggests that Asians with type 2 diabetes have a greater glycaemic response to dipeptidyl-peptidase 4 inhibitors than other races. Asian patients may also be more reponsive to acarbose. We assessed the glycaemic impact of sitagliptin by race in the global cardiovascular safety study the Trial Evaluating Cardiovascular Outcomes with Sitagliptin (TECOS). We also evaluated whether there might be an additive incretin effect with sitagliptin-acarbose combination therapy in Asian patients.
Materials and methods: 14,671 participants with type 2 diabetes and established cardiovascular disease, of whom 3,265 (22.3%) were from Asian countries, were randomised to double-blind therapy with sitagliptin or placebo. Qualifying HbA_{1c} values were 51 to 64 mmol/mol (6.5% to 8.0%). The TECOS protocol required that background blood glucose-lowering therapies remain stable during four months after randomisation unless therapeutic intensification was considered essential, facilitating an assessment of whether glycaemic effects differed between self-identified Oriental (East) Asian, Other (South) Asian, White Caucasian, Hispanic, Black and Indigenous racial groups.
Results: Median baseline HbA_{1c} in the six racial groups ranged from 54 to 57 mmol/mol (7.1-7.4%). Mean placebo-adjusted relative HbA_{1c} reduction over four months (see Table) was greater in Oriental Asians than other groups (p<0.0001) except White Caucasians (p=0.08) after adjustment for weight, height, age, and use of statin, beta-blocker and thiazide therapies. After 4 months, Oriental and Other Asians were more likely to start additional oral therapy (metformin and sulfonylureas) than insulin compared with White Caucasians (p<0.0001). Utilisation of acarbose increased in the Asian patients but no glycaemic interaction with allocated therapy was observed (adjusted p=0.12).
Conclusion: In TECOS, Oriental Asians had the greatest initial HbA_{1c} reduction with sitagliptin. The relatively good baseline glycaemic control in TECOS participants may explain the smaller absolute between-group differences than seen in earlier Phase studies. No additive glycemic effect was seen when sitagliptin was given in conjunction with acarbose.

Table. Placebo-adjusted mean (95% CI) HbA_{1c} change from baseline to 4 months by race in TECOS.

	Number	mmol/mol	%
Caucasian	9,957	-3.3 (-3.7, -3.0)	-0.3 (-0.3, -0.3)
Asian (Other)	2,178	-3.8 (-4.4, -3.2)	-0.3 (-0.4, -0.3)
Asian (Oriental)	1,087	-5.0 (-5.9, -4.2)	-0.5 (-0.5, -0.4)
Hispanic	906	-4.1 (-5.0, -3.2)	-0.4 (-0.5, -0.3)
Black	447	-3.6 (-4.8, -2.3)	-0.3 (-0.4, -0.2)

Resource use and UK-perspective costs in patients with type 2 diabetes during the Trial Evaluating Cardiovascular Outcomes with Sitagliptin (TECOS)

A.M. Gray[1], J. Leal[1], S.D. Reed[2], Y. Li[2], F. Graham[2], J.B. Green[2], K.D. Kaufman[3], L. Radican[3], J. Alfredsson[4], J. Buse[5], A. Riefflin[6,7], F. Van de Werf[8], E.D. Peterson[2], R.R. Holman[9];
[1]Nuffield Department of Population Health, Health Economics Research Centre, Oxford, UK, [2]School of Medicine, Duke Clinical Research Institute, Durham, [3]Merck & Co. Inc., Kenilworth, USA, [4]Linkoping University Hospital, Linkoping, Sweden, [5]University of North Carolina Medical School, Chapel Hill, NC, USA, [6]GMP, Husby, Germany, [7]AMD (Arbeitsmedizinischer Dienst), Flensburg, Germany, [8]University of Leuven, Leuven, Belgium, [9]Radcliffe Department of Medicine, Diabetes Trials Unit, Oxford, UK.

Background and aims: We report data from TECOS, a cardiovascular (CV) safety trial in which 14,671 participants with type 2 diabetes and established CV disease from 38 countries were randomised to sitagliptin or placebo added to usual care, and were managed to achieve individualized good glycaemic control. Sitagliptin was non-inferior to placebo for the primary composite outcome of CV death, nonfatal myocardial infarction, nonfatal stroke, or hospitalisation for unstable angina. We consider secondary and tertiary comparisons of medical resource use and costs between treatment groups.
Materials and methods: Medical resource use data were collected from randomisation to study end. Here we report UK unit costs applied to all health care resource use. Hospitalisations and outpatient visits were costed from a UK perspective using Healthcare Resource Groups and national reference costs, study medication using list prices, and other antihyperglycaemic drugs using a 2015 weighted mix of generic and proprietary drugs. All costs beyond the first year were discounted at the UK recommended rate of 3.5% annually. Hierarchical generalized linear models (HGLM) were used to account for variable practice patterns across participating countries.
Results: Mean and median follow-up was 3.0 years in both groups. Resource use and costs were similar for both treatments (Table). Sitagliptin-treated patients had 5 fewer hospitalisations per 100 patients (p=0.16). Total costs, exclusive of sitagliptin, were £6,058 vs £6,219 for sitagliptin vs placebo. Mean sitagliptin costs were £1,072 per patient. After adding study medication costs, mean total costs for the sitagliptin group were £7,130, and the mean (95% CI) cost difference between arms was £911 (£627 to £1201).
Conclusion: This large randomised trial, designed to assess CV outcomes in the setting of glycaemic equipoise between treatment groups, suggests that within a UK perspective, lower costs from small reductions in hospitalisation rates with sitagliptin slightly offset the additional treatment costs.

Table.

	Sitagliptin (n=7332)	Placebo (n=7339)	Difference (95% CI with bootstrap method)	P-value
Resource use over full follow-up period, mean (SD)				
Hospitalizations	0.66 (1.29)	0.70 (1.43)	-0.049 (-0.095 to -0.008)	0.16
Inpatient days	5.50 (16.38)	5.74 (16.54)	-0.243 (-0.768 to 0.241)	0.99
All outpatient visits	19.42 (17.36)	19.43 (17.35)	-0.008 (-0.520 to 0.583)	0.86
*Costs over full follow-up period, mean (SD)***				
Inpatient care	£2,629 (7960)	£2,760 (8262)	-131 (-406 to 116)	*
Outpatient care	£2,648 (2287)	£2,654 (2294)	-6 (-73 to 73)	0.93
Diabetes medications	£781 (870)	£805 (868)	-24 (-50 to 5)	0.81

CARMELINA® trial baseline characteristics: a cardiovascular and renal microvascular outcome trial with linagliptin in patients with type 2 diabetes at high vascular risk

V. Perkovic[1], J. Rosenstock[2], D.K. MacGuire[3], on behalf of the CARMELINA steering committee;
[1]The George Institute for Global Health, Sydney, Australia, [2]Dallas Diabetes Research Center at Medical City, Dallas, [3]Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, USA.

Background and aims: Recent cardiovascular (CV) outcome trials in type 2 diabetes (T2D) focused on populations at high risk for macrovascular complications. Generally, patients with moderate-to-severe microvascular burden, such as advanced kidney disease, were relatively underrepresented. Thus, the impact of glucose-lowering therapies on combined cardio-renal outcomes in T2D remains unclear.
Materials and methods: CARMELINA® is an ongoing, global, randomized, double-blind, placebo-controlled clinical trial designed to assess the impact of the DPP-4 inhibitor linagliptin 5 mg daily on CV and renal outcomes in a population enriched for both macrovascular and renal microvascular complications. The primary objective is to establish CV safety of linagliptin versus standard of care assessed by a composite outcome of 3-point MACE (CV death, nonfatal myocardial infarction, or nonfatal stroke). A composite renal outcome (renal death, end stage renal disease, or sustained ≥40% decrease in eGFR from baseline) is a prespecified secondary endpoint and will be tested after non-inferiority for MACE is established. All CV and renal outcome events will be confirmed by central adjudication.
Results: Baseline characteristics of the treated study population (n=6978) randomized between July 2013 and August 2016 include: (mean±SD) age 65.8±9.1 yrs, 62.9% male, BMI 31.3±5.3 kg/m², HbA1c 7.9±1.0 %. Most patients had long-standing T2D (64.7% >10 yrs) and 57.8% were treated with insulin. As defined by study inclusion criteria, established CV disease (n=3990 [57.2%]), overt CKD (i.e. GFR <60ml/min/1.73m^2; n=4348 [62.3%]) or presence of micro- (n=2896 [41.5%]) or macroalbuminuria (n=2691 [38.6%]) were frequent at baseline.
Conclusion: CARMELINA® will explore both CV and renal outcomes in patients with T2D. In addition, it will add evidence to the long-term clinical safety profile of linagliptin by including patients at advanced stages of kidney disease.

A long-term, open-label extension study to investigate the long-term safety of alogliptin in subjects with type 2 diabetes

N. Smith[1], R. Pratley[2], C. Wilson[1], Q. Mekki[1];
[1]Takeda Global Research and Development Center, Inc., Deerfield, [2]Florida Hospital Translational Research Institute for Diabetes and Metabolism, Orlando, USA.

Background and aims: Alogliptin is a potent, highly selective, orally available inhibitor of the dipeptidyl peptidase 4 enzyme. This study evaluated the long-term safety of alogliptin when used as monotherapy or in combination with other therapies in subjects with T2DM who completed 1 of 7 phase 3 studies.

Materials and methods: In this international, multicenter, open-label extension study, T2DM subjects who had completed 1 of 7 phase 3 alogliptin studies were randomized (1:1) to receive alogliptin 12.5 mg (12.5 mg completed group) or 25 mg (25 mg completed group) once a day (QD) for up to 4 years. Subjects previously rescued from 1 of the 7 phase 3 studies due to hyperglycemia received alogliptin 25 mg (25 mg rescued group). Subjects previously receiving add-on therapy continued this treatment. Investigators were free to modify or add add-on therapy per clinical need. Primary endpoints included study drug exposure and adverse event (AE) rates, including hypoglycemia. Secondary endpoints included HbA_{1c} levels, fasting plasma glucose (FPG) levels, and incidence of marked hyperglycemia (FPG ≥200 mg/dL).
Results: A total of 3323 subjects were enrolled; 3320 (99.9%) received ≥1 dose of study drug (safety set), and 1996 (60.1%) completed the 4-year treatment period. Median duration of exposure was 191.7 weeks (62.5% exposed for ≥180 weeks) in the 12.5 mg completed group (n=1394), 191.9 weeks (64.9% exposed for ≥180 weeks) in the 25 mg completed group (n=1399), and 162.0 weeks (49.0% exposed for ≥180 weeks) in the 25 mg rescued group (n=527). In the safety set, 2880 (86.7%) subjects experienced treatment-emergent AEs (TEAEs), and 806 (24.3%) had study drug-related TEAEs. Rates of TEAEs and treatment-emergent serious AEs were similar across the 3 groups (Table). Hypoglycemic episodes were self-reported by 13.1% of subjects in the safety set. Marked hyperglycemia (defined as FPG ≥200 mg/dL) was reported by 55.7% of subjects in the safety set. However, only 1 subject withdrew as a result of hyperglycemia. HbA_{1c} increased slightly then remained generally steady in the 12.5 mg and 25 mg completed groups. An immediate and sustained HbA_{1c} decrease was observed in the 25 mg rescued group.
Conclusion: Alogliptin administered as either 12 mg or 25 mg QD is well tolerated and can be used to maintain adequate glycemic control for up to 4 years in subjects with T2DM.

Table. Overview of treatment-emergent adverse events (Safety Set)

	Open-Label Treatment Group			
	Completed Phase 3		Rescued From Phase 3 Alogliptin 25 mg (n=527)	Total Alogliptin 25 mg (N=1926)
	Alogliptin 12.5 mg (n=1394)	Alogliptin 25 mg (n=1399)		
Subjects with any TEAE, n (%)	1215 (87.2)	1219 (87.1)	446 (84.6)	1665 (86.4)
Subjects with any study drug–related TEAE, n (%)	357 (25.6)	318 (22.7)	131 (24.9)	449 (23.3)
Subjects with any TEAE leading to treatment discontinuation/study termination, n (%)	98 (7.0)	86 (6.1)	40 (7.6)	126 (6.5)
Subjects with any treatment-emergent SAE, n (%)	233 (16.7)	228 (16.3)	83 (15.7)	311 (16.1)

Impact of sitagliptin on hypoglyceamia in elderly subjects with type 2 diabetes treated with insulin

R.R. Shankar, J. Long, L. Xu, E.A. O'Neill, S.S. Engel;
Merck & Co., Inc., Kenilworth, USA.

Background and aims: Hypoglycemia (HYPO) is uncommon with sitagliptin (SITA) treatment but occurs more frequently when SITA is added to insulin (INS) due to insulin's ability to cause hypoglycemia. HYPO is of special concern in elderly INS-treated patients.
Materials and methods: To assess the effect of SITA on glycemic control and event rates (ERs) of HYPO in the elderly treated with INS compared to younger (<65 years) subjects, data from two 24-week studies that compared the addition of SITA with PBO in subjects with T2DM on INS ± metformin were pooled (N=1299, 320 elderly; INS dose held stable in one, intensively titrated in the other) and treatment effect and event rates of HYPO were analyzed. We also examined ERs of HYPO by subgroups characterized by selected baseline characteristics.
Results: Reductions in A1C were similar in both age groups (Table). In general, elderly subjects had similar or lower ERs of HYPO compared to younger subjects. ERs of symptomatic HYPO and nocturnal HYPO were lower with SITA compared with PBO (Table) in both younger and elderly. In subgroups evaluated by baseline A1C, eGFR and duration of T2DM, ERs of HYPO were lower with SITA compared with PBO in both age groups.
Conclusion: In this pooled analysis of SITA vs PBO added to INS, SITA provided similar improvement in glycemic control and reductions in event rates of HYPO in both elderly and younger patients.

Angiogenic T lymphocytes are decreased in type 2 diabetes and are recruited by dipeptidyl peptidase-4 inhibitor linagliptin

D.J. Mulder[1], S.A. De Boer[1], E.S. Hoekstra[2], R.H.J. Slart[3], J.D. Lefrandt[1], W.H. Abdulahad[2], H.J. Lambers Heerspink[4], J. Westra[2];
[1]Vascular Medicine, University of Groningen, University Medical Center Groningen, [2]Rheumatology and Clinical Immunology, University of Groningen, University Medical Center Groningen, [3]Nuclear Medicine and Molecular Imaging, University of Groningen, University Medical Center Groningen, [4]Clinical Pharmacy and Pharmacology, University of Groningen, University Medical Center Groningen, Groningen, Netherlands.

Background and aims: Endothelial progenitor cells (EPCs) are involved in vascular repair and decreased in type 2 diabetes (T2D). Recently, angiogenic T lymphocytes (Tang) were identified, which facilitate EPCs in vascular repair through stromal cell-derived factor 1 (SDF-1α) mediated secretion of proangiogenic cytokines. Their role in T2D has not been investigated. Since dipeptidyl peptidase-4 (DPP4) inhibition may increase EPC levels in T2D though SDF-1α, we aimed to study whether Tang are decreased in T2D and whether their production is stimulated by treatment with the DPP4-inhibitor linagliptin.
Materials and methods: A total of 45 treatment naive T2D patients (age 63 (IQR 54-66) years, 61% male, HbA1c 6.3±0.4 (%)) without cardiovascular disease were randomized to linagliptin 5 mg/day or placebo for 26 weeks in a double-blind fashion. Additionally, 19 healthy age/gender matched controls were included (age 56 (IQR 44-67] years, 63% male). Peripheral blood mononuclear cells were isolated from venous whole blood in EDTA tubes, at baseline and 26 weeks, and in controls. Fluorescence-activated cell sorting was used to identify EPCs (CD34+ CD133+KDR+) and Tang in total CD3 (CD3+CD31+CXCR4+) and

CD4/CD8 subsets. Plasma levels of SDF-1α, interleukin 8 (IL8), and vascular endothelial growth factor (VEGF) were measured by ELISA.
Results: Total Tang number (CD3: 11.50% vs 20.39% ; p<0.0001) and in CD4 (7.65% vs 13.18%; p<0.01) and CD8 (26.68% vs 46.5%; p<0.001) subsets, were significantly lower in T2D at baseline compared with controls. While EPCs in T2D correlated negatively with IL-8 (r=-0.41; p=0.008), VEGF (r=-0.41; p=0.008) and CRP (r=-0.32; p=0.042) at baseline, no association with Tang was observed. After 26 weeks of linagliptin treatment, a clear rise in SDF-1α levels was observed (delta 166 (122) vs -7.4(28.8); p<0.0001), while IL-8 and VEGF remained stable. Furthermore, Tang increased in linagliptin treated patients and remained stable in placebo (figure; delta 1.4(2.62) vs 0.066(1.52), p=0.033 (paired), p=0.055 (for change)). The change in Tang correlated negatively with change in HbA1c (r=0.39; p=0.020). No changes in EPCs were observed.
Conclusion: This is the first study to demonstrate that the recently defined subset of angiogenic T lymphocytes are decreased in T2D. Interestingly, this placebo controlled trial suggests that linagliptin enhances their recruitment, through which DPP4-inhibitors may exert beneficial effects on vascular repair.

Treatment failure with sitagliptin compared to sulphonylureas for type 2 diabetes inadequately controlled on metformin

M. Sharma, I. Nazareth, I. Petersen;
Primary Care and Population Health, University College London, London, UK.

Background and aims: The risk of treatment failure with adding either sitagliptin or sulphonylureas to metformin for type 2 diabetes mellitus has not been comparatively evaluated in UK "real world" clinical practice. In this study, we aim to evaluate treatment failure with sitagliptin against sulphonylureas as add-on to metformin across 2 domains. The first treatment failure domain examines a failure to achieve desirable glycaemic targets while the second focuses on the requirement for augmentation of the antidiabetic regimen (intensification or switching to another anti-diabetic).
Materials and methods: We undertook a retrospective cohort study by identifying all individuals aged ≥ 18 with type 2 diabetes between 2007-2013 who had either sitagliptin or sulphonylureas added to metformin from The Health Improvement Network UK primary care database. We followed them for 30 months, till they left the practice, died or end of 2014. We used multivariable Cox regression to analyse the time before individuals on sitagliptin and sulphonylurea 1) recorded an undesirable HbA1c level of ≥ 58 mmol/mol (7.5%) and 2) underwent treatment-augmentation with another anti-diabetic as identified through issue of a prescription for an alternate anti-diabetic. The first 6 months after add-on initiation with sitagliptin/sulphonylureas were excluded from analysis to allow time for treatments to have effect. We adjusted for age, sex, baseline hbA1c, weight, duration of diabetes, smoking status, history of hypoglycaemias as well as an extensive range of comorbidities and prescribed medications at baseline.
Results: We identified 23,809 individuals; 19,564 prescribed sulphonylureas and 4,245 prescribed sitagliptin as add-on to metformin. We found that more individuals prescribed sitagliptin than sulphonylurea recorded an undesirable HbA1c level of ≥ 58 mmol/mol (7.5%) at 18 months (1.09 Hazard Ratio 95%CI 1.03 to 1.14) however, not at 36 months (0.95 HR 95%CI 0.85 to 1.06). When this analysis was restricted only to those individuals who were prescribed continuous prescriptions for 18 or 30 months of either add-on treatment and metformin (with no greater than 60 day gaps between successive issued prescriptions), no significant difference was found in the number of individuals recording a hbA1c of ≥ 58 mmol/mol (7.5%). More sitagliptin patients had their treatment augmented compared to sulphonylureas at 18 months, (3.67 HR 95%CI 3.40 to 3.96) and 30 months (2.65 HR 95%CI 2.35 to 3.00). When this analysis was restricted to those on continuous treatment, estimates remained similar for treatment augmentation.
Conclusion: Though sitagliptin users were only 9% more likely to have a recording of a undesirable HbA1c level of ≥ 58 mmol/mol (7.5%) 18 months after initiation, treatment augmentation i.e. replacement or intensification was over 3.5 times more likely with sitagliptin at 18 months and 2.6 times more likely at 30 months. This may indicate an underlying treatment inertia for "real world" patients prescribed sulphonylureas compared to those prescribed sitagliptin. This could be due to physician inertia to augment treatment due to the higher propensity of sulphonylureas to cause hypoglycaemia particularly when added to other anti-diabetic treatments. Or alternatively, the requirement for gradual dose titration with sulphonylureas (unlike sitagliptin) which may delay clinicians and patients in achieving optimal dosing and in turn augmenting treatment.

ITCA 650: a novel therapeutic approach to treating patients with type 2 diabetes

A. Whitson[1], R. Azeem[1], T. Alessi[2], M. Baron[1];
[1]Intarcia Therapeutics, Inc., Boston, [2]Intarcia Therapeutics, Inc., Hayward, USA.

Background and aims: ITCA 650 is a novel drug/device combination product containing the GLP-1 receptor agonist, exenatide, in the Medici delivery system™. ITCA 650 has the potential to continuously deliver exenatide subcutaneously (SC) for up to 12 months after sub-dermal placement of the small, 44 mm titanium osmotic mini-pump. The Medici delivery system maintains consistent therapeutic exenatide plasma levels and virtually ensures treatment adherence when the device is in situ. In clinical trials of up to 33 months which tested 3 and 6-month ITCA 650 mini-pumps, significant reductions in HbA1c and body weight were seen and treatment was well tolerated in patients with T2D who were uncontrolled on anti-diabetes medications. We present the experience with placement and removal procedures for the ITCA 650 from the FREEDOM Phase 3 program.
Materials and methods: Placement and removal of ITCA 650 is performed by trained healthcare professionals in a simple, brief, office procedure. The sterile mini-pump is placed in the sub-dermis of the abdominal wall using a placement tool and is removed or replaced through a small incision (~5 mm) and closed with Steri-Strips. Investigative site personnel were provided with a kit containing all supplies necessary to conduct the procedure and were trained and certified via a standardized online and hands-on training program prior to the initiation of any study procedures.
Results: As of 26 July 2016, 20,701 procedures to place, replace, and remove the ITCA 650 were performed in 5,134 patients by MDs, NPs, and PAs at 493 clinical sites in 28 countries. Approximately 1% of scheduled procedures to remove the device were initially unsuccessful due to user errors on the initial placement depth of the mini-pump (i.e. deep placements) and required the assistance of a surgeon or radiologist to complete (assisted removal). Since the introduction of a placement aid (depth guide) into the development program, no assisted removals have been reported. To date, only 27 (0.5%) patients permanently discontinued study treatment due to a procedure AE. Most of the discontinuations were the result of difficulty with removal of the device, and 12 events (0.2%) were for difficulty/failure with device placement. The most common (incidence by patient) application site adverse events (AEs): application site pain (1.8%), bleeding (1.7%), bruise (1.4%), vesicles (1.3%), and pruritus (1.1 %) were generally mild, transient, and reflected the normal healing process. No serious AEs due to the placement or removal procedures were observed.
Conclusion: Once or twice-yearly dosing of ITCA 650 has the potential to improve therapeutic outcomes. Over 20,000 procedures to place, replace, and remove the mini-pumps have been completed. Procedures are simple, well tolerated, easy to teach, and have been performed safely by a wide variety of healthcare practitioners.

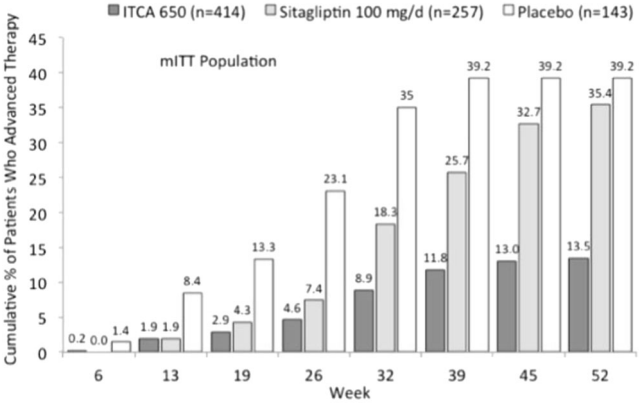
ITCA 650 improves glycaemic control and reduces the need to advance antidiabetic therapy

R. Henry[1], B. Schwartz[2], L. Kjems[2], H. Huang[2], M. Baron[2];
[1]University of California, San Diego, San Diego, [2]Intarcia Therapeutics, Inc., Boston, USA.

Background and aims: ITCA 650, an osmotic mini-pump in development for T2D, continuously delivers exenatide SC for up to 6 months after subdermal placement. Significant reductions in HbA1c and weight occurred in 2 clinical trials: FREEDOM-1, a 39-week, placebo-controlled trial in pts on OADs and FREEDOM-2, a 52-week, study of ITCA 650 vs sitagliptin (SITA) in pts uncontrolled on metformin. Advancement of antidiabetes therapy (AT), a meaningful measure of the effectiveness and sustainability of antidiabetes therapy was evaluated for the pooled populations of these trials.
Materials and methods: Combined data from 814 uncontrolled T2D pts on OADS (414 on ITCA 650, 257 on sitagliptin, 143 on placebo) was analyzed for AT. Mean baseline HbA1c was 8.6%. Data for ITCA 20 mcg/day for 13 weeks, then 60 mcg/day were pooled (n=413). AT, the addition of or increase of therapy from baseline, was protocol mandated based on predefined criteria. AT was required after Week 26 for HbA1c >8%.
Results: The majority of ITCA 650 treated pts achieved and maintained glycemic control below the threshold for AT (Fig. 1). An increase in AT occurred in all groups at Week 26 but 88% of ITCA 650 pts remained on assigned therapy at Week 39. In contrast, there was a progressive increase in the need for AT in the placebo and SITA groups after Week 26.
Conclusion: In uncontrolled T2D, ITCA 650 results in significantly improved and stable glycemic control without AT in the majority of patients.

Figure 1 Percentage of Patients who Advanced Antidiabetes Therapy on or Before Certain Weeks



ITCA 650 included FREEDOM1 and FREEDOM2; Sitagliptin was from FREEDOM2 and Placebo was from FREEDOM1.

786

SNAC-mediated absorption mechanism of action in an oral formulation of semaglutide

S.T. Buckley, S.G. Schéele, R.K. Kirk, L.B. Knudsen;
Novo Nordisk, Måløv, Denmark.

Background and aims: Oral delivery of peptides is typically hindered by the limited permeability of the gastrointestinal tract and rapid enzymatic and pH-induced degradation in the stomach. Clinically, co-formulation in a tablet of the human glucagon-like peptide-1 analogue, semaglutide, with the absorption enhancer, sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC) gives rise to therapeutically relevant exposures of semaglutide upon oral administration. In vivo data from humans and dogs illustrate that absorption takes place in the stomach in an area immediately below the tablet. These studies investigated the mechanism of absorption mediated by SNAC.
Materials and methods: The transepithelial transport of semaglutide was examined in cell monolayers of gastric epithelium (NCI-N87) upon

exposure to SNAC and compared to that in unexposed cell monolayers. The amount of semaglutide transported from the donor chamber (apical side) to the acceptor chamber (basolateral side) was measured every 15 min over 60 min and thereafter the apparent permeability coefficient (P_{app}) was calculated. To evaluate the time-course profile of the absorption-enhancing effect of SNAC, segments of rat gastric mucosa were mounted in Ussing chambers and exposed to SNAC (30 mM) for 10 min. The trans-epithelial electrical resistance (TEER) was continuously monitored prior, during and following SNAC exposure. Complementary studies examined the window of absorption for semaglutide elicited by SNAC. The P_{app} of semaglutide across rat gastric mucosa segments was measured after exposure to SNAC and upon addition of semaglutide either immediately post-SNAC exposure or following an interval of 30 or 60 min. Experimental values were expressed as fold increase in P_{app} relative to semaglutide alone. Finally, to elucidate the route via which SNAC mediates semaglutide absorption, the intracellular uptake of semaglutide was examined in NCI-N87 cell monolayers after exposure to SNAC (80 mM) or ethylenediaminetetraacetic acid (EDTA) (15-75 mM), a modulator of tight junction function, and subsequent addition of semaglutide. Cells were lysed upon termination of the experiment (60 min after semaglutide addition) and the amount of semaglutide accumulated within the intracellular fraction was quantified.

Results: The absorption enhancing action of SNAC on semaglutide was found to require concentrations in the mM range as reflected by a significant increase in the P_{app} of semaglutide across NCI-N87 cell monolayers (1×10^{-8} cm/s [control] vs 7×10^{-8} cm/s [80 mM]; $p<0.05$). Exposure of segments of rat gastric mucosa mounted in Ussing chambers to SNAC resulted in a 25% decline ($p=0.05$) in TEER, which was restored within 60 min. Emphasising its relatively short window of action, the fold change in P_{app} of semaglutide elicited by SNAC was reduced from 2.06 ±0.53 (10 min post-exposure) ($p=0.05$) to 1.30±0.27 (30 min post-exposure) ($p=0.22$) following the removal of SNAC. Intracellular accumulation of semaglutide measured in NCI-N87 gastric epithelial cells revealed a substantial increase upon exposure to SNAC compared to control cells (89.9 pmol vs 4.3 pmol, respectively; $p<0.001$). In contrast, EDTA had no significant effect. Together, these divergent patterns show that SNAC mediates absorption via the transcellular route.

Conclusion: Collectively, these studies reveal that SNAC promotes absorption of semaglutide across gastric mucosa in a concentration-dependent manner via effects on transcellular pathways, which is both transient and fully reversible.

A pharmacoscintigraphic study of the relationship between tablet erosion and pharmacokinetics of oral semaglutide

A. Connor[1], M. Donsmark[2], M.-L. Hartoft-Nielsen[2], F.L. Søndergaard[2], T.A. Bækdal[2];
[1]Quotient Clinical, Nottingham, UK, [2]Novo Nordisk, Søborg, Denmark.

Background and aims: Semaglutide, a glucagon-like peptide-1 (GLP-1) analogue, has been co-formulated in a tablet with the absorption enhancer, sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC), to allow for oral administration. This trial investigated the anatomical site of tablet erosion, the rate of tablet erosion and the gastrointestinal transit of oral semaglutide, and correlated these parameters to the pharmacokinetic properties of oral semaglutide in order to test if tablet erosion kinetics may influence the extent of absorption of oral semaglutide.

Materials and methods: In a randomised, open-label, crossover trial design, 26 healthy males (mean±SD age 38±11 years, body weight 83.4 ±11.0 kg, body mass index 25.9±2.3 kg/m^2) in the fasted state received single doses of oral semaglutide (10 mg with 300 mg SNAC) administered with 50 mL and 240 mL of water, in two different treatment periods, each followed by 4 hours post-dose fasting. Tablet erosion and gastrointestinal transit were assessed by gamma scintigraphy. Oral semaglutide tablets contained ^{111}In labelled ion-exchange resin, and the water used for tablet administration was labelled with ^{99m}Tc (to provide an outline of the stomach). Dynamic imaging was performed during the first minute after dosing, while subjects were sitting. Subsequently, static images were recorded frequently until 4 hours post-dose, while subjects were standing (and allowed to sit or remain moderately active in between static imaging time points). Semaglutide plasma concentrations were measured frequently until 24 hours after administration.

Results: Complete tablet erosion (CTE) occurred in the stomach irrespective of water volume administered with the tablet. CTE appeared to occur approximately 50% later after dosing with 50 mL vs 240 mL water, although this was not statistically significant (estimated mean time to CTE 85 vs 57 min; ratio 50/240 mL [95% confidence interval] 1.51 [0.96;2.37], $p=0.072$). Semaglutide plasma exposure ($AUC_{0\text{-}24h}$) and maximum concentration (C_{max}) were approximately twice as high when dosed with 50 mL vs 240 mL water. Slower tablet erosion and slower gastric emptying were significantly correlated with higher semaglutide exposure ($AUC_{0\text{-}24h}$ and C_{max}; all $p<0.001$). These results suggest that the higher semaglutide exposure levels observed with the lower water volume may be mediated through slower rate of tablet erosion and slower delivery to the small intestine. Overall, the safety profile was as expected for the GLP-1 receptor agonist drug class. The most frequently reported adverse events were headache, nausea and vomiting.

Conclusion: Semaglutide tablet erosion occurs in the stomach irrespective of water volume. A slower rate of tablet erosion in the stomach, as seen when administering the tablet with 50 mL vs 240 mL of water, and a delayed delivery to the small intestine result in higher semaglutide plasma exposure.

Pharmacokinetics and tolerability of oral semaglutide in subjects with renal impairment

T.W. Anderson[1], C. Granhall[1], Á. Réthy[2], F.L. Søndergaard[1], M. Thomsen[1];
[1]Novo Nordisk, Søborg, Denmark, [2]Péterfy Sándor utcai Kórház, Budapest, Hungary.

Background and aims: Semaglutide, a human glucagon-like peptide-1 (GLP-1) analogue, has been formulated in a tablet with the absorption enhancer, sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC). This study investigated the pharmacokinetics and tolerability of oral semaglutide in subjects with renal impairment or normal renal function.

Materials and methods: Based on creatinine clearance (CL_{Cr}) estimated using the Cockcroft-Gault formula, subjects were classified into 4 groups: normal renal function (CL_{Cr} ≥90 mL/min; N=24), or mild (CL_{Cr} 60-89 mL/min; N=12), moderate (CL_{Cr} 30-59 mL/min; N=12) or severe (CL_{Cr} 15-29 mL/min; N=12) renal impairment. A group of subjects with end-stage renal disease (ESRD) requiring haemodialysis was also included (N=11). Subjects received once-daily oral semaglutide (5 mg for 5 days followed by 10 mg for 5 days) in the fasting state with 120 mL water and with 30 minutes post-dose fasting. Semaglutide plasma concentrations after the 10th daily dose were compared between subjects with impaired renal function and subjects with normal renal function.

Results: There was no consistent pattern of increase or decrease in semaglutide exposure ($AUC_{0\text{-}24h,Day\ 10}$) and maximum concentration ($C_{max,Day\ 10}$) on Day 10 across renal function groups (Table). Time to maximum concentration ($t_{max,Day\ 10}$) was comparable for all groups (median of 1.0, 1.0, 1.0, 1.5 and 1.0 hour for normal, mild, moderate, severe and ESRD groups, respectively). Half-life ($t_{½,Day\ 10}$) appeared to increase slightly from normal renal function to severe renal impairment (geometric

mean of 152, 159, 163, 165 and 153 hours, respectively). Except for 1 subject in the ESRD group, semaglutide was not detected in urine. Haemodialysis did not affect semaglutide pharmacokinetics. The safety profile was as expected for the GLP-1 receptor agonist drug class with no trend towards a greater proportion of subjects with adverse events (AEs) with increasing degree of renal impairment. The most frequently reported AEs were gastrointestinal disorders.
Conclusion: There was no apparent effect of renal impairment on the pharmacokinetics and tolerability of oral semaglutide. Based on this study, renal impairment should not affect dose recommendations for oral semaglutide.

Pharmacokinetics and tolerability of oral semaglutide in subjects with hepatic impairment

F.L. Søndergaard[1], T.A. Bækdal[1], V. Kupčová[2], M. Thomsen[1], T.W. Anderson[1];
[1]Novo Nordisk, Søborg, Denmark, [2]3rd Department of Internal Medicine, Dérer´s Hospital, Bratislava, Slovakia.

Background and aims: Oral semaglutide is a novel tablet formulation of semaglutide, a human glucagon-like peptide-1 (GLP-1) analogue, with the absorption enhancer sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC). This study investigated the pharmacokinetics and tolerability of oral semaglutide in subjects with impaired hepatic function compared to subjects with normal hepatic function.
Materials and methods: Subjects were classified into groups of normal hepatic function (N=24), and mild (Child-Pugh Grade A; N=12), moderate (Child-Pugh Grade B; N=12) or severe (Child-Pugh Grade C; N=8) hepatic impairment, and received once-daily oral semaglutide (5 mg for 5 days followed by 10 mg for 5 days) in the fasting state with 120 mL water and with 30 minutes post-dose fasting. Semaglutide plasma concentrations after the 10th daily dose were compared between subjects with impaired hepatic function and subjects with normal hepatic function.
Results: Semaglutide exposure ($AUC_{0\text{-}24h,Day\ 10}$) and maximum concentration ($C_{max,Day\ 10}$) on Day 10 appeared similar across hepatic function groups (Table). There was no apparent effect of hepatic impairment on time to maximum concentration ($t_{max,Day\ 10}$; median of 1.0, 1.0, 1.0 and 1.5 hour for normal, mild, moderate and severe groups, respectively) or half-life ($t_{½,Day\ 10}$; geometric mean of 156, 142, 147 and 154 hours, respectively). The safety profile was as expected for the GLP-1 receptor agonist drug class independent of the degree of hepatic impairment. The most frequently reported adverse events were gastrointestinal disorders.
Conclusion: There was no apparent effect of hepatic impairment on the pharmacokinetics and tolerability of oral semaglutide. The results of this study suggest that dose adjustment of oral semaglutide is not necessary in subjects with hepatic impairment.

Semaglutide exposure in subjects with hepatic impairment versus subjects with normal hepatic function

	$AUC_{0\text{-}24h,Day\ 10}$ Ratio [90% CI]	$C_{max,Day\ 10}$ Ratio [90% CI]
Mild vs. Normal	0.91 [0.60;1.40]	0.92 [0.60;1.40]
Moderate vs. Normal	0.87 [0.57;1.31]	0.85 [0.55;1.30]
Severe vs. Normal	0.90 [0.61;1.32]	0.88 [0.61;1.28]

$AUC_{0\text{-}24h,Day\ 10}$: Area under the semaglutide plasma concentration-time curve from 0 to 24 hours after the 10th daily dose
$C_{max,Day\ 10}$: Maximum semaglutide plasma concentration after the 10th daily dose

Safety, tolerability and pharmacokinetics of multiple once-daily dosing of oral semaglutide in healthy males and in males with type 2 diabetes

C. Granhall[1], M. Donsmark[1], G. Golor[2], F.L. Søndergaard[1], M. Thomsen[1];
[1]Novo Nordisk, Søborg, Denmark, [2]Parexel International, Berlin, Germany.

Background and aims: Semaglutide, a glucagon-like peptide-1 (GLP-1) analogue, has been co-formulated with the absorption enhancer, sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC), in a tablet for oral administration. This trial investigated the safety, tolerability and pharmacokinetics of multiple once-daily (OD) dosing of oral semaglutide in healthy males and in males with type 2 diabetes (T2D).
Materials and methods: In this randomised, double-blind, placebo-controlled trial, 84 healthy males (mean±SD age 45±12 years, body weight 83.5±10.2 kg, body mass index 25.9±2.4 kg/m^2) and 23 males with T2D (treated with diet and exercise and/or stable doses of metformin, age 55±8 years, body weight 94.9±13.9 kg, body mass index 29.4 ±3.2 kg/m^2, HbA_{1c} 7.5±0.7%, duration of diabetes 5.6±3.2 years) received OD oral semaglutide, placebo or placebo with SNAC for 10 weeks (data not shown for placebo with SNAC). The healthy males received oral semaglutide 20 mg (N=16), 40 mg (N=32), placebo (N=18) or placebo with SNAC (N=18). The males with T2D received oral semaglutide 40 mg (N=11), placebo (N=6) or placebo with SNAC (N=6). Subjects were dose escalated starting with 5 mg OD during week 1 and 10 mg OD during week 2, increasing to 20 mg OD from week 3 and to 40 mg OD from week 5 (in the 40 mg treatment groups). Trial products were administered in the morning after an overnight fast, with 50 mL water and with 2 hours post-dose fasting.
Results: Overall, the safety profile was as expected for the GLP-1 receptor agonist drug class. A similar proportion of subjects reported adverse events (AEs) across treatment groups. The majority of AEs were mild, however the severity of AEs increased with increasing dose. The proportions of subjects with gastrointestinal disorders were 50%, 84% and 28% for oral semaglutide 20 mg, 40 mg and placebo in healthy males, and 73% and 50% for oral semaglutide 40 mg and placebo in males with T2D. Body weight reduction was greater for oral semaglutide vs placebo in healthy males (treatment difference in change from baseline, oral semaglutide - placebo [95% CI]: -4.3 kg [-6.3;-2.3] for 20 mg and -7.2 kg [-8.9;-5.4] for 40 mg) and in males with T2D (-5.4 kg [-8.5;-2.3]). In males with T2D, HbA_{1c} was reduced with oral semaglutide vs

placebo (-1.5% [-1.8;-1.3]). Total exposure ($AUC_{0\text{-}24h,SS}$) and maximum concentration ($C_{max,SS}$) of semaglutide increased with increasing dose in healthy males (estimated ratios 40/20 mg [95% CI]: 1.89 [1.23;2.92] and 1.83 [1.20;2.79]), and were similar in healthy males vs males with T2D (1.00 [0.60;1.66] and 1.00 [0.61;1.62]) (Figure). Half-life ($t_{½,SS}$) was comparable between groups (geometric means of 153, 161 and 158 hours in healthy 20 mg, healthy 40 mg and males with T2D 40 mg, respectively).

Conclusion: 10 weeks of OD oral semaglutide up to 40 mg was safe and tolerable in healthy males and in males with T2D, and the pharmacokinetic properties support that oral semaglutide is suitable for OD dosing.

791

A study of drug-drug interactions of oral semaglutide with metformin and digoxin

M. Thomsen[1], T.A. Bækdal[1], G. Golor[2], F.L. Søndergaard[1], T.W. Anderson[1];
[1]Novo Nordisk, Søborg, Denmark, [2]Parexel International, Berlin, Germany.

Background and aims: Oral semaglutide is a novel tablet in development for treatment of type 2 diabetes (T2D), containing the human glucagon-like peptide-1 (GLP-1) analogue, semaglutide, and the absorption enhancer, sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC; 300 mg). Due to absorption enhancement by SNAC and/or possible delay of gastric emptying by semaglutide, oral semaglutide may alter the absorption of concomitantly administered oral drugs. This trial investigated the effect of oral semaglutide on the pharmacokinetic properties of metformin and digoxin. Metformin is a Biopharmaceutics Classification System (BCS) class III drug (high solubility/low permeability) and was chosen for the present trial mainly because it is the most commonly used drug in patients with T2D. Digoxin has low solubility with an incomplete absorption and was chosen for the present trial mainly due to its narrow therapeutic index and because it is used in patients with T2D having cardiovascular diseases.

Materials and methods: On separate visits, in a one-sequence, crossover trial design, healthy subjects (mean±SD age 59±12 years, body weight 76.0±11.1 kg, body mass index 25.4±2.1 kg/m^2) received metformin (850 mg twice daily for 4 days) or digoxin (500 μg single dose) alone, and subsequently together with SNAC (300 mg single dose) and, on a separate occasion, together with oral semaglutide (20 mg once daily at steady state). Pharmacokinetic blood sampling was performed until 30 hours after the last dose for metformin and until 120 hours after the single dose for digoxin. Lack of effect of oral semaglutide on exposure of victim drug was concluded if the 90% CI for the ratio of Co-administration/Alone was within the pre-defined interval of (0.80;1.25).

Results: The area under the curve (AUC) of metformin was increased by oral semaglutide co-administration, while maximum concentration (C_{max}) of metformin and AUC and C_{max} of digoxin were unaffected (Table). SNAC alone did not affect AUC and C_{max} of metformin (ratio [90% CI] metformin+SNAC/metformin alone: 1.05 [0.99;1.12] and 1.06 [0.98;1.14], respectively), indicating that the increase in metformin exposure by oral semaglutide co-administration was not due to the absorption enhancing effect of SNAC. There were no apparent effects of oral semaglutide on the half-life ($t_{½}$) of metformin (geometric means of 16 and 13 hours for metformin alone and co-administered with oral semaglutide, respectively) or digoxin (42 and 43 hours for digoxin alone and co-administered with oral semaglutide, respectively). Based on the wide therapeutic index of metformin, the higher AUC of metformin when co-administered with oral semaglutide was not considered clinically relevant. The safety profile was as expected for the GLP-1 receptor agonist drug class with gastrointestinal events being the most frequent adverse events.

Conclusion: Oral semaglutide has no clinically relevant effect on the exposure of metformin and digoxin.

Exposure of victim drug when co-administered with oral semaglutide vs. when administered alone

	AUC Ratio [90% CI] Co-administration/Alone	C_{max} Ratio [90% CI] Co-administration/Alone
Metformin	1.32 [1.23;1.43]	0.98 [0.90;1.06]
Digoxin	1.03 [0.96;1.11]	0.98 [0.89;1.09]

Number of subjects contributing to the analyses: 31
CI: Confidence interval
AUC: Area under the concentration-time curve from 0 to 12 hrs at steady state for metformin, and from 0 to infinity after a single dose for digoxin
C_{max}: Maximum concentration between 0 and 12 hrs after dosing for metformin, and after a single dose for digoxin

Evaluation of the effects of water volume with dosing and post-dose fasting period on pharmacokinetics of oral semaglutide

M. Donsmark[1], J. Borregaard[1], A. Breitschaft[2], T.A. Bækdal[1], F.L. Søndergaard[1];
[1]Novo Nordisk, Søborg, Denmark, [2]Parexel International, Berlin, Germany.

Background and aims: Semaglutide has been co-formulated in a tablet with the absorption enhancer, sodium N-(8-[2-hydroxybenzoyl] amino) caprylate (SNAC), to provide the first glucagon-like peptide-1 receptor agonist (GLP-1 RA) for oral administration. Absorption of oral semaglutide when co-formulated with an absorption enhancer, like SNAC, may be sensitive to dosing conditions, such as the duration of post-dose fasting and the volume of water used for administration. Therefore, this trial evaluated the administration of oral semaglutide using different dosing conditions in order to elucidate the minimum dosing requirements needed to ensure a clinically relevant semaglutide exposure level and at the same time an acceptable safety profile.

Materials and methods: In an open-label, randomised, parallel-group trial design, 158 healthy male subjects (mean±SD age 40.5±9.7 years, body weight 82.1±9.9 kg, body mass index 25.2±2.4 kg/m^2) received oral semaglutide (10 mg formulated with 300 mg SNAC) each morning (after having fasted overnight) for 10 days. Before the first dose, subjects were randomised into 8 different treatment arms, in which oral semaglutide was administered with either 50 mL or 120 mL water, and the duration of post-dose fasting was either 15, 30, 60 or 120 minutes. Semaglutide

concentrations were measured in plasma for up to 504 hours after administration on Day 10.

Results: There was no statistically significant interaction between the effects of water volume and post-dose fasting period for semaglutide exposure ($AUC_{0\text{-}24h,Day\ 10}$) and maximum concentration ($C_{max,Day\ 10}$) on Day 10 (p=0.53 and p=0.39, respectively). $AUC_{0\text{-}24h,Day\ 10}$ and $C_{max,Day\ 10}$ were unaffected by water volume (p=0.54 and p=0.68, respectively). In a post-hoc statistical analysis conducted with post-dose fasting period as the only fixed effect (i.e., the two water volumes were combined), $AUC_{0\text{-}24h,Day\ 10}$ and $C_{max,Day\ 10}$ increased statistically significantly with longer post-dose fasting (Figure). The time to maximum semaglutide plasma concentration ($t_{max,Day\ 10}$) did not change with water volume, but increased with longer post-dose fasting (median of 0.5, 1.0, 1.5 and 2.0 hours for 15, 30, 60 and 120 minutes post-dose fasting, respectively, when the 2 groups with different water volumes were combined). Water volume or post-dose fasting period had no apparent effect on half-life ($t_{½,Day\ 10}$; geometric mean range 150-159 hours). The safety profile was as expected for the GLP-1 RA drug class. Gastrointestinal disorders were the most frequent adverse events (reported in 61% of subjects).

Conclusion: Administration of oral semaglutide in the fasting state with up to 120 mL water and a post-dose fasting period of at least 30 minutes results in clinically relevant semaglutide exposure. These dosing conditions are expected to be acceptable to patients.

BioChaperone technology enables the development of glargine GLP1-RA (liraglutide and dulaglutide) formulations

R. Soula, C. Fortier, L. Lépine, M. Bezagu, Y. Meyer, C. Mégret, B. Alluis, R. Charvet, O. Soula;
ADOCIA, Lyon, France.

Background and aims: Basal insulin-GLP1 RA combinations provide remarkable medical benefits compared to basal insulin monotherapy and lead to less GLP1-related adverse events with a simple regimen. However, leading GLP1 RA liraglutide and once a week GLP1 RA dulaglutide cannot be combined with the most used basal insulin, insulin glargine, due to formulation pH incompatibility. BioChaperone (BC) technology enables the solubilisation of glargine at neutral pH with a similar efficacy. This makes the combination of glargine with liraglutide or dulaglutide possible.

Materials and methods: BC glargine dulaglutide and BC glargine liraglutide have been evaluated for physical stability by visual imaging, flow imaging microscopy (MFI) and light scattering. Chemical stability has been followed by RP-HPLC. Effect of BC glargine alone was evaluated in a cohort of 10 fasted beagle dogs by measuring blood glucose after an single SC injection of 0.5 U/kg of BC glargine or glargine in two distinct periods.

Results: At 30°C, physically stable BC glargine dulaglutide (BC GlaD) and BC glargine liraglutide (BC GlaLira) formulations have been obtained for at least 9 weeks and 6 weeks respectively. The chemical stability of BC GlaD formulation shows a similar protein recovery to the one of commercial glargine and dulaglutide formulations with only 3% of protein related degradation products found by RP-HPLC analysis after 9 weeks at 30 °C. Furthermore, the long acting profile of glargine is maintained upon injection of BC glargine compared to commercial glargine in an in vivo dog model (figure).

Conclusion: In summary, BioChaperone technology enables the development of glargine-GLP1 RA formulations based on liraglutide and dulaglutide affording new options towards more compliant treatments for T2D patients.

794

Low incidence of gastrointestinal adverse events over time with a fixed-ratio combination of insulin glargine and lixisenatide vs lixisenatide alone

J. Trujillo[1], Y. Yan[2], M. Roberts[3], T. Dex[3], J. White[4], J. LaSalle[5];

[1]University of Colorado, Aurora, [2]Techdata Service Company LLC, King of Prussia, [3]Sanofi US, Inc., Bridgewater, [4]Washington State University, Spokane, [5]Excelsior Springs Clinic, Excelsior Springs, USA.

Background and aims: iGlarLixi, a titratable fixed-ratio combination of insulin glargine (iGlar) 100 U/ml and the glucagon-like peptide-1 (GLP-1) receptor agonist lixisenatide (lixi), was associated with low rates of nausea, vomiting, and diarrhoea (≤ 10% each) in the LixiLan phase 3 clinical programme, leading to very low discontinuation rates (≤ 1% each). This post hoc analysis assessed frequency and timing of gastrointestinal adverse events in 2 trials evaluating iGlarLixi in patients with type 2 diabetes (T2D) uncontrolled with oral antidiabetes agents and/or basal insulin vs iGlar alone or lixi alone.
Materials and methods: Pertinent data on nausea, vomiting, and diarrhoea from the randomised, open-label LixiLan-O and LixiLan-L trials were used in this analysis. The incidence of these gastrointestinal adverse events was calculated with descriptive statistics; results were summarised by treatment group.
Results: Within the first 60 days of treatment initiation, 11.7% and 9.6% of patients treated with iGlarLixi experienced gastrointestinal adverse events in the LixiLan-O and -L trials, respectively, compared with 27.5% of patients on lixi in LixiLan-O, and 4.7% and 1.4% of patients on iGlar in LixiLan-O and -L. The percentage of patients with onset of gastrointestinal adverse events from Day 60 to study end (~210 days) was 7.7% and 4.1% for iGlarLixi in LixiLan-O and -L, respectively, 6.9% for lixi in LixiLan-O, and 3.2% and 2.2% for iGlar in LixiLan-O and -L. After 80 days, incidences of new nausea, vomiting, or diarrhoea events were 3.4%, 1.1%, and 3.0%, respectively, for iGlarLixi, compared with 2.6%, 1.3%, and 2.6% for lixi in LixiLan-O. Most gastrointestinal adverse events reported for iGlarLixi were mild (53-78%) to moderate (22-45%) in severity, with only one reported severe nausea event in LixiLan-L and no severe gastrointestinal adverse events in LixiLan-O. The median durations of nausea, vomiting, and diarrhoea were 5.0, 1.0, and 3.5 days, respectively, with iGlarLixi vs 7.5, 3.0, and 3.0 days with lixi, and 2.0 days for each gastrointestinal adverse event with iGlar in LixiLan-O. In LixiLan-L, the median durations were 6.0, 2.0, and 2.5 days with iGlarLixi vs 3.0, 1.0, and 2.0 days with iGlar. The occurrence of gastrointestinal adverse events is expected with the use of GLP-1 receptor agonists. Nausea, vomiting, and diarrhoea events associated with iGlarLixi treatment were predominantly transient, mainly occurring during the initial 8-week titration period in a small proportion of patients; by week 12 they were rare. As expected, the overall proportion of patients with gastrointestinal adverse events was higher with iGlarLixi than with iGlar, but lower than with lixi; this may be due to the slow increase in lixi dose in the fixed-ratio iGlarLixi combination.
Conclusion: Patients with T2D treated with iGlarLixi show a low rate of gastrointestinal adverse events compared to lixi, and these adverse events tend to occur early and to be transient and mild, rarely requiring discontinuation.

Simultaneous vs sequential combination of insulin glargine and lixisenatide in type 2 diabetes uncontrolled on metformin

J. Rosenstock[1], F. Ampudia-Blasco[2], F. Giorgino[3], M. Liu[4], R. Perfetti[5], Y. Handelsman[6];
[1]Dallas Diabetes Research Center at Medical City, Dallas, USA, [2]Clinic University Hospital of Valencia, Valencia, Spain, [3]University of Bari Aldo Moro, Bari, Italy, [4]BDM Consulting Inc., Somerset, [5]Sanofi, Bridgewater, [6]Metabolic Institute of America, Tarzana, USA.

Background and aims: A single daily injection of basal insulin and a glucagon-like peptide-1 receptor agonist (GLP-1 RA) combined, as in iGlarLixi (a titratable, fixed-ratio combination of insulin glargine 100 U [iGlar] + lixisenatide [Lixi] recently approved for clinical use), is potentially more effective, less complex and with better tolerance than multiple injections of each component separately for the treatment of type 2 diabetes (T2DM). In this exploratory analysis, we determined whether iGlarLixi, from the LixiLan-O trial, is more effective and better tolerated than multiple separate injections of each component given sequentially, in the GetGoal Duo-1 trial, in insulin-naïve patients with T2DM, uncontrolled on metformin ± other oral antidiabetic drugs (OADs).
Materials and methods: Propensity score matching based on baseline covariates (age, race, BMI, HbA_{1c}, fasting plasma glucose [FPG], diabetes duration and OAD/metformin use) to minimize confounding factors was used to indirectly compare the treatment strategy of simultaneous administration with iGlarLixi in LixiLan-O (*N*=469) vs sequential initial iGlar therapy for 12 weeks, followed by addition of Lixi if iGlar was insufficient, in GetGoal Duo-1 (*N*=223).
Results: iGlarLixi showed significant treatment benefits vs sequential administration of iGlar and Lixi in 87 carefully matched pairs, including a greater proportion of patients reaching HbA_{1c} <7% and greater reductions in HbA_{1c} and FPG. In addition, weight loss was achieved in the iGlarLixi group but not with sequential treatment (Table). The proportion of patients reporting symptomatic documented hypoglycaemia (hypo; ≤3.9 mmol/L) and gastrointestinal (GI) adverse events was lower with iGlarLixi vs sequential treatment (hypo: 20.7% vs 25.3%; nausea: 9.2% vs 20.7%; vomiting: 1.1% vs 10.3%, respectively). Of note, the end-of-treatment insulin dose was lower in the iGlarLixi group compared with the sequentialtreatment group (mean ± SD: 31 ± 14 U vs 56 ± 26 U).
Conclusion: This indirect comparison suggests that early treatment with a simultaneous combination of basal insulin and a GLP-1 RA such as iGlarLixi may be more effective, with weight loss and less hypoglycaemia, and have better GI tolerability compared with a sequential approach of adding a GLP-1 RA when basal insulin therapy needs intensification in T2DM uncontrolled on OADs.

Efficacy and safety of insulin degludec/liraglutide (IDegLira) vs basal-bolus therapy in patients with type 2 diabetes: DUAL VII trial

L.K. Billings[1,2], A. Doshi[3], D. Gouet[4], A. Oviedo[5], H.W. Rodbard[6], N. Tentolouris[7], R. Grøn[8], N. Halladin[8], E. Jodar[9];
[1]NorthShore University Health System, Evanston, [2]University of Chicago Pritzker School of Medicine, Chicago, [3]PrimeCare Medical Group, Houston, USA, [4]La Rochelle Hospital, La Rochelle, France, [5]Santojanni Hospital and Cenudiab, Ciudad Autonoma de Buenos Aires, Argentina, [6]Endocrine and Metabolic Consultants, Rockville, USA, [7]Medical School, National and Kapodistrian University of Athens, Athens, Greece, [8]Novo Nordisk A/S, Søborg, Denmark, [9]University Hospital Quiron Salud, Madrid, Spain.

Background and aims: Basal-bolus (BB) insulin therapy is considered the gold standard regimen for treating patients with type 2 diabetes (T2D) who cannot achieve glycaemic control with basal insulin. DUAL VII therefore aimed to assess whether glycaemic control could be attained using IDegLira, with lower hypoglycaemic rates and reduced weight gain compared with BB.
Materials and methods: In a 26-week, open-label, treat-to-target trial, 506 patients with T2D uncontrolled on metformin and 20-50 U insulin glargine 100 U/mL (IGlar U100) were randomized 1:1 to IDegLira or BB therapy (IGlar U100 + insulin aspart up to 4 times a day).
Results: Mean HbA_{1c} decreased from 8.2% at baseline to 6.7% at end of trial in both arms; non-inferiority (by <0.3%) for IDegLira was confirmed (p<0.0001; Table). A similar proportion of patients achieved HbA_{1c} targets with IDegLira vs BB (66.0% vs 67.0% for <7% and 49.6% vs 44.6% for ≤6.5%, respectively). Total daily insulin dose was lower for IDegLira (40.4 U) vs BB (84.1 U) (p<0.0001). Body weight decreased with IDegLira and increased with BB (p<0.0001); the rate of hypoglycaemic episodes (HEs) was lower with IDegLira vs BB (p<0.0001). More patients achieved a triple composite endpoint (HbA_{1c} <7% with no HE in the last 12 weeks and no weight gain) with IDegLira vs BB (34.9% vs 4.7%; odds ratio 12.56 [95% CI 6.46; 24.45] p<0.0001). Mean pre- to postprandial plasma glucose increment decreased more with BB vs IDegLira (p=0.0032). Short Form Health Survey 36 Version 2 (SF-36) (mental component summary) and Treatment Related Impact Measure - Diabetes (TRIM-D) (total scores) improved more with IDegLira vs BB (p=0.0074 and p<0.0001 respectively). Adverse event rates were similar.
Conclusion: In patients with HbA_{1c} >7% on metformin and IGlar U100, IDegLira vs BB resulted in similar HbA_{1c} reductions, lower insulin dose, weight loss and lower risk of HEs.

ITCA 650 exenatide vs sitagliptin added-on to metformin: estimates of the need for further diabetes therapy

M. Baron[1], P. Prabhakar[1], L. Kjems[1], H. Huang[1], J. Rosenstock[2];
[1]Intarcia Therapeutics, Inc., Boston, [2]Dallas Diabetes Research Center, Dallas, USA.

Background and aims: The need for advancing antidiabetes therapy is a valid indicator of the effectiveness and sustainability of an antidiabetes agent. ITCA 650 is an osmotic mini-pump in development for type 2 diabetes (T2D) that continuously delivers exenatide SC for up to 6 months with subdermal placement. ITCA 650 20 mcg/day for 13 weeks followed by a maintenance dose of 60 mcg/day every 6 months was tested vs sitagliptin 100 mg (SITA) in the FREEDOM-2 study. ITCA 650 demonstrated greater reductions in HbA1c (1.5 % vs 0.8%, p<0.001) and body weight (4 kg vs 1.3 kg, p<0.001).
Materials and methods: This exploratory analysis from FREEDOM-2 assessed the need for further therapy in addition to ITCA 650 or SITA added to metformin in 530 uncontrolled T2D pts (mean baseline HbA1c 8.6%). Further therapy was protocol mandated based on predefined criteria that became more stringent over time including any HbA1c >8% after Week 26.
Results: More SITA pts advanced therapy compared to ITCA 650; the incidence increased significantly and progressively with SITA after Week 26 (Figure). In contrast, most ITCA 650 treated pts achieved and maintained glycemic control. At 52 weeks, 85.2% of pts on ITCA 650 remained on two therapies (Met + ITCA 650) compared to 64.6% on SITA.
Conclusion: In conclusion, addition of ITCA 650 for 52 weeks led to better sustained glycemic control in uncontrolled T2D on metformin, significantly reducing the need for further therapy compared to addition of SITA.

Efficacy and safety of fixed-dose combination therapy of gemigliptin/rosuvastatin compared to each mono therapy in type 2 diabetes patients with dyslipidaemia: BALANCE study

J. Bae[1], K. Min[2], Y. Kim[3], K.-A. Kim[4], E.-G. Hong[5], C.-Y. Park[6], S.-H. Kim[7], H. Yoon[7], B.-S. Cha[8];
[1]Department of Internal Medicine, Samsung Changwon Hospital, Changwon, [2]Division of Endocrinology and Metabolism, Eulji General Hospital, Seoul, [3]Department of Internal Medicine, Bundang Jesaeng Hospital, Seongnam, [4]Department of Internal Medicine, Dongkuk

university medical center, Goyang, [5]Division of Endocrinology, Department of Internal Medicine, Hallym University Dongtan Sacred Heart Hospital, Hwaseong, [6]Department of Endocrinology and Metabolism, Kangbuk Samsung Hospital, Seoul, [7]LG Chem, Seoul, Republic of Korea, [8]Department of Internal Medicine, Severance Hospital, Seoul, Republic of Korea.

Background and aims: Diabetes is highly likely to be accomapanied with dyslipidemia, which is one of the major risk factors for cardiovascular disease in type 2 diabetes mellitus (T2DM) patients. This study was to evaluate the efficacy and safety of the fixed-dose combination (FDC) therapy of gemigliptin, a potent and selective DPP-4 inhibitor and rosuvastatin, a potent HMG-CoA reductase inhibitor compared to each mono-therapy in T2DM patients with dyslipidemia.
Materials and methods: In this randomized, placebo-controlled, double-blind, phase III trial, a total of 290 T2DM patients with dyslipidemia who couldn't achieve adequate glycemic control with stable metformin mono therapy (≥1000mg/day) were randomized (1 : 1 : 1) to gemigliptin/rosuvastatin FDC (n=96), gemigliptin (n=97) or rosuvastatin (n=97). Subjects received gemigliptin 50mg and rosuvastatin with forced up-titration from 5mg to 20mg at 8-week interval, while maintained metformin dose during the study period. The primary endpoints were changes from baseline in HbA1c and low-density lipoprotein cholesterol (LDL-C) after 24 weeks.
Results: Baseline demographics and clinical characteristics were well balanced among treatment groups (mean HbA1c 7.79 ± 0.78 %; LDL-C 136.3 ± 27.8 mg/dL; age 55.9 ± 10.1 years; BMI 25.5 ± 3.2 kg/m2, duration of T2DM 6.6 ± 5.7 years). At 24 weeks, the LSM (least square mean+SE) difference of change of HbA1c (%) [(gemigliptin/rosuvastatin FDC)-(rosuvastatin)] was -0.81 ± 0.11% [95% CI(-1.04, -0.59)] and the LSM difference of % change of LDL-C (mg/dL) [(gemigliptin/rosuvastatin FDC)-(gemigliptin)] was -51.9 ± 2.7 % [95% CI (-57.3, -46.5)]. The differences in proportions achieving an HbA1c < 7% or LDL-C < 100 mg/dL were also statistically significant (p<0.001) between the FDC and the mono therapy group, respectively. There were no significant differences in adverse event among gemigliptin/rosuvastatin FDC, gemigliptin and rosuvastatin group (45.8%, 30.9% and 39.2% respectively).
Conclusion: Gemigliptin/rosuvastatin FDC was well tolerated and produced significant improvement in HbA1c and LDL-C levels in T2DM patients with dyslipidemia.

The effect of ideglira on glycaemic control and cardiometabolic risk factors compared to the non fixed administration of degludec and liraglutide

A. Sotiropoulos, A. Koutsovasilis, M. Pappa, A. Antoniou, D. Ntionias, C. Tamvakos, S. Bousboulas, T. Peppas;
3rd Internal Medicine Department and Diabetes Center, General Hospital of Nikaia-Piraeus, Nikaia, Greece.

Background and aims: IDegLira is a novel, once-daily, titratable, fixed-ratio combination of insulin degludec and the glucagon-like peptide-1 receptor agonist (GLP-1RA) liraglutide that has been developed for the treatment of people with type 2 diabetes. The efficacy and safety of IDegLira and the benefits of its complementary mode of action have been examined in the large global DUAL clinical trial program. The aim of this study is to examine the effect of the IDegLira on the glycemic control and the cardiometabolic risk factors compared to the non fixed adiministration of degludec and liraglutide.
Materials and methods: 347 patients were included in the study. 124 uncontrolled patients on oral antidiabetic drugs switched to a therapeutic regime with OADs and IDegLira (Group A), 114 patients who were under treatment with OADs and liraglutide switched to a therapeutic regime with degludec added to the existing therapeutic regime (Group B) and 109 patients under treatment with degludec and OADs switched to a therapeutic regime with liraglutide added to the existing treatment (Group C). All patients also received metformin while none of them received sulfonylurea. Follow-up was 6 months and changes in HbA1c, fasting plasma glucose, waist circumference, weight, body mass index (BMI), hypoglycemic episodes, treatment adherence (with the 8-item Morisky Medication Adherence Scale (MMAS-8)) were recorded and insulin dose in study's groups.
Results: There was no statistically significant difference at baseline between the three Groups as to age (mean age 60.53±9.47 yers, p=0.224), diabetes duration (mean value 13.56±7.72, p=0.322), HbA1c (mean HbA1c: 8.56±1.12, p=0.116) and BMI (32.14±3.56, p=0.142). The mean HbA1c after 6 months was 6.98±0.85, 7.11±1.27, 7.28±1.33 (p=0.037) for Groups A, B and C respectively. More patients achieved the therapeutic target for HbA1c in Group A (78% compared to 71% and 68% for Groups B and C (p=0.048). The weight change was -2.8±1.2 Kg for Group A, 1.1±1.4 Kg for Group B and -3.9±2.1Kg for Group C (p<0.001). Waist circumference improved in Group A (-3.1±2.2 cm) and Group C (-3.9±1.9 cm) but not in Group B (1.9±) (p=0.001). There was no difference in the hypoglycemic episodes between the three Groups (p=0.336). Greater adherence was achieved in Group A compared to Group B and C (7.55±1.23, 6.33±1.35 and 6.45±1.25 (p=0.033) respectively). Total insulin dose was lower for Group A compared to Group B and C (35.66±8.93, 38.72 ±11.25, 42±9.78 (p=0.040) respectively).
Conclusion: Uncontrolled patients on oral antidiabetic drugs when switched to a therapeutic regime with IDegLira achieved a signifficant improvement in their glycemic control along with a decrease in their body weight in most of them and with a sighifficant adherence to their therapeutic regime. The use of degludec and liraglutide in a nonfixed combination improves glycemic control and cardiomaetabolic risk factor but not as impressively as the use of IDegLira while the adherence to treatment is not signifficant enough.

Impact of lixisenatide (LIXI) dose range on glycaemic outcomes with fixed-ratio combination iGlarLixi in patients with type 2 diabetes

M. Roberts[1], W. Hurst[1], J. Newton[1], M. Lorenz[2], T. Dex[1], W. Schmider[2], N. Skolnik[3], J. Frias[4];
[1]Sanofi US, Bridgewater, [2]Sanofi Germany, Frankfurt, Germany, [3]Abington Family Medicine, Jenkintown, [4]National Research Institute, Los Angeles, USA.

Background and aims: iGlarLixi is a novel, titratable fixed-ratio combination of insulin glargine 100U/ml (iGlar) and LIXI (a glucagon-like peptide-1 receptor agonist that selectively attenuates postprandial glucose [PPG]) intended for patients with T2D not achieving glycemic targets with basal insulin or LIXI. iGlar/LIXI doses in iGlarLixi range from 15U/5 μg to 60U/20 μg. We evaluated the impact of LIXI (5-20 μg) on PPG in patients with T2D receiving LIXI alone or as part of iGlarLixi.
Materials and methods: In a 28-day study (ACT6011) in patients on oral antidiabetes drugs, PPG was suppressed by LIXI 5-20 μg (Fig. A). LIXI 5 μg reduced PPG area under the curve to a value that was 44% of that observed with LIXI 20 μg (Fig. B). In a 13-week dose-ranging trial (DRI6012), LIXI 5 μg reduced PPG by −38.2 mg/dl and HbA_{1c} by −0.47% from baseline; 47% of patients reached target HbA_{1c} < 7.0% (published data), also LIXI 5-20 μg dose was reported safe and tolerable.
Results: In a 30-week, phase 3 study (LixiLan-O) in patients uncontrolled on oral antidiabetes drugs, patients on iGlarLixi doses containing LIXI 5-10, 10-15 or 15-20 μg had clinically meaningful changes from baseline in PPG excursions −29.1, −36.0, or −52.4 mg/dl. HbA_{1c} reduced more with iGlarLixi vs iGlar and LIXI (−0.29% and −0.78% difference), with both components contributing to an overall treatment effect (published data).

Conclusion: The treatment effect on HbA_{1c} across LIXI dose categories is consistent with the overall effect, suggesting a contribution of LIXI across the entire iGlarLixi dose range (5-20 μg), even at 5 μg.

The association between iGlarLixi and patient satisfaction with their treatment's ability to control type 2 diabetes is mediated by reduced glycaemic variability (GV)

T. Dex[1], A. Roborel de Climens[2], M. Roberts[1], L. Yang[1], M. Liu[3], L. Gonder-Frederick[4], B. Kovatchev[4];
[1]Sanofi US, Bridgewater, [2]Sanofi, Paris, France, [3]BDM Consulting, Inc., Somerset, [4]University of Virginia School of Medicine, Charlottesville, USA.

Background and aims: The aim of this post hoc analysis was to evaluate the association between iGlarLixi, GV, and patients' satisfaction with their treatment's ability to control their diabetes (measured by the Diabetes Management [DM] score of Treatment-Related Impact Measure for Diabetes [TRIM-D].)

Materials and methods: LixiLan-L is a phase 3, 30-week randomized controlled trial in patients with T2D previously on basal insulin ± oral antidiabetes drugs treated with insulin glargine 100U/ml (iGlar) or iGlarLixi, a fixed-ratio combination of iGlar and the glucagon-like peptide-1 receptor agonist lixisenatide. The DM domain of TRIM-D contains questions on patients' satisfaction with diabetes treatment effects. DM scores were recorded at baseline and Week 30, together with 7-point self-measured plasma glucose (SMPG) profiles used to calculate several GV metrics. A DM score increase ≥ 8.2 is a clinically meaningful difference; patients with DM increase ≥ 8.2 were considered DM responders.

Results: At Week 30, 39.3% of iGlarLixi- vs 32.6% of iGlar-treated patients were DM responders ($P = 0.0577$). Among DM responders, iGlarLixi (vs iGlar) resulted in significantly greater reductions in GV metrics such as mean amplitude of glucose excursions (24% vs 5%; $P < 0.0001$) and area under the SMPG curve (19.1% vs 5.6%; $P < 0.0001$) indicating reduced GV. Most prominent was the reduction in the magnitude of postprandial SMPG excursions (measured by the High Blood Glucose Index) 56% for iGlarLixi vs 17% for iGlar, $P < 0.0001$. High Blood Glucose Index reduction was correlated with a greater change in DM score, particularly for iGlarLixi vs iGlar ($r = -0.30$; $P = 0.0019$ vs $r = -0.19$; $P = 0.0822$).

Conclusion: In patients with T2D, iGlarLixi reduces GV more than iGlar alone (published data). We conclude that this differential effect is preserved in the subpopulation of patients who reported more satisfaction with their treatment's ability to control their diabetes; this correlation is larger with iGlarLixi, and the self-reported effect of treatment is correlated with a reduction in the magnitude of postprandial glucose excursions.

Is double-blinding achievable in a placebo-controlled trial with the glucagon-like-peptide-1 receptor agonist liraglutide?

S. Foghsgaard[1], L. Vedtofte[1], E. Bahne[1], C. Andreasen[1], L.K. Christiansen[1], J.A. Svare[2], T.D. Clausen[3], E.R. Mathiesen[4], P. Damm[5], L.L. Gluud[1], F.K. Knop[1,6], T. Vilsbøll[1,7];
[1]Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Hellerup, [2]Department of Gynaecology and Obstetrics, Herlev Hospital, University of Copenhagen, Herlev, [3]Department of Gynaecology and Obstetrics, Nordsjællands Hospital, University of Copenhagen, Hillerød, [4]Center for Pregnant Women with Diabetes, Department of Endocrinology, Rigshospitalet, University of Copenhagen, [5]Center for Pregnant Women with Diabetes, Department of Obstetrics, Rigshospitalet, University of Copenhagen, [6]Novo Nordisk Foundation Center for Basic Metabolic Research, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, [7]Steno Diabetes Center Copenhagen, University of Copenhagen, Gentofte, Denmark.

Background and aims: Double-blinding is fundamental for bias-reduction in clinical trials. In case of interventions with substantial effect and/or side-effects, successful blinding may be difficult to obtain. Perception of the intervention may affect psychological and physical responses of the participants as well as investigators' assessment of outcomes. The aim of this study was to assess successful double-blinding in a randomised, double-blinded, placebo-controlled trial evaluating the effect of the glucagon-like peptide-1 receptor agonist, liraglutide, on glycaemic control in women with prior gestational diabetes mellitus (pGDM).
Materials and methods: Overweight, non-diabetic women with pGDM were randomised to liraglutide 1.8 mg once-daily (n=49; age: 38±5 (mean±SD) years; BMI: 32±6 kg/m^2) or placebo (n=55; age: 38±5 years; BMI: 31±3 kg/m^2) for one year. Immediately before un-blinding at one-year follow up, all participants and two principal investigators answered a five-option questionnaire whether they were "Certain" or "Thought it likely" that the participant had received active treatment, if they were "Unsure" of treatment, or if they were "Certain" or "Thought it likely" that the participant had received placebo. Blinding was defined as successful if the answer was either of the two incorrect answers or "Unsure". Successful double-blinding was defined as cases were both participants and investigators answered incorrect or "Unsure".
Results: Eighty-nine women completed one-year treatment and questionnaire. Successful blinding of participants was achieved in 32% (n=14 of 44) of liraglutide-treated cases and 27% (n=12 of 45) of placebo-treated (29% in total) with no difference between groups (p=0.593). Successful blinding of investigators was achieved in 38% (n=33 of 88) for liraglutide and 36% (n=32 of 90) of cases for placebo (37% in total). Successful double-blinding was achieved in 9% (n=4 of 45) of cases in the placebo group and in 14% (n=6 of 44) of cases in the liraglutide group with no difference between groups (p=0.478).
Conclusion: In conclusion, successful double-blinding seems low when comparing liraglutide (9%) and placebo (14%) treatment in women with pGDM. Nevertheless, successful blinding may be achieved in 29% of women with pGDM treated with liraglutide/placebo and investigators may be blind to 37% of cases regardless of allocation to active or placebo treatment. Opinions on how successful blinding can be expected remain different from study to study according to design and obvious effects of the intervention.

803

Shorter time to glycaemic control with fixed-ratio combination of insulin glargine and lixisenatide compared with insulin glargine treatment alone

J.P. Frias[1], M. Puig Domingo[2], L. Meneghini[3], R. Napoli[4], M. Liu[5], E. Soltes Rak[6], V.R. Aroda[7];
[1]National Research Institute, Los Angeles, USA, [2]Germans Trias University Hospital, Badalona, Spain, [3]University of Texas Southwestern Medical Center, Dallas, USA, [4]Federico II University School of Medicine, Naples, Italy, [5]BDM Consulting, Inc., Somerset, [6]ProUnlimited, Inc., Boca Raton, [7]Medstar Health Research Institute, Hyattsville, USA.

Background and aims: Simultaneous treatment with insulin glargine (iGlar) + lixisenatide (Lixi) as a titratable, fixed-ratio combination (iGlarLixi) is a new therapeutic option in type 2 diabetes mellitus (T2DM) in patients uncontrolled on metformin ± a second oral antidiabetic (OAD) or basal insulin. A post hoc analysis was used to evaluate time to glycaemic control with iGlarLixi vs iGlar alone in patients with T2DM uncontrolled on OADs (LixiLan-O trial) or basal insulin (LixiLan-L trial).
Materials and methods: The Kaplan-Meier method was used to estimate time to control, defined as time (days) to first achieve HbA_{1c} <7% or fasting plasma glucose (FPG) ≤7.2 mmol/L.
Results: In LixiLan-O and LixiLan-L, 60% and 46% of patients, respectively, reached target HbA_{1c} with iGlarLixi at 12 weeks (Table). In LixiLan-O, 50% of patients achieved HbA_{1c} <7% in approximately half the time with iGlarLixi vs iGlar (median, 85.0 days vs 166.0 days; HR: 1.5; p<0.0001). In LixiLan-L, the HbA_{1c} target was achieved by 50% of patients in a median time of 153.0 days with iGlarLixi, but target HbA_{1c} was never reached by 50% of patients with iGlar (HR: 2.0; p<0.0001). In contrast, when time to glycaemic control was analysed for FPG, results were comparable vs iGlar in both studies (Table).
Conclusion: In addition to lowering FPG via iGlar, iGlarLixi lowers postprandial plasma glucose, likely contributing to its greater efficacy in achieving glycaemic control vs iGlar alone. In conclusion, in patients with T2DM uncontrolled on OADs or basal insulin, iGlarLixi induced glycaemic control (HbA_{1c} <7%) earlier and in more patients vs iGlar alone.

Patient-reported outcomes with insulin degludec/liraglutide (IDegLira) vs basal-bolus therapy in patients with type 2 diabetes: DUAL VII trial

E. Jodar[1], A. Doshi[2], D. Gouet[3], A. Oviedo[4], H.W. Rodbard[5], N. Tentolouris[6], A.K. Busk[7], A. Basse[7], L.K. Billings[8];
[1]University Hospital Quiron Salud, Universidad Europea de Madrid, Madrid, Spain, [2]PrimeCare Medical Group, Houston, USA, [3]La Rochelle Hospital, La Rochelle, France, [4]Santojanni Hospital and Cenudiab, Ciudad Autonoma de Buenos Aires, Buenos Aires, Argentina, [5]Endocrine and Metabolic Consultants, Rockville, USA, [6]National and Kapodistrian University of Athens, Medical School, Athens, Greece, [7]Novo Nordisk A/S, Søborg, Denmark, [8]NorthShore University Health System Evanston and University of Chicago Pritzker School of Medicine, Chicago, USA.

Background and aims: Basal-bolus (BB) insulin therapy is considered the gold standard regimen for treating patients with type 2 diabetes (T2D) who do not achieve glycaemic control with basal insulin, but fear of hypoglycaemia and weight gain are recognised barriers to therapy intensification. The aim of this analysis was to see whether insulin degludec/liraglutide combination (IDegLira) could provide an alternative intensification option that was more acceptable to patients.
Materials and methods: In this 26-week open-label trial, 506 adult patients with T2D, HbA_{1c} 7-10% on metformin (met) and 20-50 units insulin glargine 100 units/mL (IGlar U100) were randomised 1:1 to receive once-daily IDegLira or BB insulin (once daily IGlar U100 + insulin aspart ≤4 times a day). Patients' perceived health status and treatment experiences were quantified using patient-reported outcomes (PROs) questionnaires, adding the patient perspective to treatment evaluation.
Results: Patients on IDegLira had an equal reduction in HbA_{1c}, lower burden of hypoglycaemia, fewer injections/day, and weight loss versus BB. Treatment-Related Impact Measure-Diabetes (TRIM-D) showed greater improvements in favour of IDegLira vs. BB in all domains (Table) and Total Score (estimated treatment difference [ETD] 6.50 [95% CI 4.44; 8.57] $p<0.0001$). The greatest improvements were in diabetes management (likely driven by items on avoiding hypoglycaemia/weight gain), treatment burden and compliance. Short Form Health Survey 36 v2 (SF-36) ETD was in favour of IDegLira vs. BB for the mental component summary (1.83 [95% CI 0.26; 3.40] $p=0.023$), driven by an improvement in mental health (ETD 2.29 [95% CI 0.62; 3.96] $p=0.0074$). Other SF-36 ETDs were not significant. In a motivation survey 26 weeks after randomisation, 84.5% of IDegLira patients were willing to stay on study therapy vs. 68.1% of BB patients (odds ratio 2.54 [95% CI 1.63; 3.98] $p<0.0001$) 16.8% of IDegLira patients preferred pre-trial therapy vs. 28.0% BB (odds ratio [OR] 0.52 [95% CI 0.33; 0.81] $p=0.004$).
Conclusion: IDegLira induced greater improvements in PROs, mainly in diabetes management and treatment burden, whilst achieving similar glycaemic control vs. BB in patients with HbA_{1c} 7-10% switched from met and IGlar U100.

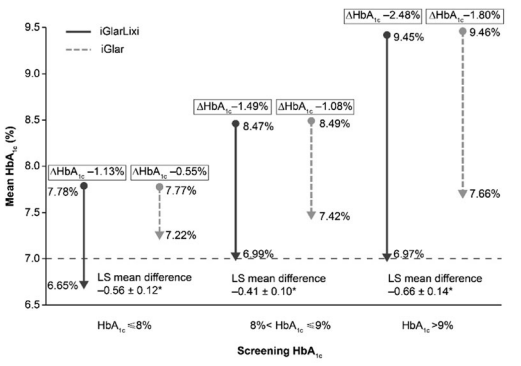
iGlarLixi reduces HbA_{1c} to a greater extent than basal insulin therapy regardless of HbA_{1c} levels at screening

E. Niemoeller[1], E. Souhami[2], Y. Wu[3], K.H. Jensen[1];
[1]Sanofi, Frankfurt, Germany, [2]Sanofi, Paris, France, [3]Sanofi, Bridgewater, USA.

Background and aims: LixiLan-L was a 30-week trial in patients with type 2 diabetes uncontrolled (7.5-10% HbA_{1c} at screening) on basal insulin ± oral agents. After a 6-week run-in with insulin glargine (iGlar), patients were treated with either a fixed-ratio combination of iGlar and lixisenatide (iGlarLixi) ± metformin or iGlar ± metformin (30-week completers: n=325 and n=331, respectively). Mean HbA_{1c} (8.5%) was reduced more from screening to study end with iGlarLixi than iGlar (−1.7% vs −1.1%; $p<0.0001$), and iGlarLixi-treated patients achieved a mean HbA_{1c} within ADA recommendations (mean study end HbA_{1c}: 6.9% vs 7.4% for iGlar). A post hoc analysis was performed to examine differences in efficacy according to pre-study levels of glycaemic control.
Materials and methods: Patients were split into three categories by HbA_{1c} level at screening: $HbA_{1c} \leq 8\%$, $8\% < HbA_{1c} \leq 9\%$, $HbA_{1c} > 9\%$. Change from screening to study end (30 weeks post-randomization) was determined by ANOVA of 30-week completers in the modified intent-to-treat population.
Results: Reductions in HbA_{1c} were greater for iGlarLixi than iGlar in all categories (−1.1%, −1.4%, −2.4% vs −0.5%, −1.0%, −1.8%, respectively; $p<0.0001$ for all). The respective mean observed HbA_{1c} levels at study end were all ≤7.0% for iGlarLixi (6.7%, 7.0%, 7.0%), but >7.0% for iGlar (7.2%, 7.4%, 7.7%; Figure).
Conclusion: Although patients with higher initial HbA_{1c} had the greatest effects for both treatment strategies, iGlarLixi was more effective in controlling HbA_{1c} irrespective of initial levels.

Figure. HbA_{1c} change in LixiLan-L 30-week completers based on screening HbA_{1c} value



30-week completers are patients who have completed the 30-week treatment period without rescue therapy.
*$p<0.0001$ for difference in LS mean ± SE from screening to Week 30 for iGlarLixi vs iGlar.

Characteristics and outcomes of type 2 diabetes patients titrated to 60U/day with insulin glargine/lixisenatide fixed-ratio combination vs insulin in LixiLan-L

L. Blonde[1], T.S. Bailey[2], J. Chao[3], T. Dex[4], J.P. Frias[5], L.F. Meneghini[6], M. Roberts[4], V.R. Aroda[7];
[1]Ochsner Medical Center, New Orleans, [2]AMCR Institute, Escondido, [3]Xinyi, Inc., Bridgewater, [4]Sanofi US, Inc., Bridgewater, [5]National Research Institute, Los Angeles, [6]University of Texas Southwestern Medical Center and Parkland Health & Hospital System, Dallas, [7]MedStar Health Research Institute, Hyattsville, USA.

Background and aims: iGlarLixi is a titratable fixed-ratio combination of insulin glargine 100U/ml (iGlar) and lixisenatide (LIXI), with a maximum daily dosage of 60U iGlar/20 μg LIXI. In LixiLan-L, patients with type 2 diabetes (T2D) uncontrolled on basal insulin ± oral antidiabetes drugs were randomized to iGlarLixi (n = 366) or iGlar (n = 365) for 30 weeks, after 6 weeks of iGlar optimization.
Materials and methods: This post hoc analysis explored characteristics and outcomes in patients on the maximal dose of iGlarLixi or iGlar allowed in the trial (60U/day) at study end.
Results: In the iGlarLixi and iGlar arms, 27.0% and 30.7% of patients, respectively, reached 60U at 30 weeks. Regardless of dose, more patients on iGlarLixi achieved HbA_{1c} < 7.0% (60U: 43%; < 60U: 66%) vs iGlar (60U: 24%; < 60U: 34%). In both arms, patients reaching 60U were younger [mean age, iGlarLixi: 57.0 years (60U) vs 60.6 years (< 60U), $P = 0.0004$; iGlar: 58.2 years (60U) vs 61.3 years (< 60U), $P = 0.0015$], had higher baseline weight [mean weight, iGlarLixi: 95.7 kg (60U) vs 84.9 kg (< 60U), $P < 0.0001$; iGlar: 91.9 kg (60U) vs 84.8 kg (< 60U), $P < 0.0001$], fasting plasma glucose (FPG) [mean FPG, iGlarLixi: 140.0 mg/dl (60U) vs 129.1 mg/dl (< 60U), $P = 0.0080$; iGlar: 140.5 mg/dl (60U) vs 128.2 mg/dl (< 60U), $P = 0.0021$], and insulin dose vs patients using < 60U (**Table**). Higher weight and insulin dose at baseline may have contributed to the need to titrate to 60U. Regardless of final dose, patients in the iGlarLixi arm had numerically greater mean HbA_{1c} reductions [iGlarLixi: −1.0% (60U) vs −1.2% (< 60U), $P = 0.1233$; iGlar: −0.5% (60U) vs −0.6% (< 60U), $P = 0.0935$] and greater postprandial glucose (PPG) reductions from baseline. Maximal dose users in both arms had lower incidence of symptomatic hypoglycaemia, but similar FPG and PPG changes from baseline vs patients using < 60U.
Conclusion: Despite similar weight-adjusted insulin doses in both arms, HbA_{1c} reduction and percentage of patients achieving glycaemic goal was greater with iGlarLixi vs iGlar in patients reaching 60U. The characteristics of 60U users may assist in guiding clinical decisions.

Insulin degludec/liraglutide (IDegLira) provides clinical benefits across all end of trial dose ranges: analyses from DUAL I and V

L.A. Leiter[1], E. Jaeckel[2], I. Lingvay[3], L.F. Meneghini[3], T. Vilsbøll[4,5], K. Begtrup[6], I.H. Langbakke[6], J.N. Harvey[7];
[1]University of Toronto, Toronto, Canada, [2]Hannover Medical School, Hannover, Germany, [3]University of Texas Southwestern Medical Center, Dallas, USA, [4]Steno Diabetes Center Copenhagen, University of Copenhagen, Gentofte, [5]Center for Diabetes Research, Gentofte Hospital, Copenhagen, [6]Novo Nordisk A/S, Søborg, Denmark, [7]Bangor University, Wrexham, UK.

Background and aims: The DUAL clinical trial program investigated the efficacy and safety of the fixed ratio combination IDegLira in various type 2 diabetes populations. IDegLira (1 dose step/unit [U] = 1 U insulin degludec [IDeg] + 0.036 mg liraglutide; max dose 50 U) lowered glycaemia more effectively than IDeg (DUAL I) or insulin glargine U100 (IGlar U100; DUAL V); with no max dose of basal insulin in either trial. This *post hoc* analysis aimed to evaluate the efficacy, hypoglycaemia risk and weight change across comparable end of trial (EOT) daily insulin dose groups upon treat to target titration, thereby assessing the effect of varying liraglutide doses within IDegLira.
Materials and methods: Patients who participated in the DUAL I and V clinical trials were grouped by their EOT insulin dose (DUAL I: <20, ≥20-<30, ≥30-<40, ≥40 U; DUAL V: <30, ≥30-<40, ≥40 U) and HbA_{1c}, weight change, hypoglycaemia rate and dose were assessed.
Results: Baseline HbA_{1c} ranged from 8.0-8.4% and HbA_{1c} reductions were greater with IDegLira (-1.5 to -2.1%) vs IDeg (-1.1 to -1.9%) or IGlar U100 (-1.2 to -1.6%) for all dose groups (Table). The percent of patients achieving an EOT HbA_{1c} <7% was higher with IDegLira vs IDeg or IGlar U100 for all dose groups, except IDegLira vs. IDeg in the ≥30-<40 U group. In DUAL V, with IDegLira, change in HbA_{1c} (both -1.8%) and the proportion of patients with HbA_{1c} <7% (68.4 vs 73.8%) were similar for EOT dose of 50 U vs. <50 U. IDegLira resulted in weight loss across dose ranges while both of the basal insulins resulted in weight gain, except in the IGlar U100 in the ≥30-<40 U group. Hypoglycaemia rates (events/patient year of exposure [PYE]) were lower for IDegLira vs. IDeg and IGlar U100, except in the DUAL I <20 U group. In DUAL I, mean EOT insulin doses for <20 U were IDegLira: 14.0 U, IDeg: 14.9 U; ≥20-<30 U IDegLira: 24.2 U, IDeg: 24.6 U; ≥30-<40 U IDegLira: 34.2 U, IDeg: 34.5 U; and ≥40 U IDegLira: 48.4 U, IDeg: 69.2 U. In DUAL V, mean EOT insulin doses for <30 U were IDegLira: 23.3 U, IGlar U100: 24.7 U; ≥30-<40 U IDegLira: 34.6 U, IGlar U100: 34.9 U; and ≥40 U IDegLira: 48.3 U, IGlar U100: 73.6 U.
Conclusion: Overall, the glucose-lowering effect, lower risk of hypoglycaemia and change in weight with IDegLira appeared consistent, supporting an effect of the liraglutide component across the dose range.

Titratable fixed-ratio vs sequential combination of insulin glargine and lixisenatide in type 2 diabetes uncontrolled on basal insulin

J.J. Meier[1], J. Vidal[2], M. Liu[3], R. Perfetti[4], J. Rosenstock[5];
[1]Ruhr-University Bochum, Bochum, Germany, [2]Hospital Clinic of Barcelona, Barcelona, Spain, [3]BDM Consulting Inc., Somerset, [4]Sanofi, Bridgewater, [5]Dallas Diabetes Research Center at Medical City, Dallas, USA.

Background and aims: Treatment of type 2 diabetes mellitus (T2DM) uncontrolled on basal insulin glargine (iGlar) may be advanced by adding lixisenatide (Lixi), a glucagon-like peptide-1 receptor agonist (GLP-1 RA), as a separate injection or switched to a titratable fixed-ratio combination of iGlar and Lixi (iGlarLixi). In this exploratory analysis, we determined if iGlarLixi, from the LixiLan-L trial, was more effective and better tolerated than sequential injections of iGlar and Lixi, from the GetGoal Duo-2 trial, in patients with long-standing iGlar-treated uncontrolled T2DM.
Materials and methods: The treatment strategy of simultaneous administration of iGlar with Lixi by switching from basal insulin to fixed-ratio combination (iGlarLixi) in the LixiLan-L trial (n=367) was compared indirectly with sequentially adding Lixi to basal insulin in the GetGoal Duo-2 trial (n=298) using propensity score-matching according to baseline covariates to minimize confounding. Baseline covariates included age, race, BMI, HbA_{1c}, fasting plasma glucose, diabetes duration and oral antidiabetic drug/metformin use.
Results: In 241 well-matched pairs comprising ~80% of participants, iGlarLixi provided significant treatment benefits vs sequential administration of iGlar and Lixi, including greater reductions in HbA_{1c}, greater proportions of patients attaining HbA_{1c} <7% and numerically greater decreases in postprandial plasma glucose excursions (Table). The proportion of patients reporting symptomatic documented hypoglycaemia (≤3.9 mmol/L; 36.8% vs 35.7%) was similar between treatments despite better glycaemic control with iGlarLixi. Fewer patients reported gastrointestinal (GI) adverse events with iGlarLixi vs sequential treatment (nausea: 10.0% vs 27.0%; vomiting: 3.3% vs 8.7%, respectively). At end-of-treatment, the insulin dose was lower with iGlarLixi vs the sequential treatment group (mean ± SD: 44 ± 12 U vs 66 ± 36 U).
Conclusion: In basal insulin-treated T2DM in need of insulin intensification, this indirect comparison suggests that switching to a titratable fixed-ratio combination of basal insulin and a GLP-1 RA, as demonstrated in this analysis with iGlarLixi, may provide better efficacy and GI tolerability over combining insulin and a GLP-1 RA in two separate injections.

Table. Efficacy of simultaneous vs sequential treatment with iGlar and Lixi in propensity score-matched participants

	iGlarLixi (LixiLan-L)* Week 24/26/30 LOCF (*N*=241)		iGlar + Lixi (GetGoal Duo-2)† Week 26 LOCF (*N*=241)		LS mean difference (95% CI)	*p*-value

Insulin degludec/liraglutide (IDegLira) is efficacious and safe in patients with type 2 diabetes with normal, mild or moderate renal impairment: analyses from phase 3 trials

J.A. Davidson[1], V.R. Aroda[2], B.W. Bode[3], H.W. Rodbard[4], A. Andersen[5], A. Kaas[5], T. Vilsbøll[6,7];
[1]Touchstone Diabetes Center, University of Texas Southwestern Medical Center, Dallas, [2]MedStar Health Research Institute, Hyattsville, [3]Emory University School of Medicine, Atlanta, [4]Endocrine and Metabolic Consultants, Rockville, USA, [5]Novo Nordisk A/S, Søborg, [6]Steno Diabetes Center Copenhagen, University of Copenhagen, Gentofte, [7]Center for Diabetes Research, Gentofte Hospital, Copenhagen, Denmark.

Background and aims: The DUAL I-V clinical trials investigated the efficacy and safety of IDegLira vs. different comparators; basal insulin, glucagon-like peptide-1 receptor agonist (GLP-1 RA) and placebo. This *post hoc* analysis aimed to evaluate the effects of IDegLira vs. comparators in patients with type 2 diabetes (T2D) as a function of baseline renal function.
Materials and methods: Patients were grouped by their baseline renal function (normal, mild or moderate impairment, with estimated glomerular filtration rates [eGFR] of ≥90, ≥60-<90 and ≥30-<60 mL/min/1.73m^2, respectively).
Results: HbA_{1c} reductions from baseline to end of trial were significantly greater with IDegLira vs. comparators in all baseline renal function groups (Figure). Across renal function groups, hypoglycaemia rates were lower with IDegLira vs. basal insulin but higher vs. GLP-1 RA and placebo, and eGFR was unchanged at the end of trial for all treatments. Adverse event rates (per patient-year of exposure) were similar for patients with normal, mild and moderate renal impairment, respectively (IDegLira [4.1, 3.8 and 4.6]; basal insulin [3.6, 3.6 and 3.5]; GLP-1 RA [4.8, 4.9 and 4.5]; placebo [3.0, 4.1 and 4.6]).
Conclusion: In conclusion, IDegLira is safe and more efficacious than comparators in patients with T2D with mild or moderate renal impairment with lower hypoglycaemia rates when compared with basal insulin. The results resemble those observed in patients with normal renal function.

Table: Estimated treatment differences (ETD) [95% CI] in HbA_{1c} reduction (%)

Study – IDegLira vs comparator	ETD [95% CI] (Normal renal function)	ETD [95% CI] (Mild renal impairment)	ETD [95% CI] (Moderate renal impairment)
DUAL I: IDegLira vs. IDeg	-0.48% [-0.63; -0.33]	-0.40% [-0.58; -0.22]	-0.83% [-1.31; -0.35]
DUAL I: IDegLira vs. Lira	-0.65% [-0.80; -0.50]	-0.56% [-0.73; -0.39]	-0.81% [-1.28; -0.34]
DUAL II: IDegLira vs. IDeg (max dose 50 U)	-1.23% [-1.52; -0.94]	-0.78% [-1.09; -0.47]	-1.30% [-2.09; -0.51]
DUAL III: IDegLira vs. unchanged GLP-1RA	-1.06% [-1.29; -0.82]	-0.84% [-1.09; -0.59]	-0.72% [-1.36; -0.07]
DUAL IV: IDegLira vs. placebo	-0.96% [-1.20; -0.72]	-1.02% [-1.25; -0.79]	-1.33% [-1.84; -0.83]
DUAL V: IDegLira vs. IGlar U100 uptitration	-0.51% [-0.71; -0.31]	-0.59% [-0.81; -0.37]	-1.44% [-2.02; -0.85]

Based on the full analysis set with last observation carried forward. Analysed using an ANOVA with treatment, baseline renal function, interaction between treatment and baseline renal function, region, baseline HbA_{1c} stratum (DUAL I), sub-study (DUAL I), concomitant diabetes treatment (DUAL I) and pre-trial medication (DUAL II, III and IV), as fixed factors and baseline HbA_{1c} as covariate. GLP-1RA, glucagon like peptide-1 receptor agonist; IDeg, insulin degludec; IDegLira, insulin degludec/liraglutide; Lira, liraglutide.

The effect on lipid profiles of iGlarLixi versus iGlar in the LixiLan-L trial

F. Giorgino[1], A. Shaunik[2], M. Liu[2], A. Saremi[2];
[1]University of Bari Aldo Moro, Bari, Italy, [2]Sanofi, Bridgewater, USA.

Background and aims: A number of studies have reported that short-acting glucagon-like peptide-1 receptor agonists (GLP-1 RAs) such as exenatide and lixisenatide (Lixi) improve postprandial proatherogenic lipids and improve vascular endothelial dysfunction. In addition, long-term use of short-acting GLP-1 RAs has been associated with favourable changes in the lipid profiles of patients with type 2 diabetes mellitus (T2DM). In this post hoc analysis, we determined whether iGlarLixi, a titratable fixed-ratio combination of insulin glargine (iGlar) and the short-acting GLP-1 RA Lixi, improved lipid levels versus iGlar alone in the 30-week LixiLan-L trial in patients with T2DM inadequately controlled on basal insulin. Additionally, we assessed whether achievement of glycaemic targets impacted the results.
Materials and methods: LixiLan-L had a 6-week run-in when iGlar was introduced or optimized; patients were then randomized to iGlarLixi or iGlar. Post hoc analyses were performed to assess the percentage change in lipid levels from baseline to Week 30. Changes in lipid levels were also assessed within subgroups according to achievement of glycaemic targets: HbA_{1c} ≤7, >7%; fasting plasma glucose ≤6.1, >6.1 mmol/L; 2-hour postprandial plasma glucose ≤10, >10 mmol/L.
Results: A total of 666 patients (iGlarLixi, *n*=335; iGlar, *n*=331) had lipid values at baseline and Week 30. Baseline lipid values and proportion of people using lipid-lowering drugs were similar between treatment groups (54% vs 55%). After 30 weeks of treatment, median percent change (25th: 75th percentiles) in fasting triglycerides showed nearly no increase (0.30% [-19.8: 24.2]) in the iGlarLixi group versus an increase of 6.50% (-15.8: 33.5) in the iGlar group; the difference was statistically significant (p=0.035). Total cholesterol did not change with iGlarLixi but increased in the iGlar group (0% [-7.3: 10.1] vs 3.4% [-5.6: 12.0], showing a trend of better cholesterol levels with iGlarLixi (p=0.059 for the difference between the two groups). Except for HDL, in subgroups of patients who had met glycaemic targets, there was an improvement in the lipid profile with iGlarLixi versus iGlar; this difference was not observed in patients who had not met glycaemic targets (Figure).
Conclusion: In patients with T2DM uncontrolled on basal insulin, achieving glycaemic control was associated with improvement in the lipid profile with iGlarLixi compared with iGlar alone. Previous studies have shown that in patients with T2DM improvements in lipid levels contribute to cardiovascular benefits.

Using machine learning algorithms to identify predictive factors of clinical outcomes with iGlarLixi or iGlar in the LixiLan-L trial

Y. Gaston-Mathe[1], T. Fan[2], A. Shaunik[2], C. Brulle-Wohlhueter[2], A. Civet[1];
[1]Quinten, Paris, France, [2]Sanofi, Bridgewater, USA.

Background and aims: Identification of predictive factors of adequate glycaemic control and hypoglycaemia occurrence in patients (pts) with type 2 diabetes mellitus (T2DM) treated with basal insulin (BI) or a fixed-ratio combination (FRC) of BI and a glucagon-like peptide-1 receptor agonist may lead to a personalized therapy approach and optimized treatment allocation. The phase III LixiLan-L (LLL) trial studied the efficacy and safety of iGlarLixi (FRC of lixisenatide + insulin glargine [iGlar]) vs iGlar alone in pts inadequately controlled with BI. The study randomized 736 pts and demonstrated the superiority of iGlarLixi vs iGlar in improving HbA_{1c}.
Materials and methods: A post hoc exploratory analysis of LLL was conducted using a sub-group discovery algorithm (Q-Finder), which tests combinations of predictors to identify those not recognized using traditional methods. A total of 600 variables including pt baseline (BL) characteristics (demography, vital signs, glycaemia, medical history, previous medications, biology, quality of life) and the evolution of key parameters in the first weeks of treatment (dose, glycaemia, other biological parameters) were used. The evaluated end of study (EoS) outcomes were glycaemic control (HbA_{1c} < 7%), change from BL (Δ) in HbA_{1c},

Δweight, and occurrence of hypoglycaemic and gastrointestinal (GI) events. To avoid bias in hypoglycaemia events triggered by the titration phase, only events occurring after 3 months were considered. All results reaching statistical significance (adjusted for multiple testing) were replicated in three independent data sets from Phase 3 studies involving a combination of lixisenatide and iGlar.

Results: HbA1c level at BL was the most relevant predictive factor for EoS glycaemic control (HbA1c < 7%) and improvement of HbA1c: a low HbA1c at BL (HbA1c ≤ 7.5%) was highly predictive of reaching HbA1c < 7% at EoS (67% probability, RR = 1.5; $p < 5\times10-14$); in contrast, a high HbA1c at BL (HbA1c ≥ 8.4%) was highly predictive of a large HbA1c improvement (ΔHbA1c = −1.21 vs ΔHbA1c = −0.65 in patients with BL HbA1c < 8.4%; $p < 5\times10-8$). In pts with high BL HbA1c, a relatively short history of BI treatment (≤ 1.6 years) was associated with a larger HbA1c decrease. Pts who titrated their insulin dose less during the first month of treatment had a higher probability (RR = 1.74; $p < 2\times10-6$) of achieving HbA1c improvement > 0.8% and no weight gain; this was highly specific to the iGlarLixi arm (45.1%) vs iGlar (16.7%). No BL characteristics were associated with a higher risk of GI AE occurrence. For pts with a low BMI, a higher frequency of hypoglycaemia (RR = 1.6, $p < 5\times10-6$; iGlarLixi: RR = 1.4, p = 0.02; iGlar: RR = 1.8, $p = 5\times10-5$) was observed. Those results were successfully replicated in the three test data sets.

Conclusion: The major role of BL HbA1c was confirmed as a predictive factor of treatment response in pts with TD2M inadequately controlled with BI at screening. The relationship between "less titration" at the beginning of treatment and HbA1c improvement is currently under investigation.

PS 063 Semaglutide sustaining the effect of GLP-1

812

Semaglutide reduces HbA_{1c} and body weight across multiple background OAD treatment categories

M. Capehorn[1], J. Frias[2], Ö. Tabak[3], S. Tadayon[4], J. Zacho[4], V.R. Aroda[5]; [1]Rotherham Institute for Obesity, Rotherham, UK, [2]National Research Institute, Los Angeles, USA, [3]Istanbul Kanuni Sultan Suleyman Education and Research Hospital, Istanbul, Turkey, [4]Novo Nordisk A/S, Søborg, Denmark, [5]MedStar Health Research Institute, Hyattsville, USA.

Background and aims: Recommended HbA_{1c} targets can be a challenge to achieve for many patients with type 2 diabetes (T2D) despite treatment with oral antidiabetic drugs (OADs). Semaglutide, a glucagon-like peptide 1 (GLP-1) analogue in development for once-weekly treatment of T2D, demonstrated superior reductions in HbA_{1c} and body weight (BW) vs comparators in the SUSTAIN 1-5 clinical trials. This post-hoc analysis evaluated the efficacy and safety of semaglutide s.c. across background OAD treatments in SUSTAIN 2-4, where semaglutide was tested in combination with 1-2 OADs.

Materials and methods: In these 3 phase 3a trials, 3133 subjects with T2D (HbA_{1c} 7.0-10.0/10.5%) were randomised to once-weekly semaglutide s.c. 0.5 or 1.0 mg vs once-daily sitagliptin 100 mg for 56 weeks (n=1231; background, metformin [MET], thiazolidinediones [TZD] or MET+TZD; SUSTAIN 2); once-weekly exenatide extended release (ER) 2.0 mg for 56 weeks (n=813; background, 1-2 OADs, MET, TZD, sulphonylurea [SU]; SUSTAIN 3; semaglutide 1.0 mg only); or once-daily titrated insulin glargine (IGlar) for 30 weeks (n=1089; background, MET or MET+SU; SUSTAIN 4). The following background therapy groups were defined for analysis: MET; MET+SU; or other OADs (TZD, MET+TZD or SU+TZD).

Results: In subjects on background MET, treatment with both doses of semaglutide significantly reduced HbA_{1c} vs comparators (**Table**). Furthermore, in subjects on background MET+SU, both doses of semaglutide significantly reduced HbA_{1c} vs comparators (**Table**). In subjects on other OAD background therapies, HbA_{1c} was significantly reduced with semaglutide 1.0 mg vs sitagliptin, with non-significant reductions observed with semaglutide 0.5 mg vs sitagliptin and semaglutide 1.0 mg vs exenatide ER (**Table**). In all background OAD subgroups, mean BW reduction was significantly greater with semaglutide 1.0 mg vs sitagliptin, exenatide ER and IGlar (all p<0.05). In MET and MET+SU-treated subjects, mean BW reduction with semaglutide 0.5 mg was significantly greater vs comparators (all p<0.0001); the reduction in the other background OAD group did not reach statistical significance. The rate of severe or blood glucose-confirmed symptomatic hypoglycaemia with both semaglutide doses was similar, or lower than, comparators irrespective of background OAD treatment.

Conclusion: Once-weekly semaglutide s.c. consistently improved HbA_{1c} and reduced BW vs comparators in subjects with T2D, with a low rate of hypoglycaemia, regardless of background OAD treatments investigated in the SUSTAIN 2, 3 and 4 trials.

Table. Change from baseline to end-of-treatment in HbA_{1c} by background OAD therapy

	Number of subjects (n)	Semaglutide 0.5 mg		Semaglutide 1.0 mg		Comparator
		Change from baseline (%)	ETD [95% CI]	Change from baseline (%)	ETD [95% CI]	Change from baseline (%)

Semaglutide reduces HbA_{1c} and body weight across baseline HbA_{1c} subgroups in the SUSTAIN 1-5 clinical trials

S. Bain[1], E. Araki[2], C. Desouza[3], S. Garg[4], L. Rose[5], G. Tsoukas[6], E. Bergan[7], J. Derving Karsbøl[7], J. DeVries[8];
[1]School of Medicine, Swansea University, Swansea, UK, [2]Kumamoto University, Kumamoto, Japan, [3]University of Nebraska Medical Center, Omaha, [4]Barbara Davis Center for Diabetes, Denver, USA, [5]Institute for Diabetes Research, Münster, Germany, [6]McGill University, Montreal, Canada, [7]Novo Nordisk A/S, Søborg, Denmark, [8]University of Amsterdam, Amsterdam, Netherlands.

Background and aims: Semaglutide, a glucagon-like peptide 1 (GLP-1) analogue in development for once-weekly treatment of type 2 diabetes (T2D), demonstrated superior reductions in HbA_{1c} and body weight vs comparators in the SUSTAIN 1-5 clinical trials. Here the efficacy of semaglutide by baseline HbA_{1c} subgroup vs placebo (as monotherapy and as add-on to insulin) and active comparators, was evaluated in a post-hoc analysis of the SUSTAIN 1-5 clinical trials.
Materials and methods: In these phase 3a trials, 3918 subjects with T2D (HbA_{1c} 7.0-10.0/10.5%) were randomised to once-weekly s.c. semaglutide 0.5 or 1.0 mg vs placebo for 30 weeks (n=388; SUSTAIN 1); once-daily sitagliptin 100 mg for 56 weeks (n=1231; SUSTAIN 2); once-weekly exenatide extended release 2.0 mg for 56 weeks (n=813; SUSTAIN 3; semaglutide 1.0 mg only); once-daily titrated insulin glargine for 30 weeks (n=1089; SUSTAIN 4); or placebo for 30 weeks (n=397; SUSTAIN 5). Subjects in SUSTAIN 2-4 were on 1-2 oral antidiabetic drugs (metformin, sulphonylureas, thiazolidinediones), while subjects in SUSTAIN 5 were on basal insulin ± metformin. Change in HbA_{1c} and body weight by baseline HbA_{1c} (≤7.5%, >7.5 to 8.0%, >8.0 to 8.5%, >8.5 to 9.0% and >9%) were analysed.
Results: Semaglutide reduced mean HbA_{1c} from baseline to end of treatment in all subgroups vs all comparators. Mean HbA_{1c} decreased by 0.7-2.5% with semaglutide 0.5 mg and 0.9-2.8% with semaglutide 1.0 mg. With comparators, change from baseline in mean HbA_{1c} ranged from a decrease of 1.8% to an increase of 0.6%. (**Table**). Across trials the reduction in HbA_{1c} was consistently greater with higher baseline HbA_{1c}. In subjects with the highest baseline HbA_{1c} (>9%), the HbA_{1c} target of <7% was achieved in 33-47% and 40-61% of subjects treated with semaglutide 0.5 and 1.0 mg, respectively, vs 3-21% with comparators; while 61-79% and 71-94% vs 7-60% achieved an HbA_{1c} level of <8%. Greater weight reduction with semaglutide vs comparators was observed across all baseline HbA_{1c} subgroups: mean body weight decreased by 2.8-5.1 kg with semaglutide 0.5 mg, 2.5-9.2 kg with semaglutide 1.0 mg, and by 2.9 kg to an increase of 2.6 kg with comparators. There was no relationship between the magnitude of weight reduction and baseline HbA_{1c} level. No new safety or tolerability issues were observed with semaglutide in the SUSTAIN 1-5 trials.
Conclusion: Semaglutide treatment consistently showed greater efficacy in lowering HbA_{1c} and body weight vs comparators, regardless of baseline HbA_{1c}. The reduction of HbA_{1c} was consistently greater with higher baseline HbA_{1c}; there was no relationship with the magnitude of weight reduction and baseline HbA_{1c}.

Table. Change in HbA_{1c} from baseline across the SUSTAIN 1–5 trials

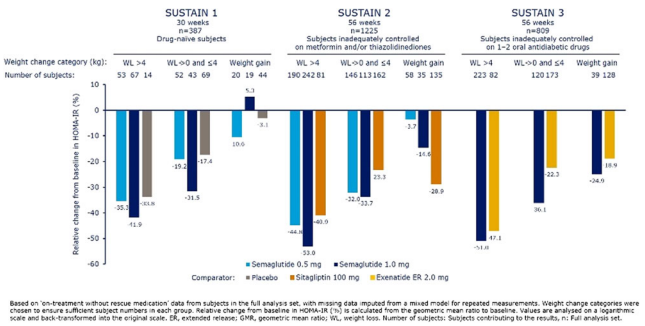
814

Semaglutide-induced reductions in insulin resistance are mediated primarily via weight loss in subjects with type 2 diabetes (SUSTAIN 1-3)

V. Fonseca[1], M. Capehorn[2], S. Garg[3], E. Jodar[4], S. Birch[5], A.G. Holst[5], J. Seufert[6];
[1]Tulane University Health Sciences Center, New Orleans, USA, [2]Rotherham Institute for Obesity, Rotherham, UK, [3]University of Colorado Denver, Denver, USA, [4]H.U. Quironsalud, Madrid, Spain,

[5]Novo Nordisk A/S, Søborg, Denmark, [6]University of Freiburg, Freiburg, Germany.

Background and aims: Semaglutide, a glucagon-like peptide-1 (GLP-1) analogue in development for the once-weekly treatment of type 2 diabetes (T2D), has demonstrated significant and clinically meaningful weight loss (WL) vs placebo and active comparators. As WL improves insulin resistance (IR), the present *post-hoc* analysis explored the association between these two parameters across three of the pivotal semaglutide trials, SUSTAIN 1-3, where it was scientifically relevant to measure IR.
Materials and methods: In the phase 3a SUSTAIN 1-3 trials, subjects were randomised to semaglutide s.c. 0.5 mg (SUSTAIN 1 and 2 only) or 1.0 mg once weekly. Comparators were placebo, sitagliptin 100 mg once daily and exenatide extended release (ER) 2.0 mg once weekly in SUSTAIN 1, 2 and 3, respectively. Change from baseline to end of treatment (30-56 weeks) in body weight and IR (assessed using homeostasis model assessments, HOMA-IR) were calculated. Change in HOMA-IR by weight change was evaluated. A mediation analysis was performed to quantify the extent of the improvement in HOMA-IR mediated by weight change (natural indirect effect) and that not mediated by weight change (natural direct effect).
Results: Mean body weight across the SUSTAIN 1-3 trials (baseline 89.5-95.8 kg) decreased significantly by 3.7-4.3 kg and 4.5-6.1 kg with semaglutide 0.5 mg and 1.0 mg, respectively, vs 1.0 kg, 1.9 kg and 1.9 kg with placebo, sitagliptin and exenatide ER ($p<0.0001$ vs all comparators). IR decreased by 27-36% and 32-46% with semaglutide 0.5 mg and 1.0 mg, respectively, vs 17%, 28% and 28% with placebo, sitagliptin and exenatide ER. Analysis of the reduction in IR by weight change showed that greater reductions in body weight were generally associated with greater reductions in IR (Figure; $p\leq0.0001$). In SUSTAIN 1, the reductions in IR were 15% and 21% greater with semaglutide 0.5 mg and 1.0 mg vs comparator, respectively, with 10% and 7% mediated by WL. Corresponding values for SUSTAIN 2 were 12% and 25%, with 9% and 23% mediated by WL. For semaglutide 1.0 mg in SUSTAIN 3, the values were 23%, with 16% mediated by WL. Across the trials, the effect mediated by WL was significant, except for semaglutide 1.0 mg in SUSTAIN 1. The effect not mediated by WL was 2-15% and not significant.
Conclusion: Semaglutide treatment consistently reduced body weight and IR in subjects with T2D in the SUSTAIN 1-3 trials. Greater WL was generally associated with greater reductions in IR. The reductions in IR observed with semaglutide vs comparators were primarily mediated by a significant effect on body weight.



Based on 'on-treatment without rescue medication' data from subjects in the full analysis set, with missing data imputed from a mixed model for repeated measurements. Weight change categories were chosen to ensure sufficient subject numbers in each group. Relative change from baseline in HOMA-IR (%) is calculated from the geometric mean ratio to baseline. Values are analysed on a logarithmic scale and back-transformed into the original scale. ER, extended release; GMR, geometric mean ratio; WL, weight loss. Number of subjects: Subjects contributing to the results; n: Full analysis set.

More semaglutide-treated subjects achieved HbA_{1c} below 7% without weight gain, hypoglycaemia, and gastrointestinal adverse events vs comparators in the SUSTAIN 1-5 trials

J.H. DeVries[1], C. Desouza[2], S. Bellary[3], J. Unger[4], E.O. Bangsgaard[5], J. Zacho[5], V. Woo[6];
[1]Faculty of Medicine, Academic Medical Center, Amsterdam, Netherlands, [2]University of Nebraska Medical Center, Omaha, USA, [3]Aston University, Birmingham, UK, [4]Catalina Research Institute, Chino, USA, [5]Novo Nordisk A/S, Søborg, Denmark, [6]University of Manitoba, Winnipeg, Canada.

Background and aims: Semaglutide is a glucagon-like peptide 1 (GLP-1) analogue in development for the treatment of type 2 diabetes (T2D). The SUSTAIN 1-5 trials evaluated s. c. semaglutide in subjects with T2D vs placebo (as monotherapy and as an add-on to insulin), sitagliptin, exenatide extended release, and insulin glargine over 30-56 weeks. Across the trials, significantly more semaglutide-treated subjects achieved HbA_{1c} targets vs comparators, as well as clinically relevant reductions in body weight (BW). However, it is important to weigh the benefits of achieving HbA_{1c} targets and weight loss against the risk of hypoglycaemia and gastrointestinal (GI) adverse events (AEs). To evaluate the potential of semaglutide in helping subjects achieve HbA_{1c} targets, additional analyses were performed with data from the SUSTAIN 1-5 trials using composite endpoints which included HbA_{1c} targets, weight gain, hypoglycaemia, and GI AEs.
Materials and methods: Analyses were performed on randomised and treated subjects using a logistic regression for two composite endpoints at the end of treatment. The first endpoint (pre-specified) was the proportion of subjects achieving HbA_{1c} <7% (53 mmol/mol), no weight gain and no severe or blood-glucose (BG)-confirmed symptomatic hypoglycaemia. The second endpoint (*post-hoc*) was the proportion of subjects achieving the pre-specified endpoint without moderate/severe GI AEs.
Results: Significantly more subjects treated with semaglutide 0.5 mg and 1.0 mg once weekly achieved the composite endpoint of HbA_{1c} <7% without weight gain or severe/BG-confirmed symptomatic hypoglycaemia vs comparators (all $p<0.0001$, Table). For the *post-hoc* endpoint, significantly more semaglutide-treated subjects achieved HbA_{1c} <7% without weight gain, severe/BG-confirmed symptomatic hypoglycaemia, and without moderate/severe GI AEs vs comparators (all $p<0.0001$, Table).
Conclusion: In a broad range of subjects with T2D participating in the SUSTAIN 1-5 trials, significantly more subjects achieved HbA_{1c} <7% with semaglutide vs comparators without weight gain or hypoglycaemia. Moreover, semaglutide remained favourable vs comparators when the composite endpoint included the component of no moderate/severe GI AEs.

Table. Proportion of subjects achieving composite endpoints across the SUSTAIN 1–5 trials

Endpoint SUSTAIN trial vs comparator (background medication, FAS)	Semaglutide 0.5 mg			Semaglutide 1.0 mg			Comparator
	%	OR	[95% CI]	%	OR	[95% CI]	%
HbA_{1c} <7% (53 mmol/mol), no weight gain and no severe/BG-confirmed symptomatic hypoglycaemia							
SUSTAIN 1 vs placebo (treatment naive, n=387)	66	12.69*	[6.57; 24.52]	65	12.45*	[6.46; 23.99]	19
SUSTAIN 2 vs sitagliptin (1–2 OADs, n=1225)	63	4.84*	[3.51; 6.68]	74	9.52*	[6.75; 13.43]	27
SUSTAIN 3 vs exenatide ER (1–2 OADs, n=809)				57	4.03*	[2.90; 5.59]	29
SUSTAIN 4 vs IGlar (1–2 OADs, n=1082)	47	5.39*	[3.72; 7.81]	64	12.88*	[8.73; 19.02]	16
SUSTAIN 5 vs placebo (basal insulin±MET, n=396)	54	17.90*	[8.26; 38.78]	67	29.93*	[13.65; 65.61]	7
HbA_{1c} <7% (53 mmol/mol), no weight gain, no severe/BG-confirmed symptomatic hypoglycaemia, and no moderate/severe GI AEs (post-hoc)							
SUSTAIN 1 vs placebo (treatment naive, n=387)	55	8.05*	[4.26; 15.21]	55	6.98*	[3.74; 13.01]	19
SUSTAIN 2 vs sitagliptin (1–2 OADs, n=1225)	54	3.46*	[2.53; 4.73]	64	5.71*	[4.14; 7.86]	25
SUSTAIN 3 vs exenatide ER (1–2 OADs, n=809)				46	2.90*	[2.10; 4.01]	25
SUSTAIN 4 vs IGlar (1–2 OADs, n=1082)	40	4.12*	[2.85; 5.96]	53	7.70*	[5.30; 11.20]	14
SUSTAIN 5 vs placebo (basal insulin±MET, n=396)	48	14.55*	[6.71; 31.55]	60	21.42*	[9.85; 46.61]	7

*p<0.0001 vs comparator. ADA, American Diabetes Association; AE, adverse events; BG, blood glucose; Exenatide ER, exenatide extended release; FAS, full analysis set (randomised and treated subjects); GI, gastrointestinal; IGlar, insulin glargine; MET, metformin; OAD, oral anti-diabetic drug.

Severe or BG-confirmed symptomatic hypoglycaemia: an episode that was severe according to the ADA classification or BG confirmed by a plasma glucose value <3.1 mmol/L (56 mg/dL) with symptoms consistent with hypoglycaemia. 'On-treatment without rescue medication' data are presented. Logistic regression with treatment, trial-specific stratification, and country as fixed factors and baseline HbA_{1c} and body weight as covariate. Missing data are imputed from the mixed model for repeated measurements for change from baseline; post-baseline data are analysed with treatment, trial-specific stratification and country as fixed factors and baseline as covariate, nested within visit.

Superior glycaemic control with semaglutide across SUSTAIN 1-5 clinical trials

A. Ahmann[1], F. Chow[2], V. Fonseca[3], R. Mehta[4], H.F. Thomsen[5], D. Thielke[5], J. Petrie[6];
[1]Harold Schnitzer Diabetes Health Center, Portland, USA, [2]Prince of Wales Hospital, Shatin, Hong Kong, [3]School of Medicine, Tulane University, New Orleans, USA, [4]National Institute of Medical Sciences and Nutrition, Mexico City, Mexico, [5]Novo Nordisk A/S, Søborg, Denmark, [6]Institute of Cardiovascular and Medical Sciences, Glasgow, UK.

Background and aims: Semaglutide, a glucagon-like peptide 1 (GLP-1) analogue in development for once-weekly treatment of type 2 diabetes (T2D), demonstrated superior reductions in HbA_{1c} vs placebo and active comparators in the SUSTAIN 1-5 clinical trials. Pre-specified analyses included change from baseline in HbA_{1c} and fasting plasma glucose (FPG), and the proportions of subjects achieving HbA_{1c} targets (<7.0% or ≤6.5%) for semaglutide 0.5 mg and 1.0 mg.
Materials and methods: In these phase 3a trials, 3918 subjects with T2D (HbA_{1c} 7.0-10.0/10.5%) were randomised to once-weekly s.c semaglutide 0.5 mg or 1.0 mg vs placebo for 30 weeks (n=388; SUSTAIN 1); vs once-daily sitagliptin 100 mg for 56 weeks (n=1231; SUSTAIN 2); vs once-weekly exenatide extended release 2.0 mg for 56 weeks (n=813; SUSTAIN 3; semaglutide 1.0 mg only); vs once-daily insulin glargine (treat-to-target) for 30 weeks (n=1089; SUSTAIN 4); or vs placebo as an add on to basal insulin for 30 weeks (n=397; SUSTAIN 5). Background medication consisted of 1-2 oral antidiabetic drugs (metformin, sulphonylureas, thiazolidinediones) in SUSTAIN 2-4 and basal insulin ± metformin in SUSTAIN 5.
Results: Semaglutide consistently reduced mean HbA_{1c} from baseline to end of treatment vs all comparators. Mean HbA_{1c} decreased by 1.2-1.5% with semaglutide 0.5 mg and 1.5-1.8% with semaglutide 1.0 mg, vs 0.02-0.9% with comparators (all p<0.0001). Furthermore, a significantly higher proportion of subjects achieved HbA_{1c} targets of <7% and ≤6.5% with semaglutide 0.5 mg and 1.0 mg than with comparators (all p<0.0001; **Table 1**). Mean FPG reductions were greater with semaglutide vs comparators: 1.6-2.5 mmol/L with semaglutide 0.5 mg and 2.3-2.8 mmol/L with semaglutide 1.0 mg vs 0.5-2.1 mmol/L with comparators (all p≤0.0002 except semaglutide 0.5 mg vs insulin glargine).
Conclusion: Once-weekly s.c. semaglutide provided significant improvements in glycaemic control across the diabetes treatment continuum, from treatment-naïve subjects to those with advanced diabetes receiving insulin. No new safety or tolerability issues were observed with semaglutide in the SUSTAIN 1-5 trials.

Table 1. Proportion of subjects achieving HbA_{1c} targets of <7.0% and ≤6.5% across the SUSTAIN trials

		Semaglutide 0.5 mg		Semaglutide 1.0 mg		Comparator
		%	OR [95% CI]	%	OR [95% CI]	%
Proportion of subjects achieving HbA_{1c} <7.0%	SUSTAIN 1 vs placebo (treatment naïve)	74	16.92* [8.44; 33.89]	72	15.70* [8.00; 30.83]	25

Treatment with semaglutide provides superior body weight reduction vs comparators in subjects with type 2 diabetes across the SUSTAIN 1-5 trials

I. Lingvay[1], J. Lüdemann[2], M. Marre[3], K. Uusinarkaus[4], V. Woo[5], H.F. Thomsen[6], N. Wijayasinghe[6], M. Davies[7];
[1]University of Texas Southwestern Medical Center at Dallas, Dallas, USA, [2]Diabetes Medical Center, Falkensee, Germany, [3]Hôpital Bichat-Claude Bernard, Paris, France, [4]CSHP DaVita Clinical Research, Colorado Springs, USA, [5]Health Sciences Center, Winnipeg, Canada, [6]Novo Nordisk A/S, Søborg, Denmark, [7]University of Leicester, Leicester, UK.

Background and aims: Semaglutide is a glucagon-like peptide 1 (GLP-1) analogue in development for the treatment of type 2 diabetes (T2D). The SUSTAIN 1-5 trials evaluated s.c. semaglutide vs comparators. This review aims to characterise the effects of semaglutide treatment on body weight (BW) in a broad range of subjects with T2D across SUSTAIN 1-5.
Materials and methods: SUSTAIN 1-5 were five phase 3a, multicentre, randomised trials involving 3,918 subjects with T2D. Subjects were treatment-naïve (n=388, placebo; SUSTAIN 1), on metformin and/or thiazolidinediones (n=1231, sitagliptin; SUSTAIN 2), taking up to two oral antidiabetic drugs (n=813, exenatide extended release [ER]; SUSTAIN 3), insulin-naïve on stable treatment with metformin ± sulphonylureas (n=1089, insulin glargine; SUSTAIN 4), or on basal insulin ± metformin (n=397, placebo; SUSTAIN 5). The primary endpoint for all trials was change from baseline (BL) in HbA_{1c}. Pre-specified analyses included change from BL in BW, proportion of subjects achieving ≥5% and ≥10% BW loss from BL, and change in waist circumference.
Results: Mean BW was significantly reduced from BL by 3.5-6.4 kg with semaglutide vs a 1.9 kg reduction to 1.2 kg increase with comparators (p<0.05 for all; Table). Significantly more semaglutide-treated subjects achieved ≥5% and ≥10% BW loss from BL vs comparators (Proportion with ≥10% BW loss from BL, OR [95% CI]: SUSTAIN 1, 0.5 mg 3.60 [1.09; 11.95], 1.0 mg 6.23 [1.98; 19.61] vs placebo; SUSTAIN 2, 0.5 mg 4.09 [2.26; 7.40], 1.0 mg 8.85 [5.01; 15.61] vs sitagliptin; SUSTAIN 3, 1.0 mg 5.39 [3.20; 9.07] vs exenatide ER; SUSTAIN 4, 0.5 mg 6.35 [2.42; 16.69], 1.0 mg 14.51 [5.70; 36.92] vs basal insulin; SUSTAIN 5, 0.5 mg 3.18 [1.05; 9.63], 1.0 mg 12.80 [4.51; 36.33] vs placebo; p<0.05 for all; Table). Furthermore, semaglutide treatment led to significantly greater reductions in waist circumference from BL (cm) vs comparators (estimated treatment difference (ETD) [95% CI]: SUSTAIN 1, 0.5 mg -1.84 [-3.40; -0.28], 1.0 mg -2.18 [-3.74; -0.61] vs placebo; SUSTAIN 2, 0.5 mg -2.10 [-2.91; -1.29], 1.0 mg -3.67 [-4.48; -2.87] vs sitagliptin; SUSTAIN 3, 1.0 mg -2.76 [-3.63; -1.89] vs exenatide ER; SUSTAIN 4, 0.5 mg -3.42 [-4.24; -2.59], 1.0 mg -4.76 [-5.59; -3.93] vs basal insulin; SUSTAIN 5, 0.5 mg -1.46 [-2.83; -0.09], 1.0 mg -4.05 [-5.42; -2.67] vs placebo; p<0.05 for all).
Conclusion: Semaglutide treatment consistently provided significant reductions in BW, BMI and waist circumference vs comparators in a broad range of subjects with T2D.

Table. Changes from baseline in BW-related parameters across SUSTAIN trials

Endpoint SUSTAIN trial vs comparator (background medication)	Semaglutide 0.5 mg		Semaglutide 1.0 mg		Comparator
Change from baseline in BW by trial	kg	ETD [95% CI]	kg	ETD [95% CI]	kg
SUSTAIN 1 vs placebo (treatment naive)	-3.7	-2.75* [-3.92; -1.58]	-4.5	-3.56* [-4.74; -2.38]	-1.0

Semaglutide consistently reduces both fasting and postprandial glucose levels across SUSTAIN 1-5 clinical trials

B. Cariou[1], J. Unger[2], E. Jódar[3], S. Birch[4], S. Tadayon[4], V.R. Aroda[5]; [1]L'Institut du Thorax, CHU Nantes, Nantes, France, [2]Catalina Research Institute, Chino, USA, [3]Facultad de Ciencias de la Salud, Hospital Universitario Quirónsalud Madrid, Madrid, Spain, [4]Novo Nordisk A/S, Søborg, Denmark, [5]MedStar Health Research Institute, Hyattsville, USA.

Background and aims: Improvements in both fasting plasma glucose (FPG) and postprandial glucose (PPG) levels are major contributors to achieving HbA_{1c} targets in subjects with type 2 diabetes (T2D). Short-acting glucagon-like peptide-1 receptor agonists (GLP-1 RAs) generally demonstrate greater improvements in PPG following injection, while long-acting GLP-1 RAs have shown greater effects on FPG with more modest effects on PPG. Semaglutide is a GLP-1 analogue in development for the treatment of T2D. Semaglutide demonstrated superior HbA_{1c} reductions (1.2-1.5% with semaglutide 0.5 mg and 1.5-1.8% with semaglutide 1.0 mg) vs comparators across the SUSTAIN 1-5 clinical trials when used as monotherapy, add-on to metformin, with 1-2 oral anti-diabetic medications or with basal insulin. The aim of this analysis was to assess the effect of once-weekly s.c. semaglutide on FPG and PPG across the SUSTAIN 1-5 trials.
Materials and methods: In these phase 3a trials, a total of 3918 subjects (HbA_{1c} 7.0-10.0/10.5%) with T2D were randomised to semaglutide 0.5 mg, 1.0 mg or placebo (n=388, SUSTAIN 1); sitagliptin (n=1231, SUSTAIN 2); exenatide extended release [ER] (n=813, SUSTAIN 3, vs semaglutide 1.0 mg only); insulin glargine [IGlar] (n=1089, SUSTAIN 4); or placebo as add-on to basal insulin ± metformin (n=397, SUSTAIN 5); for 30 or 56 weeks. The effect of semaglutide 0.5 and 1.0 mg vs comparators on FPG and PPG (mean and postprandial increments), derived from laboratory values and from the 7/8-point self-measured plasma glucose (SMPG) profile, was assessed (vs baseline) at the end of treatment based on the full analysis set using on-treatment without rescue medication data.
Results: Semaglutide reduced mean FPG from baseline (**Table**). Reductions in FPG were significantly greater with semaglutide 1.0 mg vs comparators (all p≤0.0002). Reductions were also significantly greater with semaglutide 0.5 mg vs placebo and sitagliptin (all p≤0.0002), but not vs IGlar. Semaglutide reduced mean PPG increments (**Table**). The reductions in PPG increments were significantly greater with semaglutide 1.0 mg vs comparators (all p<0.02). Reductions were also greater with semaglutide 0.5 mg vs IGlar and placebo when added to insulin (both p<0.004), but not vs placebo (monotherapy) and sitagliptin (p=0.0807 and p=0.0926, respectively). Mean SMPG levels were significantly reduced with semaglutide 0.5 and 1.0 mg vs all comparators (p<0.0001), with the exception of semaglutide 0.5 mg vs IGlar.
Conclusion: Semaglutide administered once weekly consistently reduced FPG and PPG in subjects with T2D across the SUSTAIN 1-5 trials, suggesting that both components contribute to significantly better glycaemic control vs comparators.

Table. Reduction in mean FPG and PPG increments (mmol/L) from baseline to end of treatment: semaglutide 0.5 and 1.0 mg, vs comparators

	SUSTAIN 1 Semaglutide vs placebo n=388 30 weeks	SUSTAIN 2 Semaglutide vs sitagliptin n=1231 56 weeks	SUSTAIN 3 Semaglutide vs exenatide ER n=813 56 weeks	SUSTAIN 4 Semaglutide vs IGlar n=1089 30 weeks	SUSTAIN 5 Semaglutide add-on to basal insulin vs placebo n=397 30 weeks
FPG $[ETD]_{0.5\ mg}$	−1.96*	−0.97*	n/a	0.08	−1.14‡

Efficacy and safety of once-weekly semaglutide in elderly subjects with type 2 diabetes: post hoc analysis of SUSTAIN 1-5 trials

M. Warren[1], L. Chaykin[2], D. Trachtenbarg[3], G. Nayak[4], N. Wijayasinghe[4], B. Cariou[5]; [1]Physicians East, Greenville, [2]Meridien Research, Bradenton, [3]University of Illinois College of Medicine at Peoria, Peoria, USA, [4]Novo Nordisk A/S, Sobørg, Denmark, [5]CHU de Nantes, l'Institut du Thorax, Nantes, France.

Background and aims: Semaglutide, a glucagon-like peptide 1 (GLP-1) analogue in development for treatment of type 2 diabetes (T2D), demonstrated superior reductions in HbA_{1c} and body weight (BW) across the SUSTAIN 1-5 clinical trials. This *post hoc* analysis evaluated the efficacy and safety of semaglutide vs comparators in elderly (≥65 years old) and non-elderly (<65 years old) subjects with T2D.
Materials and methods: In these phase 3a trials, subjects with T2D were randomised to once-weekly s.c. semaglutide 0.5 mg or 1.0 mg vs placebo (as monotherapy or as add-on to basal insulin), sitagliptin, exenatide extended release [ER], or insulin glargine.
Results: The analyses included a total of 854 subjects ≥65 years old (mean age: 69-70 years) and 3045 subjects <65 years old (mean age: 50-55 years). Semaglutide consistently reduced mean HbA_{1c} and BW from baseline to end of treatment in both age groups, and reductions were greater than with comparators (Table). The efficacy of semaglutide vs comparators in HbA_{1c} and BW reduction was comparable between age groups. In subjects receiving semaglutide 0.5 mg, 1.0 mg and comparators, the respective proportions of subjects reporting adverse events (AEs), pooled across trials, were comparable in the two age groups: 71.9%, 70.5% and 72.8% (≥65 years age group) vs 70.7%, 71.0% and 67.2% (<65 years age group). More subjects ≥65 years old reported serious AEs (7.1%, 7.6% and 8.9%) than <65 years old (6.3%, 7.2% and 5.0%), respectively. The severity of AEs was comparable between age groups; most AEs were mild-to-moderate. The respective proportions of subjects receiving semaglutide 0.5 mg, 1.0 mg and comparators and prematurely discontinuing treatment due to AEs were higher in the ≥65 years age group (11.1%, 10.6% and 3.8%) than in the <65 years age group (5.2%, 7.7% and 3.3%). Gastrointestinal (GI) AEs were more frequent with semaglutide than with comparators across both age groups. GI AEs were reported in 41.3%, 45.3% and 26.4% of subjects in the ≥65 years age

group receiving semaglutide 0.5 mg, 1.0 mg and comparators, respectively, and in 39.6%, 39.5% and 21.5% of subjects in the <65 years age group. Reductions in renal function, measured by the change from baseline in eGFR at week 30, were 3.2, 2.2 and 2.5 mL/min/1.73 m^2 in subjects ≥65 years of age receiving semaglutide 0.5 mg, 1.0 mg and comparators, respectively, and were 4.8, 5.4 and 3.4 mL/min/1.73 m^2 in subjects <65 years of age.

Conclusion: Semaglutide demonstrated consistent improvements in HbA_{1c} and BW vs comparators in elderly subjects ≥65 years old compared with those <65 years old. Despite a higher frequency of premature treatment discontinuation in subjects ≥65 years old, semaglutide had a similar safety profile to that of other GLP-1 receptor agonists with no clinically relevant risks observed in elderly subjects.

Table. Reduction in HbA_{1c} and body weight in subjects <65 and ≥65 years of age receiving semaglutide or comparators

		Number of subjects <65/≥65 years	Semaglutide 0.5 mg (Baseline <65/≥65 years) Change from baseline <65/≥65 years	Semaglutide 0.5 mg ETD <65 years [95% CI]	Semaglutide 0.5 mg ETD ≥65 years [95% CI]	Semaglutide 1.0 mg (Baseline <65/≥65 years) Change from baseline <65/≥65 years	Semaglutide 1.0 mg ETD <65 years [95% CI]	Semaglutide 1.0 mg ETD ≥65 years [95% CI]	Comparator (Baseline <65/≥65 years) Change from baseline <65/≥65 years

Responder analysis of subjects achieving HbA_{1c} ≥1% and weight loss ≥5% across SUSTAIN 1-5 clinical trials

H.W. Rodbard[1], S. Bellary[2], I. Hramiak[3], Y. Seino[4], R. Silver[5], E.Q. Bergan[6], S. Birch[6], V.R. Aroda[7];
[1]Endocrine and Metabolic Consultants, Rockville, USA, [2]Aston University, Birmingham, UK, [3]Western University, London, Canada, [4]Kansai Electric Power Hospital, Osaka, Japan, [5]Southern New Hampshire Diabetes and Endocrinology, Nashua, USA, [6]Novo Nordisk A/S, Søborg, Denmark, [7]MedStar Health Research Institute, Hyattsville, USA.

Background and aims: Semaglutide is a glucagon-like peptide-1 (GLP-1) analogue in development for once-weekly s.c. treatment of type 2 diabetes (T2D). Semaglutide demonstrated superior HbA_{1c} and body weight reductions vs comparators across the phase 3a SUSTAIN 1-5 clinical trials. We now report a *post-hoc* analysis of these trials evaluating the proportion of subjects who achieved a composite endpoint of both ≥1% (8.6 mmol/mol) reduction in HbA_{1c} and ≥5% weight loss.

Materials and methods: In the SUSTAIN 1-5 clinical trials, once-weekly s.c. semaglutide 0.5 mg and 1.0 mg was evaluated in 3918 subjects (HbA_{1c} 7.0-10.0% for SUSTAIN 1, 4 and 5, and 7.0-10.5% for SUSTAIN 2 and 3) with T2D. Semaglutide was evaluated vs placebo for 30 weeks (n=388; SUSTAIN 1); vs once-daily sitagliptin 100 mg for 56 weeks (n=1231; SUSTAIN 2); vs once-weekly exenatide extended release 2.0 mg for 56 weeks (n=813; SUSTAIN 3; semaglutide 1.0 mg only); vs once-daily insulin glargine (treat-to-target) for 30 weeks (n=1089; SUSTAIN 4); or vs placebo as an add-on to basal insulin for 30 weeks (n=397; SUSTAIN 5). The binary composite endpoint of subjects achieving ≥1% HbA_{1c} reduction and ≥5% weight loss was analysed by a logistic regression model, using on-treatment without rescue medication data with missing values at end of treatment, imputed from a mixed model for repeated measurements and subsequently dichotomised.

Results: The proportion of subjects achieving both ≥1% HbA_{1c} reduction and ≥5% weight loss was significantly greater with semaglutide 0.5 mg (25-35%) and 1.0 mg (38-56%) than with comparators (2-13%; p<0.0001 for all comparisons; **Figure**). The proportion of subjects achieving the composite endpoint was greater with semaglutide 1.0 mg vs 0.5 mg (p<0.0001 for SUSTAIN 2, 4 and 5; p=0.17 for SUSTAIN 1), indicating a dose-dependent effect. In SUSTAIN 1-4, severe or blood glucose-confirmed symptomatic hypoglycaemia events were fewer or similar with semaglutide vs comparators, while in SUSTAIN 5, on a background of basal insulin, more events were observed with semaglutide than with placebo. In all five trials, semaglutide was well tolerated, with a safety profile similar to that reported for other GLP-1 receptor agonists.

Conclusion: With semaglutide treatment, the proportion of subjects achieving the clinically meaningful composite endpoint of ≥1% HbA_{1c} reduction and ≥5% weight loss was statistically significantly (p<0.0001) greater than with comparators.

The impact of gastrointestinal adverse events on weight loss with semaglutide in subjects with type 2 diabetes

S. Atkin[1], V. Woo[2], R. de la Rosa[3], J. Wilding[4], Y. Yamada[5], S. Birch[6], A.G. Holst[6], B. Ahrén[7];

[1]Weill Cornell Medical College Qatar, Doha, Qatar, [2]University of Manitoba, Winnipeg, Canada, [3]Four Rivers Clinical Research, Paducah, USA, [4]University of Liverpool, Liverpool, UK, [5]Graduate School of Medicine, Akita University, Akita, Japan, [6]Novo Nordisk A/S, Søborg, Denmark, [7]Lund University, Lund, Sweden.

Background and aims: Semaglutide, a glucagon-like peptide 1 analogue in development for treatment of type 2 diabetes (T2D), demonstrated superior reductions in HbA_{1c} and body weight vs placebo and active comparators across the SUSTAIN 1-5 trials. The most common adverse events reported with semaglutide were gastrointestinal-related. In a phase 1 trial in obese subjects, semaglutide 1.0 mg was shown to reduce body weight, appetite and energy intake vs placebo. This post hoc analysis was undertaken to assess the relationship between weight loss and nausea and/or vomiting in SUSTAIN 1-5.

Materials and methods: In these phase 3a trials, subjects with inadequately controlled T2D who were drug-naïve (SUSTAIN 1), on metformin and/or thiazolidinediones (SUSTAIN 2), on 1-2 oral antidiabetic drugs (SUSTAIN 3), on metformin ± sulphonylureas (SUSTAIN 4) or on basal insulin ± metformin (SUSTAIN 5) were randomised to semaglutide s.c. 0.5 mg (excluding SUSTAIN 3) or 1.0 mg (all trials) once weekly. The populations were divided into subgroups based on reporting of any nausea and/or vomiting. A mediation analysis was also performed to separate the overall effect on weight into direct or indirect (mediated by nausea or vomiting) effects.

Results: Across the five trials, 15.2-24.0% and 21.5-27.2% of subjects experienced nausea or vomiting with semaglutide 0.5 mg and 1.0 mg, respectively, vs 6.0-14.1% with comparators. Weight loss ≥5% was achieved by 36.7-46.0% and 44.6-65.6% of subjects with semaglutide 0.5 mg and 1.0 mg, respectively, vs 7.0-18.4% with comparators. With semaglutide 0.5 mg, ≥5% weight loss was achieved by 43.7-55.0% of subjects experiencing nausea or vomiting vs 32.7-44.2% of those without these adverse events. The corresponding values for semaglutide 1.0 mg were 51.5-86.7% and 42.3-60.1%, respectively. Regardless of nausea or vomiting, weight loss was consistently greater with semaglutide vs comparators (all $p<0.01$) (Table). Overall, weight reductions with semaglutide were greater vs comparators by 2.3-6.3 kg. Only 0.07-0.5 kg of this difference was due to nausea or vomiting (indirect effects) and these effects were non-significant in most trials (except for semaglutide 1.0 mg in SUSTAIN 4 and 5); 2.2-5.9 kg was not mediated by nausea or vomiting (effects were all statistically significant).

Conclusion: Across the SUSTAIN 1-5 trials, weight loss with semaglutide 0.5 mg and 1.0 mg was consistently greater vs comparators, and the contribution to the weight loss mediated by nausea or vomiting was small, indicating that these events were not the primary cause of weight loss.

Table: Summary of changes in body weight from baseline by nausea or vomiting across the SUSTAIN 1–5 trials

	Change in body weight from baseline (kg)					
	Semaglutide 0.5 mg		Semaglutide 1.0 mg		Comparator	
Nausea or vomiting	With	Without	With	Without	With	Without
SUSTAIN 1 vs placebo n=387	−5.1 (n=27)	−3.3 (n=101)	−5.6 (n=33)	−4.3 (n=97)	0.0 (n=10)	−1.0 (n=119)
SUSTAIN 2 vs sitagliptin 100 mg QD n=1225	−5.3 (n=83)	−4.1 (n=326)	−6.8 (n=88)	−5.9 (n=321)	−2.6 (n=34)	−1.8 (n=373)
SUSTAIN 3 vs exenatide ER 2.0 mg QW n=809	-	-	−6.9 (n=97)	−5.4 (n=307)	−2.7 (n=57)	−1.6 (n=348)
SUSTAIN 4 vs titrated IGlar QD n=1082	−4.4 (n=87)	−3.2 (n=275)	−6.3 (n=98)	−4.8 (n=262)	2.2 (n=22)	1.1 (n=338)
SUSTAIN 5 vs placebo n=396	−4.2 (n=20)	−3.6 (n=112)	−8.0 (n=30)	−6.0 (n=101)	0.1 (n=8)	−1.4 (n=125)

ER, extended release; IGlar, insulin glargine; QD, once daily; QW, once weekly. Data represent the 'on-treatment without rescue medication' observation period from the full analysis set. Missing data for body weight imputed from a mixed model for repeated measures with treatment, region and stratum as fixed factors and baseline value as covariate, all nested within visit. Numbers of subjects in each trial are those exposed to at least one dose of trial drug.

Pharmacokinetics and tolerability of semaglutide in subjects with hepatic impairment

G. Arold[1], V. Kupcová[2], L. Jensen[3], T. Kvist[3], J. Pettersson[3], J. Hjerpsted[3]; [1]PRA Health Sciences, Berlin, Germany, [2]3rd Department of Internal Medicine, Dérer's Hospital, Bratislava, Slovakia, [3]Novo Nordisk A/S, Søborg, Denmark.

Background and aims: Semaglutide is a glucagon-like peptide-1 receptor agonist in development for the treatment of type 2 diabetes (T2D). Impaired hepatic function may affect the pharmacokinetics (PK) of drugs. This trial investigated whether the PK of semaglutide was altered in subjects who had various degrees of hepatic impairment (HI), versus subjects with normal hepatic function.

Materials and methods: This was a multicentre, open-label, parallel-group trial in which subjects with varying degrees of HI or normal hepatic function received a single, subcutaneous dose of 0.5 mg semaglutide. Using the Child-Pugh criteria, subjects with stable HI were assigned to one of three HI function groups (mild, moderate or severe). Subjects with normal hepatic function were enrolled for comparison. Semaglutide plasma concentrations were assessed regularly for up to 35 days (840 hours) post-dose. The primary PK endpoint was area under the semaglutide plasma concentration-time curve from time zero to infinity ($AUC_{0-\infty}$). 'No effect' was declared if the 90% confidence interval [CI] for the ratio between the HI and normal function groups was within the interval 0.70-1.43. Secondary endpoints included maximum plasma semaglutide concentration (C_{max}), time to reach C_{max} (t_{max}), terminal elimination half-life ($t_{1/2}$), renal clearance (CL/R), and protein binding (*in vitro* assessments on pre-dose plasma samples). The safety and tolerability of semaglutide was also assessed.

Results: Forty-four subjects were allocated to four HI function groups: normal (n=19), mild (n=8), moderate (n=10), and severe (n=7). Semaglutide exposure was similar across all groups (**Figure**), as the $AUC_{0-\infty}$ met the criterion of 'no effect' for all three HI groups versus the group with normal hepatic function ($AUC_{0-\infty}$ treatment ratios for: mild/normal 0.95 [90% CI, 0.77-1.16]; moderate/normal 1.02 [0.93-1.12]; severe/normal 0.97 [0.84-1.12]). In addition, semaglutide C_{max} did not appear to be influenced by hepatic function, as treatment ratios were: mild/normal 0.99 [0.80-1.23]; moderate/normal 1.02 [0.88-1.18]; and severe/normal 1.15 [0.89-1.48] (sensitivity analysis of the latter, which excluded one extreme semaglutide concentration for one subject: 1.05 [0.88-1.25]). Median t_{max} and $t_{1/2}$ were similar (54-78 hours and 150-163 hours, respectively) in all groups. Plasma protein binding was >99% in all subjects. A total of 12 adverse events were reported in 10 subjects; none were serious and all were mild or moderate, and transient. No new safety or tolerability issues were observed.

Conclusion: Semaglutide exposure was not affected by hepatic impairment. Semaglutide was well tolerated and there were no new safety issues. The results suggest that no dose adjustment of semaglutide is necessary in subjects with hepatic impairment.

Figure: Semaglutide profiles in subjects with normal hepatic function or hepatic impairment after administration of a single dose of semaglutide – geometric mean plot

The effect of liraglutide on bone turnover during exercise training in patients with type 2 diabetes

P. Mensberg[1], E. Espersen[1], K.A. Sjøberg[2], H. Storgaard[1], N.R. Jørgensen[3,4], S. Nyby[1], B. Kiens[2], E.A. Richter[2], F.K. Knop[1,5], T. Vilsbøll[1,6];
[1]Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Gentofte, [2]Department of Nutrition, Exercise and Sports, Section of Molecular Physiolgy, Faculty of Science, University of Copenhagen, Copenhagen, [3]Department of Clinical Biochemistry, Rigshospitalet - Glostrup, Glostrup, [4]OPEN, Odense Patient data Explorative Network, Odense University Hospital, Institute of of Clinical Research, University of Southern Denmark, Odense, [5]Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, [6]Steno Diabetes Center Copenhagen, University of Copenhagen, Copenhagen, Denmark.

Background and aims: Type 2 diabetes (T2D) is associated with normal bone mineral density (BMD), but an increased fracture risk. We investigated the effect of liraglutide treatment combined with exercise training on the bone formation markers osteocalcin and procollagen type-1 amino-terminal propeptide (P1NP), the bone resorption marker C-terminal telopeptide of type 1 collagen (CTX), whole-body BMD and whole-body bone mineral content (BMC) in patients with T2D.
Materials and methods: Nineteen middle-aged, dysregulated, obese, untrained patients with T2D treated with diet and/or metformin were randomized to receive once-daily injection with liraglutide 1.8 mg (n=12) or placebo (n=7) during 16 weeks. Both groups had three supervised 60-minute training sessions per week: two spinning sessions and one session with resistance training. All patients underwent a liquid meal test and a dual energy X-ray absorptiometry scan before and after the intervention.
Results: Significant increases in fasting plasma osteocalcin from 9.4±3.2 (mean±SD) to 11.0±3.6 μg/l (P=0.005) and CTX from 0.107±0.1 to 0.161±0.1 μg/l (P=0.001) were observed in the liraglutide group whereas no changes were observed in the placebo group (10.7±1.9 to 11.6±2.9 μg/l (P=0.297) and 0.155±0.1 to 0.222±0.1 μg/l (P=0.250), respectively). In the liraglutide group, area under the curve for osteocalcin during a meal test increased from 2.386±824 to 2.714±944 μg/l × min (P=0.005) and for CTX from 17.7±7.3 to 27.6±9.1 μg/l × min (P=0.003); no changes were observed in the placebo group (2.346±762 to 2.669±1016 μg/l (P=0.156) and 21.1±8.4 to 24.7±19.8 μg/l (P=0.313), respectively). Plasma levels of P1NP were unaffected in both groups. Whole-body BMD and total BMC were unchanged in both groups.
Conclusion: In conclusion, liraglutide treatment combined with exercise for 16 weeks seems to increase bone turnover without affecting whole-body BMD and BMC, respectively, in untrained patients with T2D.

Steady state blood glucose control for once weekly dulaglutide during peak and trough concentration days

H. Patel[1], L. Fernández Landó[1], N. Jia[2], C.C. Tang[3], L.S. Tham[3];
[1]Lilly USA, LCC, Indianapolis, [2]Eli Lilly and Company, Indianapolis, USA, [3]Lilly-NUS Centre for Clinical Pharmacology, Singapore, Singapore.

Background and aims: Dulaglutide (DU), a GLP-1 receptor agonist, with a half-life of ~5 days, is administered once weekly in patients with type 2 diabetes. In this post hoc analysis of AWARD-3, the sustainability of DU glycaemic effect over a 7-day interval at steady state (attained between 2-4 weeks of dosing) was assessed. AWARD-3 was considered for this analysis as it was the only monotherapy study of DU.
Materials and methods: Within 1 week prior to the Week 26 visit, patients were asked to collect 8-point self-monitored blood glucose (SMBG) profiles on any 2 non-consecutive days. All evaluable SMBG profiles with valid dosing dates were segregated according to Days 1-7 of a dosing interval. SMBG data on DU peak (Day 2/3) and trough (Day 6/7) plasma concentration days were tested for equivalence. A mixed effect model with random intercept and the time of SMBG collection (peak/trough) as a single covariate, was fitted for statistical analysis.
Results: Mean daily SMBG concentrations were found to be equivalent between DU peak and trough days for both doses (Table). Model-predicted DU concentrations (90% prediction interval) also remained above the minimum effective concentration throughout the 7-day period.
Conclusion: Throughout the weekly dosing interval at steady state, DU has a similar effect on blood glucose control during peak and trough plasma concentration days, as assessed by the change in mean daily SMBG concentrations.

	Mean Daily SMBG Concentration (mmol/L) After Once Weekly Dulaglutide Administration at Week 26[1]				
	Peak (Day 2/3) Mean ± SD	Trough (Day 6/7) Mean ± SD	Mean Difference Between Peak and Trough (90% CI)	Equivalence Margin of ±10% of Lower Mean Peak/Trough[2]	Equivalence Established Between Peak and Trough (Yes/No)
DU 1.5 mg	7.9 ± 2.0 N=48	8.3 ± 1.9 N=41	-0.4 (-0.7, -0.1)	±0.8	Yes
DU 0.75 mg	7.8 ± 2.1 N=53	7.8 ± 1.8 N=32	0.1 (-0.5, 0.1)	±0.8	Yes

Abbreviations: SMBG = self-monitored blood glucose, DU = dulaglutide, SD = standard deviation, N = number of subjects, CI = confidence interval.
[1]The regimen for SMBG 8-point profile was pre-meal and 2 hours post-meal (morning, midday, evening), bedtime and 3 AM or 5 hours after bedtime.
[2]Equivalence was established only if 90% CI was contained within ±10% of lower mean daily peak/trough SMBG concentrations.

Acute effects of lixisenatide on gastric emptying, glycaemia and 'postprandial' blood pressure responses to an oral glucose load in healthy subjects and type 2 diabetes

K.L. Jones[1], R.S. Rigda[1], M.D.M. Buttfield[2], S. Hatzinikolas[1], H.T. Pham[1], C.S. Marathe[1], T. Wu[1], K. Lange[1], L.G. Trahair[1], C.K. Rayner[1], M. Horowitz[1];
[1]School of Medicine, University of Adelaide, [2]School of Health Sciences, University of South Australia, Adelaide, Australia.

Background and aims: Postprandial hypotension (PPH), a fall in systolic blood pressure (SBP) of >20mmHg after a meal, occurs frequently in older people and patients with type 2 diabetes (T2DM) and is associated with considerable morbidity and increased mortality. Current management of PPH is suboptimal. We have shown that the magnitude of the postprandial fall in BP is greater when gastric emptying (GE) is relatively more rapid and that intravenous (iv) administration of glucagon-like peptide-1 (GLP-1), in addition to slowing GE, attenuates the postprandial fall in BP and rise in splanchnic blood flow in T2DM. We have now evaluated the effects of the short-acting GLP-1RA, lixisenatide (LIXI), on GE and the BP, superior mesenteric artery (SMA) blood flow, and glycaemic responses to a 75g oral glucose load in healthy and T2DM subjects.
Materials and methods: Fifteen healthy subjects (9M, 6F; age: 67.2 ± 2.3 yr; BMI: 25.4 ± 0.8 kg/m^2) and 15 patients with T2DM managed by diet or metformin alone (9M, 6F; age: 61.9 ± 2.3 yr; BMI: 30.3 ± 0.7 kg/m^2; duration of known diabetes: 5.3 ± 1.2 yr; HbA_1c: 6.9 ± 0.2 % (51.8 ± 2.3 mmol/mol)) had concurrent measurements of GE (scintigraphy), BP (automated machine), SMA blood flow (Doppler ultrasound) and plasma glucose for 180 min after a 75g glucose drink labelled with 20MBq

^{99m}Tc-Calcium Phytate on 2 separate days. All subjects received LIXI (10mcg sc) or placebo (PLAC) in a randomised, double-blind, crossover fashion 30 min before the drink. Data are mean values ± SEM.

Results: LIXI slowed GE (% retention at 120 min) markedly in both healthy subjects (LIXI: 72 ± 5.7% vs PLAC: 38 ± 4.1%; P<0.01) and T2DM (LIXI: 68 ± 5.5% vs PLAC: 33 ± 2.6%; P<0.01) and attenuated the fall in systolic BP (P<0.05; Figure) compared to PLAC in both healthy subjects and T2DM, with no difference between the groups. The maximum rise in SMA flow was attenuated by LIXI in both the healthy subjects (LIXI: 521 ± 68 ml/min vs PLAC: 1031 ± 173 ml/min; P<0.01) and T2DM (LIXI: 187 ± 38 ml/min vs PLAC: 360 ± 72 ml/min; P<0.01), but was greater in the healthy subjects than T2DM on both the PLAC and LIXI days (P<0.001 for both). The iAUC 0-120min for plasma glucose was greater in T2DM (P<0.005) than healthy subjects, and reduced by LIXI in both groups (Healthy subjects LIXI 60 ± 24 mmol/l*min vs PLAC 348 ± 36 mmol/l*min; P<0.001 and T2DM LIXI 204 ± 60 mmol/l*min vs PLAC 600 ± 72 mmol/l*min; P<0.001).

Conclusion: In health and T2DM, the marked slowing of GE of glucose and consequent reduction in glycaemia induced by lixisenatide (10mcg sc) are associated with attenuation of the rise of SMA flow and fall in SBP. Accordingly, lixisenatide may be useful in the management of PPH.

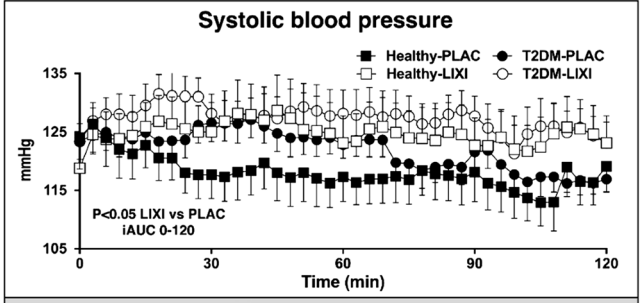

Figure: Effect of lixisenatide (10mcg sc) on systolic blood pressure in healthy subjects (n=15) and T2DM (n=15)

Autonomic neuropathy is associated with the lack of glucagon-like peptide-1 receptor agonists treatment efficacy in patients with type 2 diabetes

L. Duvnjak[1,2], T. Bulum[1,2], S. Vučković Rebrina[1];
[1]Vuk Vrhovac Clinic for Diabetes, University Hospital Merkur, [2]School of Medicine, University of Zagreb, Zagreb, Croatia.

Background and aims: While glucagon-like peptide-1 receptor agonists (GLP-1 RA) are widely used in the treatment of type 2 diabetes (T2DM), factors contributing to the lack of their efficacy have not been fully elucidated. We investigated the potential influence of cardiac autonomic neuropathy (CAN) in patients not responding to GLP1-RA.

Materials and methods: Two hundred and 14 patients with T2DM; 142 (66%) on liraglutide and 72 (34 %) on exenatide, both added to co-existing antidiabetic therapy, were divided into 2 groups (GLP-1 RA responders and non-responders) and followed for 40 months. Non-responding was defined by switching to insulin therapy at any time after intervention during 40 months of treatment. Exenatide was started as 5 μg and increased up to 10 μg twice daily. Liraglutide was started as 0.6 mg and increased up to 1.8 mg once daily. Testing of CAN was carried out on VAGUS 2100 (Sigma Medizin Technik, Thum, Germany) using a standard battery of cardiovascular tests based on heart rate variation (HRV): HRV at rest, HRV during deep breathing, Valsalva maneuver, active orthostatic test and blood pressure response to standing. The statistical data were processed by standard, vector and spectral analysis and following parameters were obtained: the coefficient of variation at rest (HRV-CV), the spectrum of low frequency power (LF) and high frequency power (HF), the coefficient of variation during deep breathing (dbHRV-CV), E / I ratio, 30 : 15 ratio and the Valsalva ratio. The resulting parameters were compared with normal values for the appropriate age, and a pathological finding of two or more parameters was considered as CAN.

Results: Non-responders (n=47), compared to responders (n=167), were older (62 vs 59 years, p=0.002), had longer diabetes duration o (14.9 vs 12.7 years, p<0.001), higher systolic (147.5 vs 143.3 mmHg, p=0.001), diastolic blood pressure (88.1 vs 86.4 mmHg, p= 0.002) and heart rate (81.1 vs 71.7 beats/min., p=0.001). The non-responders group compared to responders showed increased CAN presence (9.4% vs 4.7% and 53.1% vs 19.2%, p<0.001): significantly lower HRV-CV at rest, dbHRV-CV and Valsalva ratio, a significant attenuation for both LF and HF bands indicating lower parasympathetic or higher sympathetic nerve activity. The Cox regression model including the possible confounding variables revealed that higher HRV-CV, dbHRV-CV, E/I ratio, LF and LF/HF were associated with GLP-1 RA therapy success. For each increase in HRV-CV and dbHRV-CV of 1%, the 40 months chance for achieving glucoregulation with GLP-1RA increased by 15.6% and 12.3% respectively. The analysis of the time to insulin dependency according to cardiac autonomic function revealed that patients without CAN required insulin in 32.05 (27.25-36.87) months while patients with bordeline and pathological autonomic test results ended up with insulin therapy in 22.32 (13.85-30.78) and 21.21 (16.96-25.47) months (p<0.001 and 0.899, respectively).

Conclusion: Lack of GLP1-RA efficacy appears to be associated with CAN leading to the shortening of the time of insulin dependency in T2DM. As autonomic dysfunction could represent a significant factor leading to treatment failure, early identification of the CAN presence might be of special clinical interest. The predictive value of the relationship between GLP-1 RA efficacy and autonomic disbalance merits to be further investigated.

Efficacy of dulaglutide 1.5 mg combined with insulin in older, poorly controlled insulin-treated patients with long-standing type 2 diabetes: a post-hoc analysis

L. Fernández Landó[1], H. Patel[1], M. Yu[2], K.M. Pantalone[3];
[1]Eli Lilly and Company, Indianapolis, USA, [2]Eli Lilly and Company, Toronto, Canada, [3]Department of Endocrinology, Cleveland Clinic, Cleveland, USA.

Background and aims: This post-hoc analysis assessed the efficacy and safety of once weekly dulaglutide (DU) 1.5 mg combined with insulin in patients (pt) with type 2 diabetes (T2D), categorised by subgroups of age (<65 and ≥65 years; yr), duration of diabetes (DoD; <10 and ≥10 yr) and baseline (BL) HbA_{1c} [≤9% (≤74.9 mmol/mol) and >9% (>74.9 mmol/mol)] at 6 months (mo).

Materials and methods: A pooled analysis was conducted for efficacy of two Phase 3 randomised trials (AWARD-4 and -9) that assessed the use of DU in a similar T2D population with a pooled mean BL age: 59 yr, DoD: 13 yr and HbA_{1c}: 8.4% (68.3 mmol/mol). Weight and hypoglycaemia were analysed by individual trial. In AWARD-4, DU + lispro TID was assessed against glargine + lispro TID. In AWARD-9, DU added to glargine was assessed against placebo added to glargine. Insulins were titrated to target in both trials.

Results: At 6 mo, DU 1.5 mg significantly reduced HbA_{1c} in all subgroups (p<0.001) with the highest reduction observed in pt with BL

HbA_{1c} >9% (>74.9 mmol/mol; Table). All except 3 subgroups [DoD <10 yr, AWARD-4; BL HbA_{1c} >9% (>74.9 mmol/mol), both trials] demonstrated weight loss. The incidence of documented symptomatic hypoglycaemia was similar in all subgroups in AWARD-4 study; and in AWARD-9 study, the incidence was numerically greater in subgroups of ≥10 yr DoD, and >9% baseline HbA_{1c}. The most common adverse events observed in each trial were gastrointestinal in nature.

Conclusion: DU 1.5 mg combined with basal or prandial insulin is efficacious for pt with T2D independent of age, DoD and BL HbA_{1c}.

Baseline characteristics, Δ HbA_{1c} and percent to goal (HbA_{1c} <7% [<53 mmol/mol]) at 6 months of dulaglutide 1.5 mg patients categorised by baseline HbA_{1c}, age and duration of diabetes

The effect of liraglutide on oxidative nucleic acid modifications in women with prior gestational diabetes

E.L. Larsen[1,2], S. Foghsgaard[1], L. Vedtofte[1], E.R. Mathiesen[3], P. Damm[4], J.A. Svare[5], T.D. Clausen[6], T. Henriksen[2], H.E. Poulsen[2,7], F.K. Knop[1,8], T. Vilsbøll[1,9];
[1]Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Hellerup, [2]Department of Clinical Pharmacology, Bispebjerg and Frederiksberg Hospital, University of Copenhagen, Copenhagen, [3]Center for Pregnant Women with Diabetes, Department of Endocrinology, Rigshospitalet, University of Copenhagen, Copenhagen, [4]Center for Pregnant Women with Diabetes, Department of Obstetrics, Rigshospitalet, University of Copenhagen, Copenhagen, [5]Department of Obstetrics and Gynecology, Herlev Hospital, University of Copenhagen, Herlev, [6]Department of Gynecology and Obstetrics, Nordsjællands Hospital, University of Copenhagen, Hillerød, [7]Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, [8]Novo Nordisk Foundation Center for Basic Metabolic Research and Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, [9]Steno Diabetes Center Copenhagen, University of Copenhagen, Gentofte, Denmark.

Background and aims: Animal studies have shown that liraglutide, a glucagon-like peptide-1 analogue, lowers oxidative modifications. RNA oxidation, measured by urinary excretion of 8-oxo-7,8-dihydroguanosine (8-oxoGuo), is associated with mortality in patients with type 2 diabetes. Here, we investigated the effect of liraglutide on oxidative nucleic acid modifications in women with prior gestational diabetes mellitus (pGDM).
Materials and methods: Women with pGDM (n=104) were randomised to one-year, double-blinded intervention with liraglutide (1.8 mg, once-daily) (n=49) or placebo (n=55) followed by a one-year, open-label intervention. An age and BMI matched control group of women without pGDM was also studied (n=15) at baseline. The urinary excretion of 8-oxoGuo and 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-oxodG) was determined at baseline, after 53 weeks (52 weeks intervention followed by one week wash out), and after 104 weeks by ultra-performance liquid chromatography tandem mass-spectrometry as a measurement of whole body RNA and DNA oxidation, respectively.
Results: At baseline, similar urinary excretion of 8-oxoGuo/creatinine (mean±SD: 1.58±0.40 vs. 1.61±0.53 nmol/nmol, p=0.86) and 8-oxodG/creatinine (1.06±0.33 vs 1.20±0.54 nmol/nmol, p=0.39) was seen in women with and without pGDM. Treatment with liraglutide for 52 weeks did not affect urinary excretion of 8-oxoGuo/creatinine (delta values (mean±SD): -0.01±0.36 vs. -0.00±0.52 nmol/nmol, p=0.91) or 8-oxodG/creatinine (-0.01±0.25 vs. 0.08±0.45 nmol/nmol, p=0.31) vs. placebo treatment after a one-week washout period. Subsequent, open-label treatment with liraglutide for additionally 52 weeks vs. no further treatment did not affect urinary excretion of 8-oxoGuo/creatinine (delta values from baseline (mean±SD): 0.05±0.29 vs. 0.13±0.43 nmol/nmol, p=0.45) or 8-oxodG/creatinine (0.15±0.25 vs. 0.30±0.33 nmol/nmol, p=0.10).
Conclusion: In conclusion, women with and without pGDM exhibit similar RNA and DNA oxidations, and liraglutide treatment for two years does not seem to affect oxidative nucleic acid modifications in women with pGDM.

Efficacy of liraglutide QD vs sitagliptin QD vs insulin glargine on liver fat when combined with metformin in type 2 diabetes subjects with NAFLD (Light-on Study)

J. Yan[1], B. Yao[1], H. Kuang[2], X. Yang[1], H. Deng[1], Y. Tan[1], Q. Huang[3], T. Hong[4], Z. Shan[5], J. Dou[6], W. Yang[7], G. Qin[8], H. Yuan[9], X. Xiao[10], J. Weng[1];
[1]The Third Affiliated Hospital of Sun Yat-sen University, Guangdong Provincial Key Laboratory of Diabetology, Guangzhou, [2]The First Affiliated Hospital of Harbin Medical University, Harbin, [3]Changhai Hospital, Shanghai, [4]Peking University Third Hospital, Beijing, [5]The First Hospital of China Medical University, Shenyang, [6]Chinese PLA General Hospital, Beijing, [7]CHINA-JAPAN Friendship Hospital, Beijing, [8]The First Affiliated Hospital of Zhengzhou University, Zhengzhou, [9]Henan Provincial Peoples Hospital, Zhengzhou, [10]Peking Union Medical College Hospital, Beijing, China.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) has become epidemic in type 2 diabetes mellitus (T2DM), yet limited data are available on efficacy and safety of anti-hyperglycemic agents for liver injury. This study investigated the effects of liraglutide versus sitagliptin versus insulin glargine on liver fat combined with metformin in NAFLD patients with T2DM.
Materials and methods: Seventy-five patients with NAFLD and T2DM inadequately controlled on metformin monotherapy (at least 1500 mg/d) were randomized to receive liraglutide or sitagliptin or insulin glargine therapy for 26 weeks. The liver fat index (MRI estimated proton density fat fraction, MRI-PDFF) was measured by MRI IDEAL IQ (Iterative Decomposition of water and fat with Echo Asymmetry and Least-squares estimation). The Chi-square test, paired t test and one way ANOVA (least significant difference) were used for statistical analysis.
Results: A total of 68 patients finished the study. Baseline characteristics were similar among the three groups. There was significant improvement in glycated hemoglobin (HbA1c) in three groups (liraglutide, 7.3±0.7 % to 6.1±0.6%, P=0.001; sitagliptin, 7.5±0.9 % to 6.6±0.9%, P=0.001; glargine, 7.7±1.0% to 6.8±1.1 %, P=0.018), whereas the change of HbA1c (ΔHbA1c) from baseline was not significantly different among three groups (P>0.05). Both liraglutide and sitagliptin treatment were associated with a significant decrease in MRI-PDFF (liraglutide,17.8 ±6.8% to 13.0±7.0%, P=0.004; sitagliptin,15.9±6.0% to 12.1±4.8%, P=0.002) and weight (liraglutide, 87.9±12.5 kg to 83.9±10.9 kg, P=0.004; sitagliptin, 88.2±13.9 kg to 86.5±13.5 kg, P=0.004), but MRI-PDFF showed no significant change in glargine treatment (14.2

±5.2% to 13.3±7.1%, *P*> 0.05), nor did weight (85.2±13.8 kg to 84.1 ±14.6 kg, *P*>0.05). The changes of weight (Δweight) and MRI-PDFF(ΔMRI-PDFF) from baseline in the liraglutide group were significantly higher than those in the glargine group(*P*=0.030 and *P*=0.009 respectively), whereas Δweight and ΔMRI-PDFF from baseline has no significant difference between the liraglutide group and sitagliptin group (*P*=0.074 and *P*=0.337 respectively).

Conclusion: The liraglutide or sitagliptin therapy combined with metformin reduced the liver fat in T2DM patients with NAFLD.

Dyslipidaemia impairs effects of GLP-1 on nitric oxide action and oxidative stress in human platelets

C. Barale[1], C. Frascaroli[2], P. Cataldi[2], F. Cavalot[2], I. Russo[1];
[1]Department of Clinical and Biological Sciences, University of Turin, [2]Metabolic Disease and Diabetes Unit, San Luigi Gonzaga Hospital, Orbassano, Turin, Italy.

Background and aims: Glucagon-like peptide 1 (GLP-1) exerts important effects on the glucose homeostasis and influences the cardiovascular system. Platelets are very sensitive to the inhibitory effects of nitric oxide (NO), which is impaired and contributes to platelet hyperreactivity in Type 2 Diabetes (T2D), thus contributing to increased thrombotic events. We have recently demonstrated that, in platelets from healthy subjects, the bioactive GLP-1(7-36) and the GLP-1 analogue Liraglutide increase platelet sensitivity to NO/cGMP/PKG/VASP pathway and reduce oxidative stress. We have also found that these GLP-1 effects are reduced in T2DM. Aim of this study was to evaluate if dyslipidaemia without hyperglycemia affects GLP-1-related peptides activity on platelet response to NO and reactive oxygen species (ROS) synthesis in platelets.

Materials and methods: In platelet samples obtained from 26 non diabetic patients affected by dyslipidaemia (M/F: 13/13; age 49.4±1.9 years; BMI: 24.9±0.8 kg/m2; fasting glucose: 91.7±1.6 mg/dl, total cholesterol: 273.5±8.5 mg/dl, HDL-cholesterol: 64.8±4.1 mg/dl, triglycerides 166.7 ±21.0 mg/dl, LDL-cholesterol:182.3±7.7 mg/dl) and from 18 healthy controls (M/F:10/8; age:49.2±3.6 years; BMI: 24.3±0.8 kg/m^2), we evaluated the GLP-1(7-36) or Liraglutide (100 nmol/l) ability to influence: i)the anti-aggregating effects of the NO donor Na-nitroprusside (SNP, 5 μmol/l) with the platelet agonists ADP (10 μmol/l), collagen (4 mg/l) and arachidonic acid (AA, 1 mmol/l) (Born's method); ii)the SNP-induced VASP (pVASP) phosphorylation at ser239 (Western Blot); and iii)the ROS production induced by AA (100 μmol/l)(DCF-DA fluorescence assay).

Results: In dyslipidaemic subjects compared with healthy subjects, the effects of GLP-1(7-36) and Liraglutide on platelet response were significantly lower. In particular, in the presence of GLP-1(7-36): the percent increase of the anti-aggregating effects of SNP were 7.0±1.9 vs 23.2±4.5 (p=0.0001) with ADP, 8.3±6.8 vs 30.8±5.3 (p=0.02) with collagen and 6.6±3.2 vs 31.8±5.5 (p=0.0001) with AA; the percent increase of the SNP-induced pVASP levels was 3.5±4.3 vs 33.1±3.9 (p=0.0001); the percent reduction of ROS synthesis was 10.1±5.2 vs 30.2±7.9 (p=0.03). In the presence of Liraglutide: the percent increase of the anti-aggregating effects of SNP were 9.6±2.9 vs 35.3±4.9 (p=0.0001) with ADP, 15.0±5.2 vs 36.8±5.6 (p=0.008) with collagen, 17.0±5.2 vs 36.8±5.1 (p=0.01) with AA; the percent increase of the SNP-induced pVASP was 5.1±4.2 vs 40.1 ±5.5 (p=0.0001); the percent reduction of ROS synthesis was 15.6±5.7 vs 40.2±7.8 (p=0.01).

Conclusion: In platelets from non diabetic dyslipidaemic subjects, the ability of GLP-1(7-36) and Liraglutide to enhance the inhibitory pathway NO/PKG/VASP and reduce ROS production was greatly impaired. Our findings are suggestive for a role of dyslipidaemia per se to cause a resistance to GLP-1 effects on platelet function and for dyslipidaemia being a determinant of impaired GLP-1 action on platelets which we also observed in T2D.

Autonomic regulation may modify the weight reducing effect of liraglutide in overweight patients with type 1 diabetes

C.S. Hansen[1], C.S. Frandsen[2], J. Fleischer[3], D. Vistisen[1], L. Tarnov[4], F.K. Knop[5], S. Madsbad[2], H.U. Andersen[1], T.F. Dejgaard[1];
[1]Steno Diabetes Center, Gentofte, Denmark, [2]Endocrinology, Hvidovre Hospital, Hvidovre, Denmark, [3]Clinical Institute of Medicine, Aarhus University, Aarhus, Denmark, [4]Hillrød Hospital, Hillerød, Denmark, [5]Center of Diabetes Research, Gentofte Hospital, Gentofte, Denmark.

Background and aims: The exact mechanisms by which glucagon-like peptide-1 (GLP-1) exerts anorectic effects are unclear, but peripheral activation of vagal neurons as well as brain GLP-1 receptors seems to be involved. Vagal neurons may also be involved in the effect of GLP-1 on the pancreatic islet function. The role of the autonomic nervous system (ANS) in the efficacy of long-acting GLP-1 receptor agonists, such as liraglutide, in patients with type 1 diabetes is unknown. We assessed the effect of autonomic neuropathy on liraglutide-induced weight loss, insulin requirement and rates of hypoglycaemia. We investigated the effect of liraglutide treatment on ANS function.

Materials and methods: Lira-1 was a randomised, double-blind, placebo-controlled trial assessing the efficacy of 1.8 mg liraglutide once-daily for 24 weeks in obese and poorly controlled type 1 diabetes. ANS function was assessed by cardiovascular reflex tests (CARTs): heart rate response to deep breathing (E/I ratio), to standing (30/15 ratio) and to the Valsalva manoeuvre. Participants with two or three pathological CARTs were diagnosed as having cardiovascular autonomic neuropathy (CAN). In addition, ANS function was assessed by resting heart rate variability indices by parasympathetic measures (RMSSD and high frequency power (HF)) mixed sympathetic and parasympathetic measures (SDNN, low frequency power (LF) and total power (TP).

Results: 100 patients aged 48 (SD 12) years, with a mean HbA_{1c} of 72 mmol/mol (SD 7) and a mean BMI of 30 (SD 3) kg/m^2 were assigned to liraglutide or placebo. 30 percent of all participants had CAN. Patients with and without CAN had a similar liraglutide induced weight loss of 6.1 kg (SD 4.0) and 5.8 kg (SD 2.9) (p=0.9), respectively. One SD higher level in baseline values of the 30/15 ratio, SDNN and TP was associated with increased weight reduction by liraglutide of 0.97 kg (95% CI: 0.25;1.69, p<0.01), 0.77 kg (95 % CI 0.13;1.40, p=0.02) and 0.69 kg (95% CI -0.001;1.39, p=0.06) respectively. CAN measures were not associated with change in insulin requirements. In the liraglutide group, the rate of hypoglycaemic events was higher in patients with CAN vs. patients with no CAN. The between group rate ratio (RR) was 1.32 (95% CI 1.13; 1.54 p<0.001). A one SD higher level of HF and RMSSD was associated with lower rates of hypoglycaemia (RR<0.8, p<0.0001 for both). In the placebo group, CAN and increased values of the E/I ratio, SDNN, LF, TP and RMSSD were associated with less events (data not shown). Liraglutide treatment did not induce change in CARTs or HRV indices.

Conclusion: During treatment with liraglutide in obese type 1 diabetes patients, autonomic dysfunction but not the diagnosis of CAN was associated with less weight loss. The E/I ratio (a measure of vagal function) was not associated with weight reduction suggesting that the weight loss may be independent of the vagus nerve activity. Autonomic neuropathy

measures were not associated with insulin requirements and only parasympathetic measures were associated with hypoglycaemia in the liraglutide group.

Liraglutide treatment reduces the NA and SNP relaxant effect on the rat isolated gastric fundus: comparison with a model of non-obese type 2 diabetes

S. Silva[1,2], A. Carrêlo[1,3], B. Martins[1,2], R. Seiça[3], C. Fontes Ribeiro[1], P. Matafome[3,4];
[1]Laboratory of Pharmacology and Experimental Therapeutics/Institute for Biomedical Imaging and Life Sciences (IBILI), Faculty of Medicine, University of Coimbra, [2]Group of Pharmacology and Pharmaceutical Care, Faculty of Pharmacy, University of Coimbra, [3]Laboratory of Physiology, IBILI, Faculty of Medicine, University of Coimbra, [4]Department of Complementary Sciences, Instituto Politécnico de Coimbra, Coimbra Health School (ESTeSC), Coimbra, Portugal.

Background and aims: GLP-1R agonists (GLP-1RA) have been developed for the treatment of type 2 diabetes (T2D) and obesity because of their beneficial metabolic and anorexic effects. Regarding the gastrointestinal tract, they delay gastric emptying and inhibit gut motility through activation of GLP-1R on enteric neurons and via nitric oxide release. The main goal of this study was to understand and pharmacologically characterize the effects of GLP-RA on gastric fundus motility, in the absence and presence of T2D.
Materials and methods: Gastric fundus strips isolated from 16 weeks Wistar rats and non-obese type 2 diabetic Goto-Kakizaki (GK) rats were used to study the isometric contractile responses to GLP-1, exenatide and liraglutide in the presence and the absence of Exendin-3 (selective GLP-1R antagonist), and N^G-nitro-L-Arginine, (L-NNA, non-selective inhibitor of nitric oxide synthase). In addition 14 week male Wistar and GK rats were injected twice a day with liraglutide (200μg/Kg s.c.) or saline for 14 days, after which they were sacrificed and isometric relaxation induced by sodium nitroprusside (SNP) and noradrenaline (NA) was studied using gastric fundus strips from all 4 groups. Samples were also collected to determine GLP-1R, nNOS and p-nNOS density (Western Blotting).
Results: Functional studies showed that GLP1-RA induced concentration-dependent non-cholinergic contraction of rat gastric fundus, partially inhibited by Exendin-3 and not altered by L-NNA. Moreover GLP-1 showed more intrinsic activity in diabetic rats (E_{max} 9.09±1.44 mN, n=12) than in control rats (E_{max} 5.6±0.69 mN, n=16) ($p<0.05$, Student *t* test) and according to ANOVA followed by Tukey's multiple comparison test, exenatide showed more intrinsic activity and liraglutide was the most potent of the three GLP-1RA studied (pEC_{50} of 9.62±0.23, n=5 *versus* exenatide pEC_{50} of 8.78±0.16 and GLP-1 pEC_{50} of 8.33±0.16, n= 12). *In vivo* studies showed a significant decrease in caloric intake and body weight both in diabetic and non-diabetic liraglutide treated-rats. Additionally, a significant decrease in SNP- and NA-induced relaxation of gastric fundus strips isolated from both treated animal groups was observed: NA showed less intrinsic activity and potency in Wistar treated-rats and less potency in GK treated-rats, indicating that NA-induced relaxation was reduced by both treatment and pathology. Finally, a significant decrease of GLP-1R levels was observed in gastric fundus from treated-rats (compared to non-treated ones), but no significant changes were observed in nNOS and p-nNOS levels between the 4 groups.
Conclusion: The increased gastric fundus tonus induced by GLP-1RA may constitute a peripheral mechanism by which GLP-1RA can reduce food intake.

Effect of liraglutide on time in various glycaemic ranges in persons with type 2 diabetes treated with multiple daily insulin injections

S. Sofizadeh[1], A.F. Olafsdottir[1], S. Dahlqvist[1], I.B. Hirsch[2], J. Tuomilehto[3,4], M. Lind[1,5];
[1]Department of Medicine, NU-Hospital Group, Uddevalla, Sweden, [2]University of Washington, Seattle, USA, [3]Dasman Diabetes Institute, Dasman, Kuwait, [4]Centre for Vascular Prevention, Danube University Krems, Krems, Austria, [5]Department of Molecular and Clinical Medicine, University of Gothenburg, Gothenburg, Sweden.

Background and aims: We have earlier shown that liraglutide compared to placebo improves glycaemic control (HbA1c) and reduces body weight in persons with type 2 diabetes (T2D) treated with multiple daily insulin injections (MDI). In the current evaluation of the data from the study we further analysed effects of liraglutide compared to placebo on various glycaemic ranges including time in hypoglycaemia, euglycaemia and hyperglycaemia using masked continuous glucose monitoring (CGM).
Materials and methods: Data from the MDI-liraglutide trial randomizing 124 persons with T2D treated with MDI having an HbA1c of ≥58 mmol/mol (7.5%) and ≤102 mmol/mol (11.5%), and body mass index of 27.5-45 kg/m^2 were used. At 24 weeks 99 (80%) of patients had masked CGM data. We categorized glycaemic ranges into hypoglycemic, euglycaemic and hyperglycaemic ranges (Table).
Results: The mean percent time in hypoglycaemia was similar for persons receiving liraglutide and placebo at 24 weeks treatment, Table. The mean time in euglycaemia was greater in liraglutide group compared to placebo, 431 versus 243 min/24h (p=0.0012) and 960 versus 696 min/24h (p<0.001) for the two glycaemic cut-offs (4-7 mmol/l and 4-10 mmol/l) respectively, see Table. In contrast, the mean time in hyperglycaemia was lower in the liraglutide group compared to placebo, 456 versus 723 min/24h (p<0.001) and 134 versus 264 min/24h (p=0.0094) for the two evaluated glycaemic cut-offs (>10 mmol/l and >14 mmol/l), see Table.
Conclusion: Using masked CGM we found that adding liraglutide to persons with T2D treated with MDI increases time in euglycaemia, reduces time in hyperglycaemia without the risk of increased time in hypoglycemia.

Dulaglutide treatment reduces glycaemic excursions in people with type 2 diabetes: a post-hoc analysis of 6 phase 3 randomised clinical trials

V. Pechtner[1], G. Charpentier[2], L.-E. García-Pérez[3], V.T. Thieu[3], N. Jia[3], J.G. Jacobson[3];
[1]Lilly France, Neuilly-sur-Seine Cedex, [2]Centre Hospitalier de Corbeil, Evry, France, [3]Eli Lilly and Company, Indianapolis, USA.

Background and aims: The once-weekly glucagon-like peptide-1 receptor agonist dulaglutide (DU) demonstrated a significant HbA1c reduction and the potential for weight loss in adults with uncontrolled type 2 diabetes (T2D) in the AWARD phase 3 clinical programme. DU has also demonstrated significant reductions in fasting, pre- and postprandial glucose levels.
Materials and methods: To further understand the glycaemic effects of DU 1.5 mg and 0.75 mg, we performed a post-hoc analysis examining glycaemic excursions (morning, midday, evening and daily mean) obtained by self-monitored blood glucose testing at 6 or 12 month time points. Analysis was performed by individual study (AWARD-1, -2, -3, -6, -8 and -9), given the different background therapies. Glycaemic excursions were derived by subtracting blood glucose values before each meal from blood glucose values 2 hours after the meal.
Results: Treatment with DU 1.5 mg resulted in significant reductions from baseline in daily mean glucose excursions (change: -0.39 to -0.83 mmol/L, p<0.05) in all six trials. The effect of DU 1.5 mg on glycaemic excursions was most evident in the morning followed by the evening (Table). The trend of the glycaemic excursion reductions from baseline with DU 1.5 mg and DU 0.75 mg was similar.
Conclusion: The effect of DU treatment on glycaemic excursions may contribute to overall improvements in glycaemic control in patients with T2D treated with DU.

Effects of exenatide once weekly and dapagliflozin in combination and alone on a composite of HbA_{1c}, weight, and SBP across baseline BMI subgroups in the DURATION-8 trial

E. Repetto[1], S.A. Jabbour[2], J.P. Frías[3], E. Hardy[1], A.A. Ahmed[4], P. Öhman[1], H. Wang[1], C. Guja[5];
[1]AstraZeneca, Gaithersburg, [2]Endocrinology, Thomas Jefferson University, Philadelphia, [3]National Research Institute, Los Angeles, [4]Apex Medical Research, Chicago, USA, [5]"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania.

Background and aims: In the randomised, double-blind, active-controlled DURATION-8 study, the combination of exenatide once weekly (QW) + dapagliflozin once daily (QD) led to improvements in glycaemic measures, weight, and systolic blood pressure (SBP) in adult patients with type 2 diabetes inadequately controlled by metformin monotherapy. For exenatide QW, it is known that weight loss increases with higher BMI and may be associated with greater improvements in HbA1c and SBP. We hypothesised that improvements in a composite of HbA1c, weight, and SBP may be associated with baseline BMI and thus investigated treatment effects on these endpoints alone and as a composite of all 3 across baseline BMI subgroups.
Materials and methods: Patients received exenatide QW 2 mg + dapagliflozin 10 mg QD (N=228), exenatide QW 2 mg + placebo (N=227), or dapagliflozin 10 mg QD + placebo (N=230) added-on to metformin. All endpoints were studied at 28 weeks. In this post hoc analysis, patients in the intent-to-treat population were analysed by

baseline BMI subgroups: <25, ≥25 to <30, ≥30 to <35, ≥35 to <40, and ≥40 kg/m^2. The number and percentage of patients achieving reductions in HbA1c ≥1%, weight ≥2 kg, SBP ≥2 mmHg, and the composite of these 3 were calculated for each treatment and BMI subgroup.

Results: At baseline, mean HbA1c was 9.3% in all groups; in the exenatide QW + dapagliflozin, exenatide QW, and dapagliflozin groups, mean weight was 91.8, 89.8, and 91.1 kg, respectively, mean BMI was 33.2, 32.0, and 33.0 kg/m^2, respectively, and mean SBP was 130.5, 129.6, and 129.7 mmHg, respectively. Within each baseline BMI subgroup, proportions of patients achieving individual endpoints were generally greater for the combination than exenatide or dapagliflozin alone (Table). A greater proportion of patients treated with exenatide QW + dapagliflozin achieved the composite endpoint compared with exenatide QW or dapagliflozin alone across BMI subgroups. Within each treatment group, in general, greater proportions of patients achieved the composite endpoint as baseline BMI increased. The greatest composite benefit was observed in patients with BMI ≥35 kg/m^2 treated with exenatide QW + dapagliflozin.

Conclusion: Exenatide QW + dapagliflozin was associated with a greater proportion of patients achieving a composite endpoint of HbA1c reduction, weight loss, and SBP reduction than exenatide QW or dapagliflozin alone across all baseline BMI subgroups. More obese patients achieved the composite endpoint of HbA1c, weight, and SBP compared with overweight patients.

Table. Percentage of patients achieving specific HbA1c, weight, and/or SBP reductions in BMI subgroups

Characteristics associated with the choice of first injectable therapy among U.S. patients with type 2 diabetes

M. Yu[1], R. Mody[2], L. Fernández Landó[3], A. Shui[4], L. Kallenbach[4], L. Slipski[4], C. Piras de Oliveira[3];
[1]Eli Lilly and Company, Toronto, Canada, [2]Eli Lilly and Company, Indianapolis, [3]Lilly USA, LLC, Indianapolis, [4]Practice Fusion, San Francisco, USA.

Background and aims: The objective of this retrospective observational study was to identify and describe clinical and demographic characteristics associated with the choice of first injectable therapy (glucagon-like peptide-1 receptor agonist [GLP-1 RA] or basal insulin [BI]) by physicians among patients with type 2 diabetes (T2D).

Materials and methods: This analysis included adults with T2D who initiated GLP-1 RA or BI (index date) between November 2014 and February 2016 using data from the Practice Fusion electronic health record database. Patients with ≥1 diagnosis of T2D and ≥1 office visit between 6 and 18 months prior to the index date who were naïve to GLP-1 RAs and BI and had ≥1 HbA1c result in the 6-month baseline period were included. Gradient boosting method (GBM) and bootstrapped logistic regression were used to identify variables that influenced selection of treatment.

Results: The study included 3,546 and 7,507 GLP-1 RA and BI initiators, respectively. Descriptive analyses showed that at baseline, GLP-1 RA initiators were significantly younger (mean 58 vs 63 years) and had lower HbA1c (mean 8.2 vs 9.1%), lower Diabetes Complications Severity Index (DCSI) scores (mean 1.0 vs 1.7), and higher BMI (mean 36 vs 33 kg/m^2) compared to BI initiators. Variables selected by GBM with the highest relative importance (≥5%) in the selection of GLP-1 RA or BI were HbA1c, BMI, age, sodium-glucose cotransporter-2 inhibitor (SGLT-2i) use and DCSI score. The same variables were identified by logistic regression in all the bootstrapped samples with the addition of race. The figure below shows the odds ratio (OR) of selecting GLP-1 RA vs BI as first injectable therapy.

Conclusion: There were relevant clinical and demographic differences between the two cohorts, suggesting GLP-1 RAs and BI are prescribed to different types of patients with T2D. Key predictors that favored the choice of a GLP-1 RA as first injectable were higher BMI and previous use of an SGLT-2i; predictors that favored the choice of initiating BI were worse glycemic control, older age, and higher disease burden.

Blockade of glucagon-like peptide-1 receptors by exendin(9-39) attenuates the increase in heart rate during small intestinal glucose infusion in type 2 diabetes

C.K. Rayner, T. Wu, M. Horowitz, K.L. Jones;
Discipline of Medicine, University of Adelaide, Adelaide, Australia.

Background and aims: Glucagon-like peptide-1 (GLP-1) and its mimetics have been shown to increase heart rate (HR) in both health and type 2 diabetes. However, it remains unclear whether this effect is attributable to GLP-1 receptor signaling and, if so, whether endogenous GLP-1 modulates cardiovascular function through this pathway, particularly during the postprandial phase. Given that postprandial GLP-1 secretion is determined in part by the rate of gastric emptying, which varies substantially between individuals and is also modulated by GLP-1, we evaluated theHR and blood pressure (BP) responses to a standardised jejunal glucose infusion, in the absence and presence of the GLP-1 receptor antagonist, exendin(9-39), in patients with type 2 diabetes.
Materials and methods: 10 patients with type 2 diabetes (age 69.5 ± 2.9 years; 8 male; BMI 26.6 ± 0.9 kg/m^2; HbA1c 6.6 ± 2.2% (48.9 ± 2.3 mmol/mol); duration of known diabetes 13.6 ± 3.4 years), managed by diet or metformin alone, were each studied on two days, separated by at least 7 days, in a double-blind, randomised fashion. On each study day, a nasal-jejunal catheter was positioned with an infusion port located 50 cm below the pylorus. An intravenous (IV) infusion of exendin(9-39) (600 pmol/kg/min) or 0.9% saline was commenced 60 min before, and maintained during, a 120-min intrajejunal glucose infusion (2 kcal/min). HR and BP were measured every 5 min, using an automated device. On one day, autonomic function was assessed using standardised cardiovascular reflex tests.
Results: None had cardiovascular autonomic dysfunction. Prior to jejunal glucose infusion, neither HR (IV saline: 57 ± 3 bpm vs. IV exendin(9-39): 56 ± 2 bpm) nor BP (130 ± 7 and 71 ± 2 mmHg vs. 132 ± 6 and 73 ± 3 mmHg for systolic and diastolic BP, respectively) differed between the two study days. During jejunal glucose infusion, HR increased on both days, and the magnitude of increase was less with IV exendin(9-39) compared with IV saline (treatment effect: P = 0.009). Systolic and diastolic BP both decreased slightly during jejunal glucose infusion, without any difference between the two study days.
Conclusion: In relatively well controlled, normotensive patients with type 2 diabetes, without autonomic dysfunction, blockade of GLP-1 receptors by exendin(9-39) attenuates the HR response to small intestinal glucose infusion. These observations are indicative of a physiological role of GLP-1 receptor signalling in the regulation of postprandial cardiovascular function in type 2 diabetes.

A calculator to predict durability of HbA_{1c} response with DPP4 inhibitors, sulfonylureas and thiazolidinediones: a MASTERMIND precision medicine study

J.M. Dennis[1], W.E. Henley[1], M.N. Weedon[1], M. Lonergan[2], L.R. Rodgers[1], A.G. Jones[1], N.A. Sattar[3], R.R. Holman[4], E.R. Pearson[2], A.T. Hattersley[1], B.M. Shields[1];
[1]University of Exeter Medical School, University of Exeter, Exeter, [2]Division of Molecular & Clinical Medicine, University of Dundee, Dundee, [3]Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, [4]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, UK.

Background and aims: Precision diabetes aims to target patients with the most effective treatment based on their characteristics. Common second-line type 2 diabetes therapies are DPP4 inhibitors (DPP4i, 27% of current UK second/third line oral prescriptions), sulfonylureas (SU, 51% of prescriptions) and thiazolidinediones (TZD, 8% of prescriptions), but there is little guidance as to which therapy is best for which individuals. We aimed to develop a calculator to predict individual durability of good glycaemic control for these therapies based on routinely measured clinical characteristics.
Materials and methods: To measure glycaemic durability we developed time to glycaemic failure survival models for each therapy in UK primary care data (Clinical Practice Research Datalink (CPRD), n=102,830). Failure was defined as time to a patient reaching a confirmed HbA1c threshold of 8.5%. For SU and TZD we validated survival models in individual participant data from two head-to-head randomised trials (ADOPT n=2,725, RECORD n=2,222). For DPP4i we replicated associations between clinical characteristics and HbA1c in a prospective study (PRIBA, n=254), in which change in HbA1c at 6 months was the outcome.
Results: Lower baseline BMI was associated with greater glycaemic durability with DPP4i and SU (both p<0.001), but shorter glycaemic durability with TZD (p<0.001). With SU, males maintained good glycaemic control for longer compared to females (p<0.001), whilst females had greater glycaemic durability with TZD over males (p<0.001). There was no association between sex and glycaemic control with DPP4i (p=0.44). For all therapies, lower baseline HbA1c (p<0.001) and older age (p<0.001 were associated with greater glycaemic durability but to different degrees. Model discrimination using these characteristics was good for each therapy model (C-statistic DPP4i 0.72, SU 0.70, TZD 0.76). SU and TZD survival models validated well in external trial data (ADOPT: C-statistic 0.68 SU, 0.73 TZD) and consistent predictors of DPP4i HbA1c response were identified in the prospective PRIBA study. Findings translate into significant differences in glycaemic durability between therapies: If a female age 65 years with a starting HbA1c of 8.5% and a BMI of 35kg/m^2 remains on stable therapy the likelihood of good control (HbA1c < 8.5%) at 3 years is greatest at 84.5% (95%CI 84-85%) with TZD compared to DPP4i (66%, 95%CI 65-67%) and SU (68.5%, 95%CI 68-69%).
Conclusion: A simple calculator can predict glycaemic durability with common second-line therapies. Extending our calculator to encompass other second-line therapies and drug-specific side effects could help clinicians adopt a more personalised approach to type 2 diabetes therapy.

Influence of breakfast on clock gene and AMPK mRNA expression and postprandial glycaemia in healthy and type 2 diabetes

D. Jakubowicz[1], J. Wainstein[1], Z. Landau[1], I. Raz[2], B. Ahren[3], N. Chapnik[4], T. Ganz[1], M. Menaged[1], M. Barnea[5], Y. Bar-Dayan[1], O. Froy[4];
[1]Diabetes Unit, E.Wolfson Medical Center, Tel Aviv University, [2]Diabetes Unit, Hadassah University Hospital, Ein Kerem, Jerusalem, [3]Department of Clinical Sciences, Lund University, Lund, Sweden, [4]Institute of Biochemistry, Food Science and Nutrition, The Hebrew

University of Jerusalem, [5]Department of Molecular Genetics, Weizmann Institute of Science, Weizmann Institute, Israel.

Background and aims: The circadian clock regulates glucose metabolism by mediating the activity of metabolic enzymes, hormones, and transport systems. Meal timing not aligned with the circadian clock i.e. breakfast skipping and/or eating at hours assigned to sleep, have been associated with high HbA1C and postprandial hyperglycemia after lunch and dinner. Our aim was to explore the effect of breakfast consumption or omission on glucose homeostasis and clock gene, Ampk, and Sirt1 mRNA expression in healthy and type 2 diabetes individuals.
Materials and methods: In a crossover design, 18 healthy and 18 T2D volunteers with 14.5±1.5yr diabetes, BMI 30.7±1.1 kg/m2 and HbA1C: 7.6 ± 0.1 % were randomly assigned to a test day with breakfast and lunch (YesB) and a test day with only lunch (NoB). Postprandial clock genes (Clock, Bmal1, Per1, Per2, Cry1, Rev-erbα, Rorα) Ampk and Sirt1 mRNA expression, in white blood cells (WBC), and plasma glucose, insulin, intact glucagon-like peptide-1 (iGLP-1) and dipeptidyl peptidase IV (DPP-IV) plasma activity were assessed after breakfast and lunch.
Results: In healthy people, YesB day led to 26% upregulation of Bmal1, the positive loop of clock gene expression ($p<0.005$), to 34-43% increase of Ampk and Sirt1 ($p<0.005$), and to 30% downregulation of negative feedback loop Per2 after lunch ($p<0.05$). In the diabetic group, YesB day led to 25-42% upregulation of Bmal1, Ampk, Per1, Cry1 and Rev-erbα ($p<0.005$). Breakfast skipping (NoB day) in healthy and type 2 diabetic individuals, led to downregulation of Bmal1 and Ampk ($p<0.005$) and it was associated with ~15% elevation of AUC of glucose response after lunch and impaired insulin and iGLP-1 responses to lunch ($p<0.0001$).
Conclusion: Breakfast skipping adversely affects the expression of clock, clock-related genes and Ampk mRNA expression after lunch and was correlated with reduced insulin and iGLP-1 and increased postprandial glycemic response after lunch in both healthy and diabetic individuals. These results suggest that intake of breakfast is important for maintaining the clock gene regulation of the overall glucose metabolism both in healthy and in type 2 diabetes.

Effect of meal frequency on glucose and insulin responses in obese people with impaired glucose tolerance and with type 2 diabetes: a randomised trial

E. Papakonstantinou[1], P. Mitrou[2], M.D. Kontogianni[3], G. Dimitriadis[4]; [1]Food Science and Human Nutrition, Agricultural University of Athens, [2]Prevention and Treatment of Diabetes Mellitus and its Complications (H.N.D.C), Hellenic National Center for Research, [3]Department of Nutrition and Dietetics, Harokopio University, [4]2nd Department of Internal Medicine, Research Institute and Diabetes Center, Athens University Medical School, Attikon University Hospital, Haidari, Athens, Greece.

Background and aims: Recent studies have shown that lifestyle intervention in prediabetes reduces the progression to type 2 diabetes (DM2). However, the impact of meal frequency on glucose metabolism remains unknown. The aim of the study was to compare the effects of two isocaloric meal patterns (three- vs six meals per day) on glucose and insulin levels during an oran glucose tolerance test (OGTT) in subjects with: 1) impaired glucose tolerance (Group-A, 2-hour-blood-glucose: 140-199mg/dL), 2) type 2 diabetes (Group-B) and 3) with 2-hour-blood-glucose: 140-199mg/dl and/or blood-glucose >200mg/dL at 30 or 60 or 90min (Group-C).
Materials and methods: In a randomized, crossover, 24-weeks study, 2x2 factorial design, Group-A (n=15, aged 44(4)y, body mass index (BMI) 33(1)kg/m2), Group-B (n=20, aged 52(3)y, BMI 33(1)kg/m2) and Group-C (n=12, aged 52(4)y, BMI 32(2)kg/m2), followed a weight maintenance diet (%carbohydrates:protein:fat:45:25:35), consumed either as a three-or a six-meal pattern, for 12 weeks. Antropometric measurements, diet compliance and subjective hunger, satiety and desire to eat were assessed biweekly. All subjects underwent a 75g glucose-OGTT for measurements of blood glucose and insulin (every 30min for 120min) at the beginning and end of each intervention. HaemoglobinA1c (HbA1c), blood lipids and hepatic enzymes were measured at the beginning and end of each intervention.
Results: Body weight remained stable throughout the study. HbA1c, 2-hour postprandial blood glucose and insulin resistance (HOMA-IR) were decreased with 6-meals vs 3-meals in Group-B ($p=0.006$, $p=0.01$ and $p=0.049$, respectively). Time to peak for blood glucose was decreased with 6-meals vs 3-meals in Group-C ($p=0.046$). Subjective hunger and desire to eat were significantly lower after 6-meals vs 3-meals in all groups ($p=0.03$ and $p=0.029$, respectively). No differences were found before and after the 3-and-6-meal patterns for fasting glucose, fasting insulin, iAUC for glucose, iAUC for insulin, blood lipids and hepatic enzymes (p for all>0.05).
Conclusion: The six-meal pattern improved glycemic control in people with DM2 compared to isocaloric three-meals. The six-meal pattern decreased subjective hunger and desire to eat in all groups compared to isocaloric three-meals. As a result, increased meal frequency may be an important component of medical nutrition therapy in people with impaired glucose metabolism.

Caffeine consumption and mortality in diabetes: an analysis of NHANES 1999-2010

J.S. Neves[1], L. Leitão[2], R. Magriço[3], M. Bigotte Vieira[4], C. Viegas Dias[5], A. Oliveira[6], D. Carvalho[7]; [1]Department of Endocrinology, Diabetes and Metabolism, São João Hospital Center; Department of Surgery and Physiology, Cardiovascular Research Center, Faculty of Medicine of University of Porto (FMUP), Porto, [2]Neurology Department, Prof. Doutor Fernando da Fonseca Hospital, Amadora, [3]Nephrology Department, Garcia de Orta Hospital, Lisbon, [4]Nephrology and Renal Transplantation Department, Lisboa Norte Hospital Center, Lisbon, [5]Family Health Unit of Dafundo, ACES Lisboa Ocidental e Oeiras, Lisbon, [6]Department of Endocrinology, Diabetes and Metabolism, São João Hospital Center, Porto, [7]Department of Endocrinology, Diabetes and Metabolism, São João Hospital Center, FMUP; Institute for Research and Innovation in Health (i3S), Porto, Portugal.

Background and aims: An inverse relation between coffee consumption and mortality has been reported in the general population. Coffee consumption has also been associated with a risk reduction for the development of type 2 diabetes. However, the association of caffeine consumption with mortality of patients with diabetes remains unclear.
Materials and methods: We examined the association of caffeine consumption with mortality among 1,568 women and 1,484 men with diabetes in a prospective nationwide cohort, using the continuous National Health and Nutrition Examination Survey (NHANES) 1999-2010. Caffeine consumption was assessed at baseline using 24h dietary recalls. Cox proportional hazard models were fitted to estimate hazard ratios (HR) for all-cause, cardiovascular and cancer-related mortality among women and men according to caffeine consumption and its source (coffee, tea or soft drinks), adjusting for potential confounders (age, race, education level, annual family income, smoking status, body mass index, daily carbohydrate consumption, alcohol consumption, years since diabetes diagnosis, hypertension, diabetic kidney disease, retinopathy, macrovascular complications and insulin treatment).
Results: A dose-dependent inverse association between caffeine consumption and total mortality was observed in women with diabetes

(p=0.002). Adjusted HR for death among women who consumed caffeine, as compared with women who did not, were: 0.49 (95% confidence interval [CI], 0.33-0.74) for less than 100mg of caffeine per day, 0.43 (95% CI, 0.26-0.70) for 100 to <200mg of caffeine, and 0.34 (95% CI, 0.20-0.57) for 200mg or more of caffeine per day (p=0.007). This association was not observed in men with diabetes (p=0.887). There was no significant association between total caffeine consumption and deaths from cardiovascular diseases or cancer, both in men and women. Regarding the source of caffeine consumption, women with diabetes who consumed more caffeine from coffee had reduced risk of all-cause (p=0.007) and cardiovascular death (p=0.041). Women who consumed more caffeine from tea had reduced mortality from cancer (p=0.009). No associations between source of caffeine consumption and all-cause, cardiovascular or cancer mortality were observed in men.

Conclusion: Our study showed a dose-dependent protective effect of caffeine consumption on all-cause mortality among women. The effect on mortality appears to depend on the source of caffeine, with a protective effect of coffee consumption on all-cause mortality and cardiovascular mortality, and a protective effect of caffeine from tea on cancer mortality among women with diabetes.

PS 066 Novel approaches to glucose-lowering

842

Efficacy and safety of diacerein in patients with inadequatedly controlled type 2 diabetes: a randomised controlled trial

C.R.L. Cardoso, N.C. Leite, G.F. Salles;
Internal Medicine, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil.

Background and aims: Diacerein is an immune-modulator anti-inflammatory drug with potential beneficial actions in type 2 diabetes. The objective was to assess the efficacy and safety of a 1-year diacerein treatment in improving glycemic control of patients with inadequately-controlled type 2 diabetes.

Materials and methods: It was a randomized, double-blinded, placebo-controlled trial performed on a tertiary-care university hospital. 512 patients with type 2 diabetes were screened, 142 with HbA_{1c} between 7.5% and 9.5% entered an 8-week run-in phase, and 84 were randomized to a 48-week treatment with placebo (41 patients) or diacerein 100 mg/day (43 patients).The primary outcome was the difference in mean changes of HbA_{1c} between treatment groups. Secondary outcomes were other efficacy and safety measurements (fasting glycemia, serum lipids, renal and hepatic function, hematological- inflammatory indices, weight and blood pressures). A general linear regression with repeated-measurement variables, adjusted for age, sex, diabetes duration and each baseline value, estimated the differences between groups. Both intention-to-treat and per-protocol analysis, excluding 10 patients who interrupted treatment (8 diacerein and 2 placebo), were performed.

Results: Mean baseline HbA_{1c} was 8.2% in both groups. Diacerein reduced HbA_{1c} in contrast to placebo by 0.35% (95% CI: -0.68 to -0.02; p=0.038) in intention-to-treat and by 0.41% (95% CI: -0.75 to -0.06%; p=0.023) in per-protocol analysis. The peak of diacerein effect occurred at the 24^{th}-week of treatment (-0.61%; p=0.014 and -0.71%; p=0.005, respectively), but it attenuated towards non-significant differences at the 48^{th}-week. No significant effect of diacerein was observed in other efficacy and safety measures. Diarrhea occurred in 65% of the patients using diacerein and caused treatment interruption in 16%. Mild hypoglycemic events were equally observed in both groups; however, more patients in the diacerein group reduced baseline anti-diabetic medication and more patients in the placebo group increased it during treatment.

Conclusion: Diacerein reduced overall mean HbA_{1c} levels, with peak of effect at the 24^{th}-week of treatment, but with attenuation towards the 48^{th}-week. The drug was well tolerated, without any serious adverse events, except for diarrhea; and it may be indicated as adjunct treatment in patients with type 2 diabetes, particularly in those with concomitant symptomatic osteoarthritis.

Imeglimin monotherapy in Japanese patients with type 2 diabetes: results from a randomised, 24-week, double-blind, placebo-controlled, phase IIb trial

J. Dubourg[1], K. Ueki[2], H. Watada[3], W. Ogawa[4], R. Orza[1], B. Jacolin[1], M. Kasuga[5], P. Fouqueray[1];
[1]POXEL S.A., Lyon, France, [2]Diabetes Research Center, National Center for Global Health and Medicine, Tokyo, [3]Department of Metabolism and Endocrinology, Juntendo University, Tokyo, [4]Division of Diabetes and Endocrinology, Kobe University, Kobe, [5]National Center for Global Health and Medicine, Tokyo, Japan.

Background and aims: Imeglimin is the first in a novel class of glucose-lowering drugs. Imeglimin is acting on the two key defects in type 2 diabetes mellitus (T2DM) improving both insulin secretion in response to glucose and insulin sensitivity, through a unique mechanism of action targeting mitochondria.
This study was designed to determine the efficacy and safety/tolerability of imeglimin monotherapy at 3 doses compared to placebo in Japanese patients with T2DM after 24 weeks of treatment.
Materials and methods: In this randomized, double-blind, placebo-controlled dose ranging trial, Japanese adults with T2DM were randomized 1:1:1:1, using a web-based system, to twice daily oral imeglimin 500 mg, 1000 mg, 1500 mg or matched placebo. Randomization was stratified according to baseline glycosylated hemoglobin (HbA1c) and to previous andiabetic treatment status (naïve versus previously treated patients). All patients went through a wash-out/run-in period of 6 to 10 weeks before randomization. The primary efficacy endpoint was the placebo-adjusted dose-dependent reduction in HbA1c from baseline after 24 weeks of treatment, evaluated in all randomized treated patients with at least one post-baseline assessment. Secondary endpoints included changes in fasting plasma glucose, insulin, C-peptide concentrations, percentage of responders (HbA1c < 7 %) and patients requiring rescue therapy as well as safety and tolerability. Pre-dose PK was assessed at each visit and within 6 hours post-dose after 4 weeks of treatment.
Results: The clinical part of the study is completed. 299 patients were randomized. At baseline, preliminary results showed a ratio of 67% men, a mean age of 59.8 ± 9.7 years and mean body mass index of 25.5 ± 4.4 kg/m². Mean baseline HbA1c was 7.9 ± 0.7 %. Ninety % (268) of the patients completed the study up to 24 weeks. No suspected unexpected serious adverse reaction (SUSAR) were reported during the course of the study.
Conclusion: Full results will be available Q2 2017. This study will be presented in its integrality at the time of the congress.
Clinical Trial Registration Number: JapicCTI-153086

The dual amylin and calcitonin agonist KBP-042 is superior to both amylin and calcitonin monotherapy and able to override amylin resistance

A.T. Larsen, S. Gydesen, S.T. Hjuler, M.A. Karsdal, K. Henriksen;
Nordic Bioscience, Herlev, Denmark.

Background and aims: Amylin agonists induce weight loss and improve post-prandial glucose regulation, and the amylin analogue Pramlintide is approved as treatment of diabetes as a supplement to insulin; however, amylin lacks potency and has a very short-lived activity *in vivo*. Dual amylin and calcitonin receptor agonists (DACRAs), such as KBP-042, are novel candidates for treatment of T2D and obesity due to their beneficial effects on body weight, blood glucose and insulin sensitivity, effects that are superior to those of amylin. However, it is unclear whether the dual agonism has beneficial effects on metabolism, independent of the amylin receptor mediated effects. Here we compared the effects of the dual agonist KBP-042 to effects of the selective receptor agonists amylin and calcitonin on regulation of body weight, blood glucose and insulin sensitivity. In addition, we evaluated KBP-042 mediated effects following initial amylin therapy.
Materials and methods: High-fat fed Sprague Dawley rats were treated 4 weeks by subcutaneous continuous infusion with either dual agonist KBP-042 (5 μg/kg/d), rat amylin (300 or 1000 μg/kg/d), rat calcitonin (300 or 1000 μg/kg/d) or vehicle. In addition a group received KBP-042 (5 μg/kg) by a daily subcutaneous injection. After 4 weeks of treatment, all treatment groups were switched to receive KBP-042 (5 μg/kg/d) for 10 days. Food intake and body weight were monitored throughout the study, while glucose tolerance, insulin secretion and gastric emptying were assessed before the treatment switch.
Results: KBP-042 induced a large weight reduction in the initial phase of the study, then the body weight stabilized and a sustained reduction in body weight was obtained (~15% vehicle corrected, $p<0.01$) independent of delivery route. Initially, both doses of amylin had a marked effect on body weight while calcitonin only had a slight effect (ns), however, the high dose of amylin (1000 μg/kg/d) lost efficacy compared to the low dose. All treatments significantly reduced food intake in the initial phase of the study, KBP-042 and amylin being superior to calcitonin. Calcitonin and the high dose of amylin lost the effect on food intake within few days of treatment, corresponding to the observed regain in body weight. KBP-042 and the lower dose of amylin (300 μg/kg/d) showed a prolonged significant reduction in food intake compared to vehicle. Moreover, KBP-042 and low dose amylin improved oral glucose tolerance, although only KBP-042 did so significantly ($p<0.05$). In addition, KBP-042 reduced the rate of gastric emptying to 59.6 % of vehicle. Switching treatment to KBP-042 induced a transient drop in food intake and a sustained reduction in body weight, in all groups not pretreated with KBP-042. KBP-042 even rescued the reduced amylin response and induced a full response on body weight despite amylin resistance.
Conclusion: In conclusion, the dual agonist KBP-042 had beneficial effects on body weight, appetite, gastric emptying and insulin sensitivity superior to activating either the amylin or the calcitonin receptor alone. Infusion of a high dose of amylin lost efficacy, indicating amylin resistance, an effect not seen with the more efficacious dose of KBP-042. Interestingly, KBP-042 was able to induce a full response on body weight independent on the former treatment and even despite amylin resistance.

The MetAP2 inhibitor ZGN-1061 improves glycaemia in high fat diet-induced obese mice

B.F. Burkey[1], J.E. Vath[1], M. Wyman[1], S. Vickers[2], S. Cheetham[2], K. Dickinson[2], G. Birmingham[2], T.E. Hughes[1];
[1]Zafgen, Boston, USA, [2]RenaSci, Nottingham, UK.

Background and aims: Methionine aminopeptidase 2 inhibitors (MetAP2i) are a promising new therapeutic approach for the treatment of diabetes. Beloranib is a prototype MetAP2i which, when tested in obese type 2 diabetes subjects, resulted in 2.0% reduction in HbA1c and 13% body weight loss from baseline following 26 weeks of treatment. A novel MetAP2i, ZGN-1061, is in Phase 1 clinical testing. ZGN-1061 is a potent and selective inhibitor of MetAP2 enzyme activity and shows similar effects on obesity as beloranib in animal models, but has an improved safety profile in model systems of thrombotic risk. The aim of this study was to evaluate the anti-diabetic potential of ZGN-1061 in diet-induced obese (DIO) and relate these changes to weight loss and change of body composition.
Materials and methods: Male C57BL/6J mice were placed on a high fat diet (45% kcal as fat) for 34 weeks then were treated with ZGN-1061 at doses of 0.03, 0.1 and 0.3 mg/kg (SC, QD) or beloranib at 0.1 mg/kg (SC, QD) for 4 weeks (n=10/group). Body weight, food intake, DEXA body composition and oral glucose tolerance test (OGTT) were assessed.
Results: ZGN-1061 dose dependently reduced body weight by 4.4%, 17.0%, and 29.5% after 29 days of treatment. In comparison, beloranib achieved 31.5% weight loss. Mice in the 0.3 mg/kg 1061 and 0.1 mg/kg beloranib dose groups were still losing weight over the final week of the study suggesting dosing longer than one month could show greater weight loss. Energy intake (kJ/gram lean mass) was transiently reduced in the two higher ZGN-1061 dose groups as well as the beloranib group by 23%, 28% and 31% at day 16, respectively. However, by the end of the study energy intake was no different from vehicle in all drug treated groups. At day 27 body composition as measured by DEXA show ZGN-1061 reduced the % fat and increased the % lean mass at both the mid and high dose groups with no change in the low dose group. On day 30 an OGTT was performed. Baseline fasted glucose was reduced relative to vehicle by 12.3%, 16.4% and 27.1% in the ZGN-1061 dose response. Beloranib had a 23.7% reduction of fasted glucose. Oral glucose tolerance

was improved with treatment as shown by 12.0%, 27.2% and 33.2% reductions of the glucose AUC 0-120 and 25.4%, 44.4% and 60.1% reductions of insulin AUC 0-120 across the ZGN-1061 doses. Calculation of HOMA-IR reveal a marked drug effect to reduce the insulin resistance index at all dose levels of ZGN-1061, where the lowest dose improved HOMA-IR by 40.3% and the highest dose by 81.2%.

Conclusion: The MetAP2i ZGN-1061 dose-dependently improves glycemic control and insulin sensitivity in DIO mice. Weight loss at the higher doses likely contributes to the improvement of glucose control, however, glucose was reduced even at the lowest dose which was weight neutral and had no effect on fat mass after one month of dosing.

Group	Dose (mg/kg)	BW (g)	% Fat mass	% Lean mass	Glucose (mM)	Glucose AUC 0-120	Insulin (ng/ml)	Insulin AUC 0-120

A novel GPR40 agonist HD-6277 comparison to Fasiglifam and LY2922470 in type 2 diabetic rats

C. Kim, Y.-S. Kim, G. Yang, S. Kang, S. Lee, H.-S. Choi, D.-Y. Kim, H.-E. Yoo, J. Yang, J.-K. Rhee, D.-H. Kim;
Hyundai Pharm. CO., LTD., Yongin, Republic of Korea.

Background and aims: G protein-coupled receptor 40/free fatty acid receptor 1 (GPR40/FFA1), is highly expressed in pancreatic β-cells and mediates free fatty acid-induced insulin secretion. Recently, new drugs, i.e., agonists of GPR40, have been used for preventing and treating type 2 diabetes mellitus (T2DM). HD-6277 is one such novel oral agonist of GPR40 under development as a once-a-day drug for the treatment of T2DM. Here, we studied the pharmacological effect of HD-6277 and compared the glucose-lowering effects with fasiglifam (TAK-875), a selective, potent, and orally bioavailable GPR40 agonist terminated in phase III clinical trials. Additionally, we compared the pharmacological potency between HD-6277, fasiglifam, and LY2922470.

Materials and methods: hGPR40-CHO, INS-1, and NCI-H716 cell lines were used to assess the effects of HD-6277 in vitro. The in vivo effect of HD-6277 was examined in Sprague-Dawley (SD) rats, Zucker Diabetic Fatty (ZDF) rats and Zucker Fatty (ZF) rats, using an oral glucose tolerance test (OGTT) and an insulin tolerance test (ITT). We also measured the GLP-1 levels on cynomolgus monkeys.

Results: HD-6277 showed more effective in vitro profile than fasiglifam in calcium influx assay (EC_{50} = 13 nM) and IP accumulation assay (EC_{50} = 7.5 nM). In comparison of pharmacological effects between HD-6277, fasiglifam and LY2922470, HD-6277 increased glucose-stimulated insulin secretion (GSIS) in INS-1 cells and SD rats. In fasted SD rats, while glibenclamide (10 mg/kg, p.o.) induced hypoglycemia, HD-6277 (10-100 mg/kg, p.o.) neither caused hypoglycemia nor enhanced insulin secretion. HD-6277 increased GLP-1 secretion in in vitro and in vivo, whereas fasiglifam did not. Then we evaluated the efficacy of HD-6277 in type 2 diabetic rats. In subchronic study with male ZDF rats, HD-6277 improved glycemic control (OGTT) and increased GLP-1 and insulin secretion. In male ZF rats, an oral administrations for 10~11 weeks, HD-6277 improved insulin sensitivity (ITT) and HbA_{1c} level. The impaired insulin action was recovered by HD-6277 treatment in liver and adipose from the rats. In the cynomolgus monkey study, HD-6277 also showed a significant increase in GLP-1 secretion (P<0.05).

Conclusion: The pharmacological potency of HD-6277 was higher than fasiglifam and similar to LY2922470. HD-6277 improved glycemic control in type 2 diabetic rats, which was related to enhancement of insulin signaling and GLP-1 secretion. Therefore, we propose HD-6277 as an effective candidate for the treatment of T2DM.

Efficacy and safety of DS-8500a, a GPR119 agonist, in Japanese patients with type 2 diabetes: a randomised, double-blind, placebo-controlled, 12-week study

Y. Yamada[1], Y. Terauchi[2], H. Watada[3], Y. Nakatsuka[4], K. Shiosakai[4], T. Washio[4], T. Taguchi[4];
[1]Akita University Graduate School of Medicine, Akita, [2]Yokohama City University Graduate School of Medicine, Yokohama, [3]Juntendo University Graduate School of Medicine, Tokyo, [4]Daiichi Sankyo Co., Ltd., Tokyo, Japan.

Background and aims: G-protein coupled receptor 119 (GPR119) is a promising target for the treatment of type 2 diabetes mellitus (T2DM). Pancreatic β-cells and intestinal L cells express GPR119, enabling a single drug to promote both insulin and GLP-1 secretion. In this study, the efficacy and safety of 12-week treatment with the GPR119 agonist DS-8500a was compared with placebo and sitagliptin 50 mg in Japanese patients with T2DM.

Materials and methods: We conducted a randomized, double-blind, parallel-group Phase 2b comparison study across 25 sites in Japan. In total, 368 Japanese patients aged ≥20 years with T2DM and HbA1c levels ≥7.0% and <10.0% were randomized to receive placebo, DS-8500a (25, 50, or 75 mg once daily), or sitagliptin 50 mg once daily for 12 weeks. The primary efficacy endpoint was change in HbA1c from baseline to week 12. Secondary endpoints included change in fasting plasma glucose (FPG), $AUC_{0\text{-}3h}$ for glucose during a meal tolerance test (MTT), 2-hour postprandial glucose (2hr-PPG), and change in lipid parameters (total, LDL- and HDL-cholesterol; triglycerides) from baseline to week 12. Safety endpoints included adverse events, occurrence of hypoglycemia, and clinical and laboratory variables.

Results: Patient demographics did not differ significantly across the groups. DS-8500a demonstrated dose-dependent lowering of HbA1c compared with placebo at week 12 (25 mg, −0.21% [p=0.0233]; 50 mg, −0.34% [p=0.0004]; 75 mg, −0.45% [p<0.0001]). DS-8500a 50 mg and 75 mg also demonstrated significant lowering effects on FPG compared with placebo (50 mg, −12.7 mg/dL [p=0.0004]; 75 mg −14.4 mg/dL [p<0.0001]), as well as glucose $AUC_{0\text{-}3h}$ (50 mg, −50.6 mg/dL×h [p=0.0020]; 75 mg, −59.7 mg/dL×h [p=0.0003]) and 2hr-PPG (50 mg, −18.5 mg/dL [p=0.0102]; 75 mg, −22.0 mg/dL [p=0.0022]). Although the glucose-lowering effects of other GPR119 agonists are typically abrogated after 2 to 4 weeks of treatment, the decrease in FPG by DS-8500a administration was maintained over time up to 12 weeks. However, DS-8500a (at any dose) did not lower any of the above parameters to a greater extent than sitagliptin. Compared with placebo and sitagliptin, DS-8500a 50 and 75 mg significantly reduced total cholesterol (−7.0% [p<0.0001], −6.2% [p=0.0002]), LDL-cholesterol (−7.3% [p=0.0044], −8.1% [p=0.0014]), and triglycerides (−32.7% [p<0.0001], −30.9% [p<0.0001]), and significantly increased HDL-cholesterol (5.9%, [p=0.0032], 6.6%,[p=0.0009], respectively). All doses of DS-8500a were well tolerated. Two cases of clinically relevant drug-related hypoglycemia occurred in the DS-8500a 50 mg group.

Conclusion: DS-8500a was well tolerated, and demonstrated significant glucose-lowering effects and favorable changes in lipid profile up to 12 weeks compared with placebo in Japanese patients with T2DM.

GLP-1 receptor variants markedly differentiate glycaemic response to GLP-1 receptor agonists: a DIRECT study

A.Y. Dawed[1], A. Mari[2], T.J. McDonald[3], M.G. Hong[4], S. Sharma[5], N.R. Robertson[6], A. Mahajan[6], M. Walker[7], S. Gough[8], K. Zhou[1], I. Forgie[1], H. Ruetten[9], A.G. Jones[3], E.R. Pearson[1], for the DIRECT consortium;
[1]Division of Molecular and Clinical Medicine, University of Dundee, Dundee, UK, [2]CNR Institute of Neuroscience, Padua, Italy, [3]NIHR Exeter Clinical Research Facility, University of Exeter and Royal Devon and Exeter Hospital, Exter, UK, [4]Affinity Proteomics, Science for Life Laboratory, School of Biotechnology, KTH - Royal Institute of Technology, Solna, Sweden, [5]Research Unit of Molecular Epidemiology, Institute of Epidemiology II, Helmholtz Zentrum Muenchen, Germany, [6]Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, [7]Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, [8]Oxford Centre for Diabetes Endocrinology and Metabolism, NIHR Oxford Biomedical Research Centre, Oxford, UK, [9]Sanofi-Aventis Deutschland GmbH, TMED, Frankfurt, Germany.

Background and aims: Glycaemic response to GLP-1 Receptor Agonist (GLP-1RA) treatment varies markedly among patients with Type 2 Diabetes (T2D) yet the mechanism for this variation is uncertain and only short-term glycaemic response can predict who will have a marked mid-long-term response and who will respond less. Common missense variants in the GLP-1R have previously been reported to alter GLP-1 mediated insulin secretion in non-diabetic individuals. We aimed to investigate how GLP-1R variants alter glycaemic response to the GLP-1RA.
Materials and methods: We performed a meta-analysis across the DIRECT, PRIBA and GoDARTS cohorts. A total of 1156 T2D subjects were followed-up for 6 months after initiation of GLP-1RA treatment. Patients were treated predominantly with Exenatide or Liraglutide. The association of GLP-1R variants, rs6923761 (Gly168Ser) and rs10305420 (Pro7Leu), with reduction in glycated haemoglobin (HbA1c) after treatment were assessed using multiple linear regression in an additive model.
Results: Gly168Ser and Pro7Leu variants in the GLP-1R were independently associated with reduced efficacy of GLP-1RA to lower HbA1c (Gly168Ser β (HbA1c change per allele) = -0.18%, p = 0.001, Pro7Leu β = -0.14%, p = 0.01). We then derived a genetic risk score, summing up these two variants. The 22% of the population who carry no risk allele in either of the variants had a mean HbA1c reduction of 1.39% [1.21-1.58] (15.2 mmol/mol [13.2-17.3]) in response to GLP-1RA. In contrast the 17% percent of the population who carry 3 or more risk alleles had a much lower glycaemic response to GLP1RA treatment 0.86% [0.66-1.13] (9.4 mmol/mol [7.0 - 11.9]), a difference of 0.53% [5.8mmol/mol] ($p < 0.001$). There was no significant impact of these SNPs on weight change in response to GLP-1RA suggesting the variants impact on the glycaemic lowering mechanisms of GLP-1RA rather than weight lowering mechanisms.
Conclusion: Missense variants in the GLP-1R have a large clinical impact on glycaemic response to GLP-1RA. The frequencies of these variants are not rare, making this the largest, most common pharmacogenetic effect described to date in T2D.

The changing landscape of diabetes drug therapy in a nationwide population of people with type 2 diabetes

L. Brierley[1], S. McGurnaghan[1], L. Blackbourn[1], P.M. McKeigue[2], H.M. Colhoun[1,3];
[1]The Institute of Genetics and Molecular Medicine, University of Edinburgh, [2]Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, [3]Department of Public Health, NHS Fife, Kirkcaldy, UK.

Background and aims: Recent years have seen the availability of several new drug classes for treating type 2 diabetes (T2DM) as well as recommendations for earlier intensification of therapy. Here in the total population of Scotland with T2DM, we examined the change over the past 10 years in prevalent treatment intensity as proxied by numbers of diabetes drugs. We also report the current class-specific usage of diabetes drugs.
Materials and methods: Using the Scottish Care Information Diabetes national registry, which covers the entire Scottish population with T2DM, we describe the prevalence of issued prescriptions for diabetic drug usage in two periods: mid-2005 to mid-2006, and mid-2015 to mid-2016. Differences in proportions were tested by direct comparison of the age-standardised estimates and their 95% CIs.
Results: Table 1 shows the prevalence of numbers of drugs being used in the two time periods. The age-standardised prevalence of intensive therapy (3+ non-insulin drugs or insulin) increased from 13.77% (95% CI 13.59 - 13.94) to 18.11% (17.95 - 18.28). Among those who initiated intensive therapy during the given year, the average duration of diabetes by time of initiation was slightly longer in 2015/16 than 2005/6. In both periods examined, the majority of patients were receiving monotherapy or dual therapy, largely comprising metformin and sulphonylureas. In 2005/6, metformin, sulphonylureas, and insulin comprised 45.08%, 29.27%, and 13.40% of all prescriptions, respectively. In 2015/16, metformin, sulphonylureas, and insulin comprised 46.43%, 22.07%, and 11.56% of all prescriptions, respectively. Among the remaining prescriptions, the next most prevalent classes were dipeptidyl peptidase-4 (DPP-IV) inhibitors (9.75%), thiazolidinediones (4.04%), sodium-glucose co-transporter-2 (SGLT2) inhibitors (3.23%), glucagon-like peptide 1 (GLP-1) receptor agonists (2.80%), and other (0.12%). Of those who initiated a non-metformin, non-sulphonylurea, non-insulin drug within 2015/16 (n=19655), 6.44%, 39.77% and 38.88% of users had been treated previously in this period with 0, 1 or 2 drugs before their initiation, respectively.
Conclusion: Over the past 10 years, as new drug classes have become available, there has been an increase in the prevalence of intensive therapy of diabetes. However, the duration of diabetes at which intensification occurs has not reduced. New drug classes are largely being used as second and third line treatments.

	2005/6	2015/16
N	173565	263843
0 drugs	35.52%	34.61%
1 non-insulin drug	31.06%	30.14%

Single and multiple dose evaluation of a novel MetAP2 inhibitor: results of a randomised, double-blind, placebo-controlled clinical trial

J. Malloy, D. Zhuang, T. Kim, D. Kim, K. Taylor;
Zafgen, Inc, Boston, USA.

Background and aims: Methionine aminopeptidase 2 (MetAP2) inhibitors reduce fat biosynthesis and increase fat oxidation and lipolysis, resulting in weight loss and reduced hunger. A MetAP2 inhibitor, beloranib, resulted in 13% weight loss and 2.0% reduction in A1C from baseline in midstage clinical trials but development was halted due to an imbalance of venous thromboembolic events in beloranib-treated subjects vs. placebo. Nonclinical studies of a second generation MetAP2 inhibitor, ZGN-1061, demonstrate rapid absorption and clearance of ZGN-1061, which is hypothesized to reduce exposure at endothelial cell targets and minimize prothrombotic effect.
Materials and methods: This first-in-human clinical trial of ZGN-1061 subcutaneous injection assessed safety, pharmacokinetics (PK), and preliminary efficacy. The clinical trial included a single ascending dose (SAD) phase in healthy subjects (BMI 23-<30 kg/m^2) and a multiple ascending dose (MAD) phase in subjects with BMI 27-40 kg/m^2. Target engagement was assessed using ZGN-1061 bound to MetAP2 and evidence of MetAP2 inhibition. Results of the completed SAD doses (0.2, 0.6, 1.2, 2.4, 3.6, and 4.8 mg) and the MAD doses (0.2, 0.6, and 1.8 mg twice weekly for 4 weeks) are reported.
Results: The SAD phase included 39 subjects (ZGN-1061 N=28, placebo N=11), primarily male with mean age 31 and BMI 26 kg/m^2. ZGN-1061 maximum plasma concentrations (C_{max}) increased linearly with dose and occurred within 30 minutes of dosing, while half-life was less than 1 hour, indicating rapid absorption and clearance. ZGN-1061 was well tolerated across the doses tested. The most common adverse events (AEs) were headache and procedural site irritation; no dose-related patterns were observed. There were no serious AEs and no evidence of venous thromboembolism. MetAP2 binding and evidence of MetAP2 inhibition increased with dose; maximal values were observed at doses ≥1.2 mg. The MAD phase included 29 subjects (ZGN-1061 N=22, placebo N=7), primarily male with mean age 40 and BMI 33 kg/m^2. PK results were consistent with SAD findings although C_{max}, overall exposure, MetAP2 binding, and MetAP2 inhibition were increased after repeated dosing. Safety observations were comparable to the SAD phase. Efficacy measures indicated trends for greater weight loss and favorable biomarker changes with ZGN-1061 relative to placebo.
Conclusion: Consistent with preclinical studies, ZGN-1061 was rapidly absorbed and cleared. Preliminary safety results indicate that ZGN-1061 was well tolerated with no safety signals or venous thromboembolic events over the range of doses tested. These results support the evaluation of ZGN-1061 in larger clinical trials of longer duration.

Co-administration of tesofensine/metoprolol: improvement in heart rate with significant body weight reduction in overweight or obese subjects with type 2 diabetes

R.V. Dvorak[1], L. Plum-Mörschel[2], G. Andersen[3], P. Kašparová[1], J. Arrubla[3], B. Edsberg[1];
[1]Saniona A/S, Ballerup, Denmark, [2]Profil Mainz GmbH & Co.KG, Mainz, [3]Profil Institut für Stoffwechselforschung GmbH, Neuss, Germany.

Background and aims: Tesofensine (TESO) is a presynaptic reuptake inhibitor of the neurotransmitters noradrenaline, dopamine, and serotonin, suppressing appetite and reward centres in the brain and increasing energy expenditure. In earlier trials, TESO showed statistically and clinically meaningful weight reduction in obese subjects, but also increases in heart rate (HR) and blood pressure (BP) at therapeutically relevant doses. In this double-blind, randomized, placebo-controlled trial we examined the effect of co-administration of 0.5 mg TESO with 100 mg of the β1-selective beta-blocker metoprolol (MET) on HR, BP, body weight, tolerability and safety in overweight or obese subjects with type 2 diabetes (T2D) on metformin therapy with or without one additional anti-diabetic oral agent.
Materials and methods: Sixty subjects with T2D (39M/21F; mean ± SD age: 63 ± 6 yrs; weight: 96 ± 16 kg; HbA1c 7.7 ± 0.4%; HR: 66 ± 8 bpm; SBP: 134 ± 7 mmHg; DBP: 84 ± 5 mmHg), were randomly assigned to receive either TESO+MET or matching placebo (PLAC) once daily for 90 days. Fifty-eight subjects completed the study. HR over 24 hrs (primary endpoint) was measured by continuous telemetry and BP in regular intervals during an inpatient stay. Body weight and safety assessments were performed every 2 or 4 weeks, laboratory assessments at the baseline and at end of treatment (EOT). Least square mean differences were compared between treatments using repeated measures ANCOVA with baseline as covariate and treatment as fixed effect.
Results: TESO+MET led to a statistically significant reduction in mean 24-h HR by 3.8 bpm vs. PLAC, and a reduction in SBP and DBP which did not reach statistical significance. Also, a significant reduction in body weight, which exceeded the one observed with PLAC by 3.5 kg (table). TESO+MET was well tolerated. The most frequently reported adverse events were sweating, nausea, dry mouth and headache. There were no clinically significant findings in ECG, haematology or biochemistry. There was only one serious adverse event observed on the PLAC.
Conclusion: Addition of metoprolol to tesofensine fully mitigated the increases in HR/BP observed with tesofensine alone and still led to significant weight loss in subjects with T2D without any structured background weigh loss program. TESO+MET was well tolerated with no new or unexpected safety findings and may therefore offer a favourable benefit/risk profile in obese subjects with T2D.

	TESO		PLAC		Difference in change from baseline (95% CI)	p-value

Sustained improvement of type 2 diabetes in 250 hypogonadal men with and without testosterone therapy (TTh) for 9 years: real-life data from a registry study

K.S. Haider[1], A. Haider[1], G. Doros[2], F. Saad[3];
[1]Urology Practice, Bremerhaven, Germany, [2]Epidemiology and Statistics, Boston University, Boston, USA, [3]Medical Affairs Men's Healthcare, Bayer AG, Berlin, Germany.

Background and aims: The prevalence of hypogonadism in men with T2DM can be as high as 50%. In an ongoing registry on effectiveness and safety of testosterone undecanoate injections (TU) started in 2004 in a urological setting, more than 1/3 of patients have T2DM.
Materials and methods: Of 696 men with testosterone deficiency (total testosterone ≤12.1 nmol/L), 250 (36%) have T2DM. T2DM had been diagnosed and is treated by their family physician. In the urology office, 133 men received TU 1000 mg/12 weeks (T-group), 117 had opted

against TTh and served as controls (CTRL). Most measurements were performed 1-4 times a year for up to 11 years. 8-year data are reported. Mean changes over time between groups were compared by mixed effects model for repeated measures with random effect for intercept and fixed effects for time, group and their interaction and adjusted for age, weight, waist circumference, fasting glucose, blood pressure and lipids to account for baseline differences between groups.

Results: Mean age (years): 61.8±5.4 (T-group), 64.9±4.3 (CTRL). Mean HbA_{1c} progressively decreased from 8.8±0.9 to 6.1±0.4% after 8 years in the T-group ($p<0.0001$). The decrease was statistically significant vs. previous year for all 8 years. In CTRL, mean HbA_{1c} increased from 7.5 ±0.5 to 8.2±0.5% ($p<0.0001$). The estimated adjusted difference between groups was -3.1% ($p<0.0001$). Fasting glucose decreased from 7.6±1.1 to 5.3±0.1 mmol/L ($p<0.0001$) in the T-group and slightly increased from 5.8±0.3 to 5.9±0.3 mmol/L in CTRL (NS). The estimated adjusted difference between groups was -0.8 mmol/L ($p<0.0001$). HOMA-IR was only available for the T-group. It decreased from 10.2±2.0 to 3.6±0.8 after 8 years ($p<0.0001$). The decrease was statistically significant vs. previous year for the first 3 years. Insulin in serum was only available for the T-group. It decreased from 29.6±4.2 to 15±3.4 mU/L ($p<0.0001$) with statistical significance vs. previous year for the first 4 years. At baseline 54 patients in the T-group were on insulin and received a mean dose of 32.4 ±12.1 units. The mean dose requirement declined to 19.7±11.0 ($p<0.0001$) with statistical significance vs. previous year for the first 4 years. In the T-group, 106 (80%) achieved HbA_{1c} <6.5%. In CTRL, only 1 patient achieved HbA1c <6.5%. All but 9 men experienced an increase in HbA_{1c}. Waist circumference progressively decreased from 111.1±7.4 to 100.7±5.5 cm in the T-group and increased from 110.1±7.2 to 111.7 ±7.3 cm in CTRL. The adjusted estimated difference between groups at 8 years was -13 cm ($p<0.0001$ for all). Weight change from baseline was -19.4±4.8% in the T-group and +2.0±2.8% in CTRL. Estimated adjusted difference between groups: -20.2% ($p<0.0001$ for all). Since all injections were administered in the doctor's office and documented, there was a 100% adherence to TTh.

Conclusion: Long-term TTh with TU in hypogonadal men with T2DM improved glycaemic control compared to untreated controls. In patients in the testosterone group receiving insulin, the dose could be substantially reduced. The observed effects may have been mediated by reductions in weight and waist circumference. Correcting hypogonadism in men with T2DM sustainably supports standard diabetes treatment.

853

No progression from prediabetes to type 2 diabetes in 45 hypogonadal men receiving testosterone therapy (TTh) for up to 9 years: real-life data from a registry study

A. Haider[1], K.S. Haider[1], G. Doros[2], F. Saad[3];
[1]Urology Practice, Bremerhaven, Germany, [2]Epidemiology and Statistics, Boston University, Boston, USA, [3]Medical Affairs Men's Healthcare, Bayer AG, Berlin, Germany.

Background and aims: In individuals aged 45 years, the lifetime risk to progress from prediabetes to diabetes was recently reported as 74.0%. The recommended prevention strategy is weight loss. Since long-term TTh in hypogonadal men results in sustained weight loss, we studied hypogonadal men with Prediabetes defined by HbA_{1c} of 5.7-6.4% in the context of an ongoing registry on effectiveness and safety of testosterone undecanoate injections (TU) started in 2004 in a urological setting.

Materials and methods: Of 400 men with symptomatic testosterone deficiency (total testosterone ≤12.1 nmol/L), 45 (11.3%) had prediabetes. They were all treatment-naïve regarding antidiabetic therapy. The majority had presented to the urology office with complaints of erectile function or urinary function. All men men received TU 1000 mg/12 weeks (T-group) following an initial 6-week interval. No structured recommendations for lifestyle modifications were provided. Most measurements were performed 2 to 4 times a year for up to 11 years. 9-year data are presented.

Results: Mean age was 55.2±8.0 years. Mean HbA_{1c} steadily decreased from 5.9±0.2 to 5.2±0.2% after 9 years ($p<0.0001$). Fasting glucose decreased from 5.5±0.2 to 5.3±0.1 mmol/L ($p<0.05$). The triglyceride:HDL ratio, a surrogate marker of insulin resistance, decreased from 7.3±1.8 to 3.5±0.7 ($p<0.0001$). The TyG index, another surrogate parameter of insulin resistance and predictor for the risk of incident diabetes, decreased from 9.5±0.2 to 9.1±0.1 ($p<0.0001$). Weight progressively decreased from 99.7±14.2 to 85.1±7.4 kg ($p<0.0001$). The decrease was statistically significant compared to the previous year for the first 7 years. Waist circumference decreased from 102.4±6.7 to 94.5±5.6 cm ($p<0.0001$). The decrease was statistically significant compared to the previous year for the first 4 years. BMI decreased from 32.0±48 to 27.7±2.9 kg/m^2 ($p<0.0001$). The decrease was statistically significant compared to the previous year for the first 7 years. Mean weight change from baseline was -17.9% ($p<0.0001$). No patient progressed from prediabetes to T2DM during the entire observation period. 44 patients' last measured HbA_{1c} was <5.7% which is below the prediabetes range. Only 1 patient's last HbA_{1c} was 6.0%. Since all testosterone injections were administered in the doctor's office and documented, there was a 100% adherence to TTh.

Conclusion: Long-term TTh with TU in hypogonadal men with prediabetes completely prevented progression from prediabetes to type 2 diabetes. This effect may have been mediated by weight loss which was demonstrated by sustained reductions in weight and waist circumference. In addition, it is known that testosterone increases lean body mass and reduces fat mass, changes in body composition which are beneficial over and beyond weight loss alone.

Prevalence of type 2 diabetes and prediabetes in hypogonadal men and effects of testosterone treatment: real-life experience from a controlled registry study

U. Wissinger[1], A. Yassin[2], G. Doros[3], F. Saad[4];
[1]Medical Affairs Established Products, Bayer AG, Berlin, [2]Institute for Urology and Andrology, Norderstedt, Germany, [3]Epidemiology and Statistics, Boston University, Boston, USA, [4]Medical Affairs Men's Healthcare, Bayer AG, Berlin, Germany.

Background and aims: The high prevalence of hypogonadism in men with T2DM is well established. There is less information about the prevalence of hypogonadism in prediabetes.

Materials and methods: In a controlled registry study of 505 hypogonadal men in a urology office, 147 (29.1%) had T2DM. Their mean age at baseline was 62.7±8.3 years. 94 men received testosterone therapy (TTh, T-group) with testosterone undecanoate injections (TU) 1000 mg/12 weeks following an initial 6-week interval for up to 12 years. 53 men had opted against TTh and served as controls (CTRL). 253 (50.2%) men had prediabetes, defined by an HbA_{1c} from 5.7-6.4%. Mean age: 61.5±9.6 years. 175 men received TTh for up to 12 years, 78 served as controls (CTRL). 8-year data are reported.

Results: T2DM: Weight (kg) decreased from 107.8±13.2 to 97.7±12.3 in the T-group ($p<0.0001$) and increased from 95.8±10.7 to 99.5±15.5 in CTRL ($p<0.0001$ for both). Waist circumference (cm) decreased from 114.0±10.7 to 105.6±10.8 in the T-group and increased from 103.2±8.9 to 105.0±12.2 in CTRL ($p<0.0001$ for both). BMI (kg/m^2) decreased from 34.1±4.1 to 30.8±3.9 in the T-group and increased from 30.5±3.8 to 32.3 ±5.0 in CTRL ($p<0.0001$ for both). Fasting glucose (mmol/L) decreased from 7.9±2.3 to 5.9±1.7 in the T-group and from 6.9±2.6 to 6.2±3.9 in CTRL ($p<0.0001$ for both). HbA_{1c} decreased from 7.9±1.0 to 7.0±1.2% in the T-group ($p<0.0001$) and remained stable from 6.8±0.9 to 6.7±1.0% in CTRL. 74 of 94 patients (78.7%) with T2DM in the T-group had their last

measured HbA_{1c} <6.5%, but only 9 of 52 (17.3%) men in CTRL, regardless of concomitant treatment modalities. Prediabetes: Weight (kg) decreased from 96.0±11.7 to 89.3±9.8 in the T-group (p<0.0001) and increased from 92.1±9.9 to 98.2±6.3 in CTRL (p<0.0001 for both). Waist circumference (cm) decreased from 104.7±7.1 to 98.4±6.6 in the T-group and increased from 99.9±9.0 to 106.0±3.2 in CTRL (p<0.0001 for both). BMI (kg/m^2) decreased from 30.5±3.9 to 28.3±3.4 in the T-group and increased from 29.5±2.8 to 30.4±2.2 in CTRL (p<0.0001 for both). Fasting glucose (mmol/L) decreased from 5.3±0.9 to 4.9±0.7 in the T-group (p<0.0001) and increased from 4.9±1.4 to 5.0±0.9 in CTRL (p<0.05). HbA_{1c} decreased from 5.9±0.2 to 5.6±0.4% in the T-group and increased from 5.9±0.2 to 6.1 ±0.6% in CTRL(p<0.0001 for both).. No patient in the T-group progressed from prediabetes to overt T2DM. 152/175 had their last measured HbA_{1c} <5.7% and were no longer in the prediabetes category. In CTRL, 30/ 78 (38.5%) men in CTRL progressed from prediabetes to T2DM.

Conclusion: Long-term TTh with TU in unselected hypogonadal men with a high prevalence of T2DM and prediabetes resulted in weight loss and improvements in glycemic control whereas untreated controls experienced worsening of all parameters. Testosterone treatment of hypogonadal men fully prevented progression from prediabetes to T2DM.

Early results of the first Brazilian patients with generalised congenital lipodystrophy on treatment with metreleptin

J.G. Lima[1], N.N. Lima[1], M.C.F. Santos[1], T.C. Vieira[1], P.H.D. Silva[1], L.H.C. Nobrega[1], M.F.P. Baracho[1], S.M.B. Jeronimo[2];
[1]Medicina Clinica, Hospital Universitario Onofre Lopes, [2]Instituto de Medicina Tropical - IMT, Natal, Brazil.

Background and aims: Generalized congenital lipodystrophy (GCL) is an autosomal recessive disease characterized by difficulty in storing body fat and, consequently, very low serum levels of leptin. They present with diabetes, hypertriglyceridemia and ectopic fat deposit, as in the liver. In Brazil, we have one of the largest series of this rare disease.

Materials and methods: Eleven patients (6 men and 5 women; 5 adults and 6 children, 12.6 ± 9.3 years of age) with GCL (3 Type 1, 5 type 2 and 3 non-genotyped patients) were treated with subcutaneous metreleptin injections. Only the adults had diabetes (n = 5). To quantify the appetite, we used the simplified nutritional appetite questionnaire. Blood tests were performed before the start of treatment and, 1 and 3 months later. Parametric data are shown as mean ± SD or as median (minimum-maximum) if nonparametric. Comparisons were made between the results of baseline and the 3 months after treatment. A p-value < 0.05 was considered statistically significant.

Results: The mean dose of metreleptin was 0.46±0.28 mg/day. It was well tolerated and no patient stopped the use. Five patients had some skin reactions in the local of injection and one child patient had important anorexia needing to decrease the dose for one week. Fasting triglyceridemia [225(35-1473) vs. 111(48-309) mg/dL, p=0.01], aspartate aminotransferase [31(22-87) vs. 26(9-38) UI/L, p=0.009], alanine aminotransferase [51(25-152) vs. 26(11-63) UI/L, p=0.01] and gamma glutamyl transferase [25(12-66) vs. 16(11-45) UI/L, p=0.005)] reduced significantly. Fasting glycemia (151.5±108 vs. 107.5±38.9mg/dL, p=0.09), glycated hemoglobin (7.2±3.2 vs. 6.0±1.7%, p=0.09), total cholesterol (133±29.9 vs. 113.9±28.4 mg/dL, p=0.06) and HDL cholesterol (28.6±7.4 vs. 28.0±5.0 mg/dL, p=0.69) decreased, but it was not statistically significant. One diabetic patient stopped insulin use and started oral hypoglycemic pills; other patient decreased insulin dose and another patient decreased the oral hypoglycemic pill to half dose. Despite these reductions, fasting glycemia (239.4±107 vs. 142.6±30.9 mg/dl) and glycated hemoglobin (9.9±3.2 vs. 7.2±1.9%) reduced significantly in diabetic patients. The mean appetite score (maximal 20 points) was 18.3 and decreased to 14.9 after 1 month, but increased to 16.1 after 3 months. The BMI decreased significantly (18.2 ±3.5 to 17.0±3.3 kg/m2, p=0.01).

Conclusion: Metreleptin use can bring early improvements in glycemia, triglyceridemia, and liver enzymes. The effect decreasing the appetite is as precocious as one month of use, but in some patients the appetite increase at 3 months.

Disclosure: **J.G. Lima:** None.

Impact of metreleptin on hepatomegaly in patients with generalised lipodystrophy

E.A. Oral[1], E. Chiquette[2], J.H. Lewis[3], A. Long[2], T. Salinardi[2], R. Brown[4];
[1]Brehm Center for Diabetes, Ann Arbor, [2]Aegerion Pharmaceuticals, Cambridge, [3]Georgetown University Hospital, Washington, [4]National Institutes of Health, Bethesda, USA.

Background and aims: Lipodystrophy syndromes are clinically heterogeneous, inherited or acquired, and often life-threatening. The underlying pathogenesis of generalized lipodystrophy (GL) is the irreversible widespread deficiency of adipose tissue leading to low leptin levels. Due to the lack of adipocytes, excess calories accumulate as triglycerides (TG) in ectopic locations such as the liver. Ectopic liver fat can progress to hepatomegaly, steatohepatitis, portal hypertension, cirrhosis, and liver failure. This study examined the effect of leptin replacement therapy (metreleptin, ML) on liver volume (LV) and key metabolic parameters in adult and pediatric patients with GL.

Materials and methods: This is a post hoc analysis of an open label, prospective study of ML in patients with GL conducted at the NIH. LV by MRI was assessed for all available patients enrolled from 2000-2008. Normal LV was calculated as 25 mL/kg of body weight. Mild, moderate, and severe hepatomegaly were defined as ≤1.25 multiple of normal (MN), 1.25-2.5 MN, and >2.5 MN, respectively. TG, A1c, AST, and ALT were measured at baseline and after ML treatment.

Results: Among the 34 evaluable patients with GL enrolled through 12/31/2008, 21 had both baseline and follow-up liver volumetric measurements. At baseline, all had enlarged livers with a mean ± SD LV of 3357.7 ± 1121.7 mL, ranging from 1.1-6 x normal. The majority of patients were female (67%), 57% had congenital GL, and the mean age was 24 ± 16 years. At baseline, 91% had diabetes, 76% had hypertriglyceridemia, and 2 had autoimmune hepatitis. For patients assessed within a year after initiating ML (n=21, mean treatment duration 9.8 ± 2.8 months), LV decreased by 24.5 ± 16.6%. Longer exposure (n=14, 46.7 ± 24.4 months) appeared to have a larger decrease in LV relative to baseline of 34.7 ± 18.9%. Treatment with ML for one year resulted in significant reductions in A1c [n=19, -2.1 ± 1.2%], AST [n=19, -46.8 ± 63.0 U/L], ALT [n=19, -69.7 ± 101.7 U/L], and TG [n=15, -43.7 ± 36.7%]. ML was generally well tolerated; most commonly reported adverse events were abdominal pain and hypoglycemia. Among the subgroup of 13 pediatric patients who were < 18 years (mean 14 ± 3 years), all had an enlarged liver at baseline (mean ± SD LV of 3459 ± 1178 mL), ranging from 1.2-6 x normal. For pediatric patients assessed within a year after initiating ML (n=13, mean treatment duration of 9.4 ± 3.2 months), LV decreased by 25.2 ± 15.4%. Longer exposure (n=9, 46.2 ± 26.9 months) appeared to have a larger decrease in LV relative to baseline of 34.3 ± 18.1%. Treatment with ML for 1 year resulted in significant reductions in A1c [n=11, -2.2 ± 1.4%], AST [n=11, -56.3 ± 75.3 U/L], ALT [n=11, -90.5 ± 128.6 U/L], and TG [n=9, -43.1 ± 30.8%]. Similar to the larger cohort, ML was generally well-tolerated in pediatric patients; gastrointestinal disorders including abdominal pain and pancreatitis were the most commonly reported adverse events. The 2 pediatric patients with pancreatitis also reported it in their past medical history, prior to ML treatment initiation.

Conclusion: Moderate to severe hepatomegaly, usually due to hepatic TG accumulation, is a common feature in patients with GL. In addition to its metabolic effects, this post hoc analysis provides additional evidence that ML may have a clinically significant and sustained effect in reducing LV in adult and pediatric patients with GL.

Co-administration of tesofensine and metoprolol: improvements in body weight and liver fat content in patients with type 2 diabetes

G. Andersen[1], T. Heise[1], B. Edsberg[2], D. Lamers[1], T. Jacobsen[2], L. Plum-Mörschel[3], R.V. Dvorak[2];
[1]Profil Institut für Stoffwechselforschung GmbH, Neuss, Germany, [2]Saniona, Ballerup, Denmark, [3]Profil Mainz GmbH & Co.KG, Mainz, Germany.

Background and aims: Tesofensine (TESO) is an inhibitor of the monoamine presynaptic reuptake of the neurotransmitters noradrenaline, dopamine and serotonin suppressing appetite and reward centres in the brain and increasing energy expenditure. TESO demonstrated strong weight reducing effects in Phase 2 clinical studies in obese subjects, but also an increase in blood pressure and heart rate at therapeutically relevant doses. In this double-blind, randomized, placebo-controlled trial we investigated the effect of co-administration of 0.5 mg TESO with 100 mg of the β1-selective beta-blocker metoprolol (MET) on body weight, body composition and metabolic endpoints in subjects with T2D on metformin therapy with or without one additional anti-diabetic oral agent.
Materials and methods: Sixty subjects with T2D [mean±SD age: 62.8±6 yrs; weight: 96.4±16.4 kg; BMI: 32.6±5.3 kg/m²; waist circumference: 111.4±11.8 cm; HbA1c 7.7±0.4%], were randomly allocated to once daily treatment with TESO+MET or matching placebos (PLAC) for 90 days. Fifty-eight subjects completed the study. Anthropometric assessments including body weight and waist circumference as well as vital signs and safety parameters were assessed every 7-14 days. Liver fat (by magnetic resonance spectroscopy) and metabolic endpoints were measured at baseline and end of treatment (EOT) in a sub-set of the patients.
Results: TESO+MET led to a progressive weight reduction which was significantly greater than the minor changes observed with PLAC (table). Accordingly, treatment with TESO+MET led to a significantly greater reduction in mean waist circumference compared with PLAC. While TESO+MET showed no significant advantages in glycaemic parameters (HbA1c, 1.5-Anhydroglucitol, fasting plasma glucose (FPG) and area under the curve of the 9-point glucose profile) or lipids, there was a strong trend to significantly larger improvements in liver fat which decreased with TESO+MET, but increased with PLAC. TESO+MET was well tolerated with nausea, hyperhidrosis, headache and dry mouth being the most frequent adverse events (AEs). No serious AE occurred with TESO+MET. Most importantly, there were no deleterious effects on heart rate and blood pressure with TESO+MET, but rather a significant reduction in mean 24 hr heart rate (LS-mean difference between treatments in change of baseline -3.8 bpm, p=0.0038).
Conclusion: This study demonstrates that a tesofensine/metoprolol co-administration significantly reduces body weight as well as waist circumference and trends to improve liver fat in patients with T2D without any negative effects on heart rate and blood pressure.

PS 068 Novel approaches to glycaemic control

858

Endoscopic proximal intestinal exclusion with EndoBarrier therapy is associated with improvement in gonadal function in obese men with diabetes

A. Basu[1], P. Sen Gupta[1], M. Yadagiri[1], B.M. McGowan[2], R.S. Drummond[3], H. Jones[4], S.A. Amiel[5], R.E.J. Ryder[1];
[1]Diabetes Department, Sandwell and West Birmingham NHS Trust Hospital, Birmingham, [2]Diabetes Department, Guys & St Thomas hospital NHS Foundation Trust, London, [3]Diabetes Department, Glasgow Royal Infirmary, Glasgow, [4]Diabetes Department, Barnsley Hospital NHS Foundation Trust, Barnsley, [5]Diabetes Department, Kings College London, London, UK.

Background and aims: Previous evidence has linked obesity with low testosterone levels and improvement in gonadal function with weight loss. Our aim was to ascertain whether weight loss with Endobarrier® was associated with and improvement in testosterone levels and hence gonadal function in obese men with Type 2 diabetes.
Materials and methods: This was a sub-study of a larger multi-centre, randomised controlled trial investigating the efficacy of Endobarrier® therapy, a 60cm endoluminal sleeve implanted in the proximal intestine. This was a proof-of-concept study. Testosterone levels were measured prior to initiating treatment and 12 months later prior to implant removal. Free testosterone was estimated using the Vermeulen equation.
Results: There were 22 male participants with mean age 49.1(±10.8) years and diabetes duration of 11.4(±5.2) years. 15/22 patients that received Endobarrier®, mean weight loss was 9.9 (SE2.1) Kg (p<0.001) with a maximum weight loss of 25.6kg. Only one patient did not lose weight; HbA1c improved by 22.1 (SE5.4) mmol/mol[2.0%; SE0.49] (p=0.001). The total testosterone levels improved by 1.9 (SE 0.78)nmol/L (p=0.03). The estimated free testosterone level after adjusting for the change in weight and HbA1c improved by 77% (p=0.001; adjR^2 = 0.65 for model).
Conclusion: The study indicates that Endobarrier® therapy is associated with a significant improvement in free testosterone levels in men, independent of change in glycaemic control and body weight. This may imply return of gonadal function in some men following therapy.

Table: Characteristics of the 22 male patients who completed treatment with Endobarrier . P-values reflect change from baseline with 5% significance

Jejunal diversion, a novel malabsorbtive procedure, improves metabolic control and augments the incretin effect in obese subjects with type 2 diabetes

M. Mraz[1,2], J. Klouckova[3,2], P. Kavalkova[2], A. Cinkajzlova[3,2], H. Kratochvilova[3,2], Z. Lacinova[3,2], P. Sramkova[4], K. Dolezalova[4], M. Fried[4], M. Haluzik[3,2];
[1]Department of Diabetes, Institute for Clinical and Experimental Medicine, [2]Institute for Medical Biochemistry and Laboratory Diagnostics, General University Hospital, [3]Centre for Experimental Medicine, Institute for Clinical and Experimental Medicine, [4]OB Klinika, Prague, Czech Republic.

Background and aims: Jejunal diversion (JD) is a novel metabolic surgical procedure using side-to-side jejuno-jejunostomy to create a partial intestinal by-pass in a less invasive manner compared with other malabsorbtive operations, thus far used predominantly in experimental animals. The aim of our study was to assess the effects of JD on anthropometric, metabolic and hormonal parameters of patients with obesity and type 2 diabetes mellitus (T2DM).
Materials and methods: Fifteen obese T2DM subjects (8 males, aged 52.7 ± 6.1 years) were examined before and 3 and 12 months after JD. Postprandial effects of JD were evaluated using a 5-hour oral glucose tolerance test (oGTT).
Results: JD rapidly and sustainably reduced body weight (BMI 34.1 ± 3.5 vs. 31.9 ± 3.5 vs. 31.0 ± 3.7 kg/m^2 for 0 vs. 3 vs. 12 months, p<0.001) and improved glucose control (HbA_{1C} 78.9 ± 9.5 vs. 62.3 ± 11.4 vs. 54.1 ± 12.3 mmol/mol, p<0.001) and lipid profile (LDL 2.68 ± 0.72 vs. 1.94 ± 0.75 vs. 2.03 ± 0.80 mmol/l, p=0.014; triglycerides 3.67 ± 3.96 vs. 1.81 ± 0.99 vs. 1.86 ± 1.31 mmol/l, p=0.012). JD further augmented the incretin effect by increasing postprandial levels of GLP-1 along with the reduction of insulin and glucagon, while GIP, PP, amylin and ghrelin were not affected. Interestingly, bile acid levels peaked already 3 months after JD with a subsequent return to baseline at 12 months, in spite of no change being observed in their intestinal regulator fibroblast growth factor 19 (FGF-19). JD was accompanied by a reduction in serum ferritin (133.2 ± 97.6 vs. 66.9 ± 47.4 μg/l for 0 vs. 12 months, p=0.004), vitamin B12 (491.6 ± 216.6 vs. 264.3 ± 139.5 ng/l, p<0.001) and zinc (16.2 ± 1.6 vs. 14.0 ± 2.8 mmol/l, p=0.013) without influencing any other nutritional parameters.
Conclusion: In obese subjects with T2DM JD induces significant weight loss and improvement in metabolic control that persist for at least 12 months after operation. Changes in GLP-1 and bile acids might be at least partially responsible for these effects.

Duodenal mucosal resurfacing demonstrates sustained improvement in glycaemic parameters in type 2 diabetes: 12 month data

A.C.G. van Baar[1], M. Nieuwdorp[2], L. Crenier[3], A. Mertens[4], R. Batterham[5], F. Holleman[6], P. Vignolo[7], G. Costamagna[8], J. Deviere[9], R. Haidry[10], L. Rodriguez[7], M.G. Neto[11,12], J.J. Bergman[1], G. Mingrone[13]; [1]Gastroenterology & Hepatology, Academic Medical Center, Amsterdam, [2]Internal and Vascular Medicine, Academic Medical Center, Amsterdam, Netherlands, [3]Endocrinology, Erasme University Hospital, Brussels, [4]Clinical and Experimental Endocrinology, Catholic University of Leuven, Leuven, Belgium, [5]Centre for Obesity Research, University College London, London, UK, [6]Internal Medicine, Academic Medical Center, Amsterdam, Netherlands, [7]CCO Clinical Center for Diabetes, Obesity and Reflux, Santiago, Chile, [8]Digestive Endoscopy, Policlinico Gemelli, Catholic University of Rome, Rome, Italy, [9]Gastroenterology, Erasme University Hospital, Brussels, Belgium, [10]Gastroenterology, University College Hospital, London, UK, [11]Bariatric Endoscopy Service, Gastro Obeso Center, São Paulo, Brazil, [12]Florida International University, Miami, USA, [13]Internal Medicine, Catholic University, Rome, Italy.

Background and aims: Duodenal exclusion via bariatric surgery has been shown to confer an insulin sensitizing metabolic benefit that is, in part, weight-independent. Duodenal Mucosal Resurfacing (DMR) is an endoscopic procedure that rejuvenates the duodenal mucosa through hydrothermal ablation and may confer similar metabolic benefits using a less invasive procedure. Here we report the 12 months glycaemia data following a single DMR procedure in patients with T2D.
Materials and methods: Data were extracted from a single arm, open label, multicentre study in which type 2 diabetes patients on oral glucose lowering medication with baseline HbA1c 7.5 - 10.0%, and age 25 - 75 years received a single DMR procedure. Sulfonylurea's were discontinued before DMR and other glucose regulating medication was kept stable for at least 6 months post DMR. Hereafter medication modifications were made at the treating physician's discretion following the local or international guidelines. Efficacy was analysed in a modified intent-to-treat cohort (patients who received ≥1 ablation) and a sub-group of patients (n=15) with preserved beta-cell function (baseline fasting plasma insulin, FPI >15 uU/mL). Change from baseline in HbA1c, fasting plasma glucose (FPG), and Homeostasis Model Assessment index (HOMA-IR) were analysed using paired t-tests. Data are reported as mean ± SD.
Results: Baseline parameters (n=27) were: age, 55.0 ± 9.0 y; diabetes duration, 6.0 ± 2.5 y; BMI, 32.5 ± 4.2 kg/m^2; HbA1c, 8.7 ± 1.0 %. On average, HbA1c remained lower than baseline over 12 months after a single DMR procedure; reductions at 6, 9 and 12 months were, -1.0 ± 1.0% (p < 0.001), -1.1 ± 1.5% (p = 0.001), -0.7 ± 1.2% (p=0.008). Similarly, FPG and HOMA-IR were lower relative to baseline, with reductions of -33.9 ± 48.7 mg/dL, and -3.8 ± 4.9 (p=0.002), at 12 months. In the cohort with baseline FPI >15 uU/mL, the mean HbA1c reductions were, -1.4 ± 1.1% (p < 0.0003), -1.6 ± 1.8% (p = 0.006), and -1.3 ± 1.3% (p=0.002), at 6, 9, and 12 months. A modest reduction in mean body weight was observed throughout 12 months (at 12 months; -1.5 ± 4.2 kg, p = 0.08) for the full cohort.
Conclusion: A single DMR procedure produced sustained reductions in HbA1c, FPG, and HOMA-IR out to 12 months, with robust glycaemic effects in patients with preserved beta-cell function. Larger, randomized controlled studies are planned to further establish the efficacy, safety and durability of the metabolic effects associated with DMR.

Mesenchymal stromal cells from the umbilical cord (UCX®): A role in protection against non-alcoholic fatty liver disease?

I. Sousa-Lima[1], M.J. Meneses[1,2], I. Ferreira[1], H. Cruz[3], J.M. Santos[3], M.P. Macedo[1,4]; [1]CEDOC, Chronic Diseases Research Centre, NOVA Medical School|Faculdade de Ciências Médicas, Universidade NOVA de Lisboa, [2]ProRegeM PhD Programme, NOVA Medical School/Faculdade de Ciências Médicas da Universidade Nova de Lisboa, [3]ECBio – R&D in Biotechnology, S.A., Lisbon, [4]Department of Medical Sciences, Institute of Biomedicine-iBiMED, University of Aveiro, Aveiro, Portugal.

Background and aims: Mesenchymal Stromal Cells (MSCs) have been shown to have promising therapeutic applications, mainly due to their immunomodulatory, anti-inflammatory, pro-angiogenic and regenerative properties. Umbilical cord tissue-derived expanded MSCs, UCX®, consists of a specific population of MSCs from the umbilical cord tissue (UC-MSCs), isolated according to a patented technology. Preclinical studies using UCX® have demonstrated the safety and quality of the cells, as well as their efficacy in animal models for several immune-related and cardiovascular diseases. However, the role of the UCX® in diet-induced obesity and non-alcoholic fatty liver disease (NAFLD) remains widely unknown.
Materials and methods: Male C57Bl/6 mice were used. The mice were divided in three experimental groups according to the type of diet and UCX® administration. The mice were given ad libitum access to a normal- (Chow) or hyper-caloric diet (HFat), from ages 6 to 18 weeks. The HFat group was further divided into two groups: HFat and HFat-UCX®, the latter being treated with UCX® every week for a total of 7 weeks (from ages 11 to 18, via an intraperitoneal injection of 10E6 cells). Mice were monitored weekly for body weight, blood glucose and food/calorie intake, as well as a close observation of their behavior, for distress signals. After 5 weeks of diet and at the end of the study both insulin sensitivity and glucose tolerance were determined. At the end of

the study several organs and tissues were collected for further analysis. Livers were stained by H&E (Hematoxylin & Eosin) and their content in cholesterol and triglycerides was determined.
Results: As expected HFat diet promoted body weight gain (20.53 ± 0.156g n=4 vs. 24.02 ± 0.759g n=9, p<0.05), fasting hyperglycemia (79.50 ± 3.617mg/dL n=4 vs. 109.9 ± 8.324mg/dL n=9, p<0.05) and glucose intolerance (24140 ± 2788 n=4 vs. 30110 ± 2118 AUC A.U. n=9), compared to the control littermates under a Chow diet. Mice were at this point considered as being in a pre-diabetic state. After the treatment HFat-UCX® animals were protected against body weight gain, compared to the untreated HFat mice (33.83 ± 3.676g vs. 31.85 ± 1.379g, n=4). HFat-UCX® animals had lower fasting glucose levels (134 ± 3.122mg/dL vs. 106.2 ± 2.956mg/dL, n=4/5, p<0.001) and improved glucose tolerance (44800 ± 5275 vs. 59023 ± 6919 AUC A.U., n=4, p<0.05). Food intake was unaffected by the UCX® treatment. HFat-UCX® animals show a decreased liver/body weight ratio and ectopic lipid accumulation, assessed by H&E staining. Compared to the untreated HFat mice, HFat-UCX® mice, show decreased accumulation of triglycerides (45.63 ± 1.896 vs. 37.90 ± 2.816 mg/g of liver weight n=4, p=0.0632) in the liver.
Conclusion: The preliminary data suggests that UCX® may have a protective role in diet-induced obesity and NAFLD. The mechanism through which the cells protect against lipid accumulation in the liver needs to be further investigated.

LY3298176, a novel long-acting GIP/GLP-1 coagonist, shows enhanced activity on weight loss and energy utilisation whilst maintaining its efficacy for glycaemic control

K. Bokvist, R. Brown, T. Coskun, A. Cox, R. Cummins, S. Estwick, T. Farb, J. Ficorilli, M. Marcelo, L. O'Farrell, A. Patel Lewis, X. Peng, J. Shaw, D. Wainscott, J. Alsina-Fernandez;
Eli Lilly and Company, Indianapolis, USA.

Background and aims: Commonly used glucagon-like peptide-1 receptor (GLP-1R) agonists provide very substantial reductions in $HbA1_c$ as well as clinically meaningful weight loss; however, it remains unknown if combining GLP-1R activity with glucose-dependent insulinotropic peptide receptor (GIPR) activity results in a treatment with improved efficacy. In this study we evaluated GLP-1R and GIPR activation, glucose lowering and weight loss in vitro and in vivo using a novel acylated long-acting GIP/GLP-1 coagonist peptide, LY3298176.
Materials and methods: Peptide analogues were made using an automated peptide synthesizer and evaluated in GIPR and GLP-1R binding and functional assays. Insulin secretion was studied in isolated primary rat islets as well as in vivo in rodents. Weight loss studies were carried out in high fat fed C57Bl6 mice and glycaemic control was evaluated at the end of a 2 week dosing period. Energy utilization was determined by the aid of Oxymax chambers and whole body QNMR was used to determine body composition at the end of the weight loss study.
Results: LY3298176 binds to human (h) GIPR and GLP-1R with an affinity (K_i) of 34 and 230 nM, respectively. Half-maximal concentrations in the functional cAMP generation assays in cells that over-express hGIPR and hGLP-1R were 11 and 71 nM, respectively. LY3298176 does not bind to or activate the human glucagon receptor at concentrations ≤7.5 μM. LY3298176 dose-dependently enhanced insulin secretion from rat or mouse islets. Furthermore, LY3298176 enhanced insulin secretion in islets from GIPR knockout mice as well as in islets from GLP-1R knockout animals. In rats, LY3298176 both enhanced insulin secretion in an intravenous glucose tolerance test as well as inhibited gastric emptying of a semi-liquid meal. Half maximal doses (ED_{50}) were 0.87 nmol/kg (insulin secretion) and 11.8 nmol/kg (gastric emptying). LY3298176, given every 72 hours (hrs) for 2 weeks, dose-dependently induced weight loss in high-fat diet induced obese mice. The weight loss amounted to 38% at the highest dose administered (100 nmol/kg) and the ED_{50} was estimated to 5 nmol/kg. The weight loss was predominantly loss of fat mass (>80%) and was associated with reduced food intake and a 10-15% increase in energy utilisation. Improved plasma and liver lipids were also observed. Interestingly LY3298176, contrary to what is known for GLP-1, didn't increase corticosterone secretion in rats. The terminal elimination half-lives of subcutaneously administered LY3298176 were ≈10hrs and 146hrs in rats and dogs, respectively.
Conclusion: Our data suggest that LY3298176 is a potent and efficacious glucose-lowering agent that provides substantial weight loss. We see weight loss that appears to be associated with increased energy utilisation, something typically not seen using GLP-1 analogues alone. The 146hr elimination half-life in dogs suggests that LY3298176 is suitable for once-weekly dosing.

Crossover study comparing bioavailability of a capsule formulation of the glucagon receptor antagonist LGD-6972 to an oral solution formulation in healthy subjects

J.D. Pipkin[1], E. Vajda[1], L. Biernat[2], D.J. Klein[2], Y.-X. Li[2], M. Zangmeister[2], R. Zhou[2], L. Zhi[1], K. Marschke[1];
[1]Ligand Pharmaceuticals Incorporated, San Diego, [2]Medpace, Inc., Cincinnati, USA.

Background and aims: LGD-6972 is a novel, orally bioavailable small molecule glucagon receptor antagonist (GRA) being developed as an adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus (T2DM). In a single- dose Phase 1 study using an oral solution formulation in Captisol (betadex [β-cyclodextrin] sulfobutylether sodium), LGD-6972 demonstrated favorable safety, tolerability and pharmacokinetics (PK) in normal healthy volunteers (NHV) and in subjects with T2DM, and dose dependent reductions in fasting plasma glucose (FPG). PK/PD modeling predicted an efficacious exposure and dose range for a subsequent multiple dose Phase 1 study. Multiple doses of LGD-6972 oral solution demonstrated favorable safety, tolerability and PK in T2DM subjects and a robust, dose-dependent reduction of FPG (maximal decrease of 3.15 mmol/L in baseline adjusted values on day 14). This Phase 1, single-center, randomized, open-label, single-dose, 2-period complete crossover study was conducted to compare the relative bioavailability of an oral capsule formulation of LGD-6972 to the solution formulation in NHV.
Materials and methods: A total of 12 subjects were enrolled in the study. In 2 treatment periods, subjects received each of the following treatments as a single oral dose, under fasting conditions (6 subjects per treatment in each period): Treatment A - 15 mg LGD-6972 administered as 3 × 5 mg capsules; Treatment B - 15 mg LGD-6972 administered as 4 mL × 3.75 mg/mL solution. Serial blood samples were collected for LGD-6972 plasma concentration determination, and safety was assessed during the 48 hours following each dose. Subjects were discharged from the study site on day 3 and returned on days 4, 7, and 14 for follow-up procedures.
Results: Bioequivalence between Treatment A and Treatment B was demonstrated for area under the plasma concentration versus time curve from time 0 (predose) to the last measurable concentration ($AUC_{0\text{-last}}$), AUC from time 0 (predose) to 312 hours postdose ($AUC_{0\text{-}312h}$), and AUC from time 0 (predose) to infinity (extrapolated) ($AUC_{0\text{-}\infty}$) (90% confidence intervals [CI] = [83.2, 109], [83.9, 108], and [83.9, 108], respectively). Bioequivalence was not demonstrated for maximum observed concentration (C_{max}) (90% CI = [75.6, 103]); however, a sensitivity analysis indicated that this may have been due to high variability in individual subject PK concentrations with the sampling schedule and small sample size for the design. Other PK parameters, including time to maximum observed concentration (T_{max}), half-life ($t_{1/2}$), elimination rate constant (λ_z), oral

clearance (CL/F), and apparent volume of distribution (V_d/F), were similar between treatments. Fasting glucose in subjects receiving Treatment A or Treatment B was reduced compared to baseline at 24 and 48 hours post-dose, returning to baseline by day 7. All treatment-emergent adverse events during the study were mild in severity, and no subject had a serious adverse event or discontinued from the study due to an adverse event.
Conclusion: Overall, single oral doses of 15-mg LGD-6972, administered as capsules or solution, were safe and well tolerated. The observed PK profile for the capsule formulation supports its use in the 12-week, Phase 2a study in subjects with T2DM currently underway.

The novel glucagon receptor agonist SAR438544, first in human safety, pharmacokinetic and pharmacodynamic data from a study in healthy volunteers

M. Hompesch[1], P. Grosjean[2], L. Morrow[1], Y. Hijazi[3], M. Ishibai[4], L. Teichert[3], K. Bergmann[3];
[1]ProSciento, Inc, Chula Vista, USA, [2]ProSciento, Inc, Chilly-Mazarin, France, [3]Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany, [4]Sanofi R&D, Chilly-Mazarin, France.

Background and aims: SAR438544 is a novel synthetic agonist of the glucagon receptor in a stable formulation for subcutaneous (SC) injection to treat hypoglycemia. A first-in-human, randomized, double-blind, glucagon and placebo-controlled, single ascending dose study to evaluate safety, tolerability, PK and PD of SAR438544 was conducted in healthy volunteers.
Materials and methods: Twenty subjects (mean age: 30.8 ± 6.4 years; Male: 80%; mean BMI 24.5 kg/m^2) were enrolled in one of two dose cohorts (10 per cohort) and were randomized to either SAR438544 (N=6) with 50 μg in cohort 1 and 150 μg in cohort 2, placebo (N=2) or 1 mg glucagon control (N=2). Safety and tolerability were monitored. All subjects completed the study per protocol, and were included into safety, PK and PD analyses.
Results: There were no severe or serious TEAEs, and no AE of special interest. PK profiles showed a slight over dose-proportional increase in SAR438544 C_{max} (mean ± SD) of 1.82 ± 0.531 ng/mL (at 50 μg), 8.05 ± 0.749 ng/mL (at 150 μg) vs. 4.37 ± 1.47 ng/mL (at 1 mg glucagon). The t_{max} median (min - max) was 1.25 (1 - 1.5) h, 1 (0.75 - 2) h vs. 0.13 (0.08 - 0.17) h and $t_{1/2}$ (mean ± SD) was 1.34 ± 0.281 h, 1.22 ± 0.367 h vs. 0.795 ± 0.0676h for SAR438544 at 50 and 150 μg, and glucagon 1 mg, respectively. PD profiles showed a dose-dependent increase in mean BG-C_{max} (mmol/L) for SAR438544 at 50 and 150 μg with no BG response in the placebo group. The BG response for glucagon was greater than that for SAR438544. The mean values of BG-C_{max} (mean change from baseline) were 5.07 (0.19), 5.45 (0.49), 7.21 (2.37) vs. 9.26 (4.25) mmol/L for placebo, SAR438544 50 and 150 μg, and glucagon 1 mg, respectively.
Conclusion: In conclusion, this first-in-human study demonstrated that the stable formulation of this glucagon receptor agonist was well tolerated, safe and active at the doses tested.

First-in-class PET tracer for the glucagon receptor

O. Eriksson[1,2], M. Bossart[3], T. Haack[3], I. laitinen[3], P. Larsen[3], O. Plettenburg[4], L. Johansson[5], S. Pierrou[5], M. Wagner[3], I. Velikyan[6];
[1]Antaros Medical AB, Uppsala, [2]Uppsala University, Uppsala, Sweden, [3]Sanofi-Aventis, Frankfurt, [4]Helmholtz Zentrum, München, Germany, [5]Antaros Medical AB, Mölndal, [6]Uppsala PET-Centre, Uppsala, Sweden.

Background and aims: The glucagon receptor (GCGR) is emerging as an important target in anti-diabetic therapy, especially as part of the pharmacology of dual glucagon/glucagon-like-peptide-1(GCG/GLP-1) receptor agonists. However, currently there are no suitable target engagement biomarkers for in vivo proof of binding mechanism and specificity for GCGR. For a GCG/GLP-1 receptor dual agonist, knowledge about the proportion of occupied receptors in vivo could promote the understanding of the physiological effect in terms of weight loss and glycemic control. Thus, it is imperative to develop target engagement markers of GCGR drug interactions in order to enable development of dual agonists. Here we describe a first-in-class GCG Positron Emission Tomography (PET) ligand, suitable for development as a tool for in vivo analysis of GCGR occupancy in the clinic.
Materials and methods: The GCGR selective agonist peptide S01-GCG was developed from analogues of modified glucagon. Potencies at rat, cynomolgus monkey and human GCGR were assessed by a functional cAMP assay in GCGR transfected HEK293 cells. Chelate conjugated peptide, S01-GCG, was radiolabeled with Gallium-68 (^{68}Ga) radionuclide. [^{68}Ga]DO3A-S01-GCG was evaluated for selectivity (co-incubation with 10 μM GCG, 10 μM unlabeled DO3A-S01-GCG or 1 μM GLP-1), affinity (n=5) and internalization (n=3) in GCGR transfected HEK293 cells as well as in frozen liver sections from rat, cynomolgus monkey and man by autoradiography (n=3). In vivo biodistribution, dosimetry as well as GCGR specificity studies (co-administration of 1 mg/kg DO3A-S01-GCG peptide) were evaluated in Sprague Dawley rats (n=24).
Results: S01-GCG displayed functional potency for the GCGR in the range of the natural ligand but limited potency for the GLP-1 receptor. ^{68}Ga-radiolabelling of DO3A-S01-GCG was highly reproducible with specific activity in excess of 50 MBq/nmol with high reproducibility and with radiochemical purity >95%. [^{68}Ga]DO3A-S01-GCG binding to transfected cells and liver sections of all studied species was mediated by the GCGR, with negligible cross-reactivity to GLP-1R. In cells, GCGR binding triggered internalization of [^{68}Ga]DO3A-S01-GCG. Affinity to the human GCGR in transfected cells was 17±8 nM. *In vivo*, [^{68}Ga]DO3A-S01-GCG displayed retention exclusively in liver, spleen and kidney of the rat. The binding in liver and spleen, but not kidney, was GCGR-selective as it could be competed away >80% by co-injection of unlabeled DO3A-S01-GCG. The human predicted absorbed doses (kidneys 0.54 mSv/MBq and effective dose 20 μSv/MBq) allows for repeated clinical scanning annually.
Conclusion: We present evidence of a first-in-class PET tracer targeting the GCG receptor, with suitable properties for clinical development. This tool has potential to provide direct quantitative evidence of GCG receptor occupancy in humans.

A novel long-acting glucagon analog (HM15136) offers favorable stability, PK/PD, and therapeutic potentials in congenital hyperinsulinism animal model

S. Jung, J. Kim, Y. Park, S. Bae, I. Choi, Y. Kim, S.-C. Kwon;
Hanmi Parmaceutical, Seoul, Republic of Korea.

Background and aims: Congenital hyperinsulinism (CHI) is a rare genetic disorder characterized by unregulated insulin secretion which leads to persistent and severe hypoglycemia. The available therapeutics have limited efficacy and lead to poor treatment adherence due to frequent dosing and/or need for intravenous infusion. Although glucagon has been considered as one of the most potent therapeutic options, its utilization is limited due to poor solubility, limited stability at physiological pH, and short duration of action. To overcome these limitations, we have developed a novel long-acting glucagon analog, HM15136. HM15136 consists

of a glucagon analog conjugated to the human aglycosylated Fc fragment via a short PEG linker. This study investigated the therapeutic potential of HM15136 by evaluating its 1) solubility and stability, 2) in vitro biological functions, and 3) PK/PD in rodent models.

Materials and methods: Solubility of HM15136 at pH7.0, and solution stability at 4 and 25°C were evaluated via LC (liquid chromatography) analysis. Intracellular signaling was measured as cAMP accumulation in CHO cells stably expressing human glucagon receptor (GCGR). The effects on glucose production were investigated in rat primary hepatocytes by assessing glycogenolysis and gluconeogenesis rates. For PK assessments, blood samples were collected after single subcutaneous or intravenous administration of HM15136 in SD rats, and HM15136 concentration was quantified using an in-house established ELISA. To test in vivo efficacy, rats made hypoglycemic by exogenous insulin were administrated with HM15136, and the blood glucose (BG) level was monitored. To evaluate long-term therapeutic efficacy, CHI mimetic rats were established by implanting an osmotic pump releasing insulin.

Results: First, HM15136 showed improved solubility at pH 7.0, compared to native glucagon (≥17 vs. 0.03 mg/mL), and displayed superior solution stability over time both at 4 and 25°C condition. HM15136 induced intracellular cAMP accumulation through GCGR (vs. glucagon, 12% and 21% for human and mouse receptor, respectively). Consistent with these results, HM15136 promoted glycogenolysis and gluconeogenesis in rat primary hepatocytes in a dose-dependent manner, validating the glucose producing ability of HM15136. The half-life of native glucagon and HM15136 in SD rats was determined as 5 min and 36 hr, respectively. Moreover, HM15136 showed high bioavailability (89.5%)in SD rats. Finally, in vivo efficacy studies indicated that HM15136 not only rapidly reversed acute hypoglycemia, but also sustainably increased BG in human CHI mimetic rats after single administration or when dosed mimicking human weekly administration.

Conclusion: Based on solubility/stability results, HM15136 possess more favorable physicochemical features than native glucagon. In addition, in vitro results confirmed the glucagon-like action of HM15136. Together with improved bioavailability and longer half-life, prolonged BG increasing ability in disease models suggests a once-weekly dosing potential of HM15136. HM15136 may represent a treatment for the unmet medical need of CHI.

PS 069 SGLT2 inhibitors in the real world

867

Characteristics of patients with type 2 diabetes initiating canagliflozin compared with other treatment regimens in the UK

G. Hamilton[1], J. Diels[2], A. Schubert[3];
[1]Janssen-Cilag Ltd, High Wycombe, UK, [2]Janssen Research & Development, Beerse, Belgium, [3]Janssen-Cilag Poland, Warszawa, Poland.

Background and aims: This study describes demographic and clinical characteristics of patients with type 2 diabetes mellitus (T2DM) initiating canagliflozin (CANA), a sodium glucose co-transporter 2 inhibitor (SGLT2i), compared with those who initiated other antihyperglycaemic agents (AHAs) in the United Kingdom.

Materials and methods: This analysis was based on retrospective data in the United Kingdom extracted from Clinical Practice Research Datalink between 2012 and 2015 (N = 149,767).

Results: Among patients initiating CANA, mean age was 59.5 years, HbA1c was 9.5%, body mass index (BMI) was 34.8 kg/m^2, and T2DM duration was 9.2 years. Patients initiating SGLT2i and glucagon-like peptide-1 receptor agonists (GLP-1 RA) tended to be younger, have higher HbA1c, and were more likely to be on background AHAs compared with patients initiating metformin (MET), sulphonylureas (SU), dipeptidyl peptidase-4 inhibitors (DPP-4i), and pioglitazone (PIO). Patients initiating GLP-1 RA tended to have the highest BMI (mean [standard error (SE)] = 37.2 [0.09] kg/m^2), followed by patients initiating SGLT2i (mean [SE] = 34.7 [0.09] kg/m^2; Figure). The time since T2DM diagnosis was similar across AHA classes, except for MET, which tends to be used as initial therapy.

Conclusion: These findings show that patients initiating CANA in the United Kingdom generally have characteristics similar to those initiating GLP-1 RA, but may differ compared with patients initiating MET, SU, DPP-4i, and PIO.

Figure. Distribution of baseline BMI with CANA and other AHAs.

Dapagliflozin compared to DPP4i treatment is associated with lower risk of kidney disease, heart failure and all-cause death: CVD-REAL Nordic

J.W. Eriksson[1], A. Norhammar[2], J. Bodegard[3], M. Thuresson[4], P. Fenici[5], D. Nathanson[6], M. Kosiborod[7], H.L. Gulseth[8], T. Nyström[6], K.I. Birkeland[8,9];

[1]Medical Sciences, Uppsala University, Uppsala, [2]Karolinska Institutet, Stockholm, [3]AstraZeneca Nordic-Baltic, Södertälje, [4]Statisticon AB, Uppsala, Sweden, [5]AstraZeneca, Cambridge, UK, [6]Södersjukhuset, Stockholm, Sweden, [7]Saint Luke's Mid America Heart Institute, Kansas City, USA, [8]Oslo University Hospital, [9]University of Oslo, Oslo, Norway.

Background and aims: A main goal of T2D management is to prevent organ complications, including renal and cardiovascular disease (CVD). We aimed to investigate associations of hospitalization for kidney disease (HKD), hospitalization for heart failure (HHF) and all-cause death (ACD) with use of either dapagliflozin or DPP4 inhibitors (DPP4i) in T2D patients.
Materials and methods: Using nationwide registries in Norway and Sweden, all T2D patients dispensed with glucose lowering drugs during 2013—2016 were identified and clinical events were collected. All new users of dapagliflozin (essentially the only SGLT2 inhibitor used) and new users of DPP4i were identified. Then, propensity score matching, 1:3, was performed by using extensive data on patient characteristics, co-morbidities and drug treatment. HKD is defined as any hospital care (in- or outpatient visit) with the main diagnosis of chronic, acute and unspecified kidney disease. HHF is defined as any hospital care (in- or outpatient visit) with the main diagnosis of heart failure. Cox survival models estimated hazard ratio per country and weighted averages are presented.
Results: Out of a total of 77,074 new users of dapagliflozin and DPP4i, 34,328 T2D patients remained following propensity score matching (dapagliflozin, n=8582; DPP4i, n=25,746). These groups were well balanced at baseline; 61 years, 41% women, 21% CVD, 19% microvascular disease, 1% kidney disease, mean follow-up 0.98 years, a total of 33,612 patient-years. Dapagliflozin was associated with lower risk of HKD, HHF and ACD compared to the DPP4i group (Table).
Conclusion: In T2D patients, dapagliflozin was associated with lower risks of hospitalization for kidney disease, hospitalization for heart failure and all-cause death when compared to DPP4i treatment.

	Dapagliflozin N=8582		DPP4i N=25,746		Weighted average estimates Dapagliflozin vs DPP4i; N=34,328

Real-world persistence and HbA_{1c} goal attainment in type 2 diabetes patients initiated on canagliflozin or a glucagon-like peptide-1

M. Pfeifer[1], P. Lefebvre[2], D. Pilon[2], M. Ingham[1], M.-H. Lafeuille[2], B. Emond[2], R. Kamstra[2], C. Wysham[3];
[1]Janssen Scientific Affairs, LLC, Raritan, USA, [2]Groupe d'analyse, Ltée, Montreal, Canada, [3]Rockwood Clinic, Spokane, USA.

Background and aims: This study compared real-world persistence and HbA1c goal attainment in patients with type 2 diabetes mellitus (T2DM) initiated on oral canagliflozin 300 mg (CANA) versus injectable glucagon-like peptide 1 (GLP-1).
Materials and methods: Adults with T2DM newly initiated on CANA 300 mg or a GLP-1 (i.e., albiglutide, dulaglutide, exenatide, or liraglutide; with date of initiation as the index date) were identified from the QuintilesIMS EMRs - US database (03/29/2012-04/30/2016). Inverse probability of treatment weighting accounted for differences in baseline characteristics. Outcomes were compared using weighted Cox models (hazard ratios [HRs] and confidence intervals [CIs]) and Kaplan Meier curves and included time to: HbA1c <8%, discontinuation (gap >90 days), add/switch to a new antihyperglycaemic agent (AHA), and the composite of failure to maintain HbA1c <8% or add/switch to a new AHA. Attaining an HbA1c goal of <8% was evaluated among patients with baseline HbA1c ≥8%. Failure to maintain HbA1c <8% was evaluated among patients starting at HbA1c <8% (from index date) or reaching HbA1c <8% (from first day HbA1c below goal).
Results: 11,435 CANA and 11,582 GLP-1 patients (62.6% liraglutide) formed the weighted study cohorts, with well-balanced baseline characteristics and HbA1c. Time to HbA1c <8% was comparable (HR [95% CI]: 0.98 [0.91, 1.06]; p = 0.642) as was failure to maintain HbA1c <8% (HR: 1.00 [0.90, 1.11]; p = 0.988). CANA patients were 30% less likely to discontinue than GLP-1 patients (HR [95% CI]: 0.70 [0.66, 0.74]; p <0.001; median time to discontinuation 12.4 vs. 8.6 months) and were 28% less likely to add/switch to a new AHA (HR: 0.72 [0.68, 0.77]; p <0.001; median 21.3 vs. 15.1 months). CANA patients were 17% less likely to either fail to maintain HbA1c <8% or add/switch to a new AHA (HR [95% CI]: 0.83 [0.77, 0.90]; p <0.001; median 15.4 vs. 12.6 months).
Conclusion: Reaching and maintaining HbA1c below 8% was comparable between CANA and GLP-1 patients; however, fewer CANA patients required the addition/switch to a new AHA vs. GLP-1 patients.

Glycaemic control, weight loss, and use of other antihyperglycaemics in patients with type 2 diabetes initiated on canagliflozin or sitagliptin: a real-world analysis

M. Ingham[1], P. Lefebvre[2], D. Pilon[2], M.-H. Lafeuille[2], B. Emond[2], R. Kamstra[2], M. Pfeifer[1], M.S. Duh[3], C. Wysham[4];
[1]Janssen Scientific Affairs, LLC, Raritan, USA, [2]Groupe d'analyse, Ltée, Montreal, Canada, [3]Analysis Group, Inc., Boston, [4]Rockwood Clinic, Spokane, USA.

Background and aims: Real-world (RW) data showing benefits of canagliflozin (CANA) over sitagliptin (SITA) are emerging. This study assessed glycaemic control, weight loss, durability of glycaemic control, and use of other antihyperglycaemic agents (AHA) in patients initiated on CANA versus SITA.
Materials and methods: Adults with type 2 diabetes mellitus (T2DM) initiated on CANA or SITA (i.e., index date) were identified from the QuintilesIMS Real-World Data Electronic Medical Records - US database (03/29/2012-04/30/2016). Inverse probability of treatment weighting accounted for differences in baseline characteristics between cohorts. Outcomes included HbA1c over time and time to: reaching HbA1c goal (<7%, <8%, <9%), weight loss ≥5%, failure to maintain HbA1c goal, add/switch to a new AHA, and the composite of failure to maintain HbA1c goal or add/switch to a new AHA. HbA1c over time was assessed using moving averages at 3-month intervals pre and post-index. HbA1c goals were evaluated among patients with baseline HbA1c above goal. Failure to maintain HbA1c goal was evaluated among patients with baseline HbA1c below goal or who reached goal following index treatment initiation. Time-to event outcomes were compared using weighted Cox models and Kaplan Meier curves.

Results: A total of 14,165 CANA patients and 15,528 SITA patients formed the study population. Baseline characteristics and HbA1c were well balanced between weighted cohorts. Post-index, mean HbA1c declined in both cohorts and was significantly lower ($p < 0.01$) in CANA versus SITA patients at each interval, up to 30 months (except 21 months, $p = 0.18$). CANA patients were 12 to 15% more likely to reach HbA1c goals of <7%, <8%, or <9% (all $p < 0.01$) and 47% more likely to lose ≥5% of body weight ($p < 0.01$), relative to SITA patients. CANA patients were 31% less likely to add/switch to a new AHA (median time to switch 20.3 vs. 13.1 months) and 10 to 15% less likely to fail to maintain their HbA1c <7%, <8%, or <9% (all $p < 0.01$). Combining these two endpoints as a proxy for treatment failure, CANA patients were 12 to 16% less likely to fail to maintain goal or add/switch to a new AHA (all $p < 0.01$).

Conclusion: In a RW analysis, CANA patients were more likely to reach HbA1c goals, weight loss goals, and to maintain HbA1c below goal compared to SITA patients. They were also less likely to add new AHAs and to either fail to maintain or add/switch to a new AHA. These findings suggest a higher durability of glycaemic control in patients initiated on CANA relative to SITA.

Disclosure: **M. Ingham:** Employment/Consultancy; Janssen Scientific Affairs, LLC.

Conclusion: Canagliflozin reduced HbA1c, weight, BMI, systolic blood pressure and ALT by clinically and statistically significant amounts in a wide range of real-world UK patients with type 2 diabetes. Rates of genital infection and urinary tract infection were similar to those found in clinical trials. Hypoglycaemia only occurred in patients on insulin.

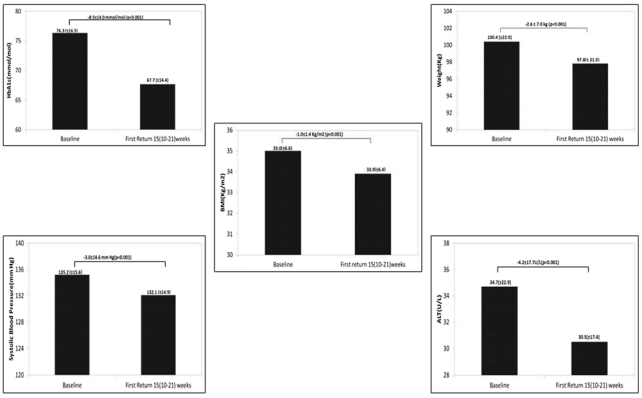

Figure: Mean (±SD) HbA1c (n=462) , weight (n=421), BMI (n=364), systolic blood pressure (n=444)and ALT(n=315), baseline vs first return (after median (interquartile range) weeks) to clinic following commencement of canagliflozin.

One year metabolic outcomes in the ABCD nationwide canagliflozin audit

M. Yadagiri[1], A. Robinson[2], K. Darzy[3], P. Winocour[3], A. Strzelecka[4], I.W. Gallen[5], A. Bickerton[6], S. Phillips[7], A. Evans[7], R.E.J. Ryder[1];
[1]Diabetes Department, Sandwell and West Birmingham NHS Trust Hospital, Birmingham, [2]Diabetes Department, Royal United Hospital Bath NHS Trust, Bath, [3]Diabetes Department, Queen Elizabeth II Hospital, Welwyn Garden City, [4]Diabetes Department, Antrim Area Hospital, Antrim, [5]Diabetes Department, Royal Berkshire Hospitals NHS Trust, Berkshire, [6]Diabetes Department, Yeovil District Hospital NHS Trust, Yeovil, [7]Diabetes Department, Cheltenham General Hospital, Cheltenham, UK.

Background and aims: The ABCD nationwide canagliflozin audit was launched in January 2016 to evaluate the efficacy and safety of canagliflozin in real clinical use in the UK.

Materials and methods: One year on, 40 contributors from 21 centres across the UK have submitted data on 687 canagliflozin-treated patients (61.8% males, mean (±SD) aged 59.8 ±10.8 years, weight 100.4±21.9 kg, BMI 34.9±6.6 kg/m^2 and HbA1c 76.3±16.6mmol/mol, median (range) duration of diabetes 7.0(2.7-12.0) years. Those with baseline and follow-up HbA1c within a median (range) of 14.8(10.2-21.0) weeks were included in the analysis.

Results: Mean (±SD) HbA1c fell by 8.5±14.0 mmol/mol from 76.3 ±16.5 mmol/mol to 67.7±14.4 mmol/mol (n=462, $p<0.001$) and weight fell by 2.6±7.0 kg from 100.4±22.0 kg to 97.8±21.5kg (n=421, $p<0.001$). BMI dropped by 1.0 ±1.4 Kg/m² from mean of 35.0±6.6 Kg/m² to 33.9±6.4 Kg/m² (n=364, $p<0.001$), systolic blood pressure fell by 3.0±14.6 mmHg from mean of 135.2±15.6 mm Hg to 132.1±14.9 mmHg (n=444, $p<0.001$) and alanine aminotransaminase (ALT) levels dropped by 4.2±17.7 U/L from 34.7±22.9 U/L to 30.5±17.4U/L (n=315, $p<0.001$) (figure). Out of 254 patients treated with canagliflozin where data was provided, 8.2% (n=21) had genital infections requiring treatment, 2.7% (n=7) urinary tract infection, 6.7% (n=17) minor, 1% (n=3) moderate and 1 %(n=3) severe hypoglycaemia respectively. All the hypoglycaemia cases were on insulin.

872

Baseline characteristics and treatment patterns of Canadian CAnagliflozin REgistry (CanCARE): assessment of canagliflozin treatment in usual clinical practice in Canada

V. Woo[1], H. Bajaj[2], A. Bell[3], M. Clement[4], N. Georgijev[5], F. Camacho[6], M. Culham[5];
[1]University of Manitoba, Winnipeg, [2]LMC Diabetes & Endocrinology, Toronto, [3]University of Toronto, Toronto, [4]University of British Columbia, Vancouver, [5]Janssen Inc, Toronto, [6]Damos Inc, Waterloo, Canada.

Background and aims: Although extensively studied in randomized controlled clinical trials, there is limited information on the effects of canagliflozin (CANA) in a real-world practice setting in Canada.

Materials and methods: This prospective cohort study enrolled SGLT2 inhibitor naïve T2DM adult patients with A1c ≥7% and eGFR ≥ 60 mL/min/1.73m^2 who were on a stable anti-hyperglycemic agent (AHA) regimen and were initiated on CANA as part of their optimal treatment approach. The objectives of this baseline analysis are to evaluate patient profiles and treatment patterns at the time of CANA initiation.

Results: Table 1 summarizes baseline characteristics of the study. A total of 528 T2DM patients in 28 centers (58% general practitioners - GPs, 42% specialists) initiated CANA treatment, with 83% starting on 100 mg and 17% on 300 mg dose. CanCARE included a diverse study population (67.4% Caucasian; 17.0% South Asian; 5.3% East Asian, 4.9% African/African American; 3.4% Other/Not Reported) of males (60.6%) and females (39.4%). Metformin (89%), DPP-4 inhibitors (43%), sulfonylureas (40%) and insulin (24%) were the most prescribed AHAs at baseline. Of patients on insulin (mean dose 60 IU (±49), 69% were treated by specialists. More patients treated by specialists had an A1c >8.5% (44%) and had a T2DM diagnosis for >10 years (59%) while more of those treated by GPs had an A1c of 7.5 - 8.5% (46%) and had a diagnosis of T2DM for <5 years (39%).

Conclusion: CANA is being prescribed in a broad variety of patient populations in Canada.

Table 1. Baseline Characteristics and Initial Treatment Patterns of Canagliflozin Treated Patients

Patient Characteristic	N=528 Unless Otherwise Noted
Age, y	60.7 ± 10.78
Duration of Diabetes, y	9.8 (7.30)
Cardiac Disorders, n (%)	84 (15.9%)
A1c, mean (std)	8.4 (1.21)
Systolic Blood Pressure (mmHg)	130.9 ±12.89 (N=526)
Diastolic Blood Pressure (mmHg)	78.4 ± 9.33 (N=526)
Body Mass Index (kg/m^2)	32.1 ±6.41 (N=523)
eGFR (mL/min/1.73m^2)	86.8 ±23.95 (N=513)
Canagliflozin Initiation Treatment Patterns, n (%)	
Canagliflozin Only	13 (2.5%)
Canagliflozin + 1 non-insulin AHA	126 (23.9%)
Canagliflozin + 2 non-insulin AHAs	177 (33.5%)
Canagliflozin + 3 non-insulin AHAs	78 (14.8%)
Canagliflozin + Insulin +/- non-insulin AHA	127 (24.1%)
Antihypertensive medications	382 (72.3%)
Lipid lowering medications	428 (81.1%)

Notes: For categorical variables values are n (%) with % = 100*n/N with N = 528; for continuous variables values are mean ± std (N).

873

Predictors of response to SGLT2-inhibitors and DPP4-inhibitors

B.M. Shields[1], J. Dennis[1], W. Henley[1], M. Weedon[1], M. Lonergan[2], L. Rodgers[1], A. Jones[1], N. Sattar[3], R. Holman[4], E. Pearson[2], A. Hattersley[1]; [1]University of Exeter Medical School, Exeter, [2]University of Dundee, Dundee, [3]University of Glasgow, Glasgow, [4]University of Oxford, Oxford, UK.

Background and aims: Stratified medicine targets treatment according to patient characteristics. We have shown simple criteria of sex and obesity can predict differential response to thiazolidinediones and sulfonylureas. SGLT2 inhibitors and DPP4-inhibitors are also second-line therapies used to treat type 2 diabetes, with different mechanisms of action. We aimed to determine whether patient characteristics predicted differential response to these two therapies.
Materials and methods: Patients with prescription records and valid 6-month response (change in HbA1c from baseline) for DPP4-inhibitors (n=21117) or SGLT2-inhibitors (n=3071) were identified from the UK Primary Care Clinical Practice Research Datalink. Regression models were used to identify predictors of response, with βs presented as the change in HbA1c per 1 standard deviation increase in the predictor (negative βs representing a better response at higher values of the predictor).
Results: Higher eGFR was associated with a lesser response to DPP4-inhibitors but a better response to SGLT2-inhibitors (β[SE]= 0.22[0.09] v -1.81[0.26], p<0.0001). Higher BMI and triglycerides were associated with a lesser response to DPP4 inhibitors compared with SGLT2 inhibitors (BMI: β[SE]=0.99[0.1] v -0.13[0.24], triglycerides: 0.76[0.14] v -0.36[0.37], p<0.001 for both). For both DPP4-inhibitors and SGLT2-inhibitors, higher baseline HbA1c (DPP4: β[SE]=-8.46[0.11]; SGLT2: β[SE]=-9.36 [0.26], p<0.0001 for both), and shorter duration of diabetes (DPP4: β[SE]=0.45[0.08]; SGLT2: β[SE]=1.57[0.21], p<0.001 for both) were associated with a greater reduction in HbA1c at 6 months.
Conclusion: These preliminary analyses identify simple criteria that may partly explain variability in the response to SGLT2-inhibitors and DPP4-inhibitors. The associations between eGFR and 6-month response to SGLT2-inhibitors and DPP4-inhibitors go in opposite directions, indicating potential criteria to aid treatment decisions in Type 2 diabetes.

874

Efficacy and safety of SGLT2 in Ramadan

H.M. Omran, A. Khalifa, A. Bashier;
Dubai Health Authority, Dubai, United Arab Emirates.

Background and aims: It is estimated that approximately 40-50 million people with diabetes worldwide fast during the holy month of Ramadan. During this fasting period, Muslims abstain from food and drinks (including oral medications) from dawn to dusk. The risk of hypoglycemia varies according to oral anti-diabetic agent used for treatment[1] ,which is of significant concern in insulin, sulfonylureas and/or non-sulfonylurea insulin secretagogues.however in consider safe to continue other anti-diabetic as lower risk of hypoglycemia . SGLT2 is a low-affinity, high capacity glucose transporter located in the proximal tubule in the kidneys, and it is responsible for 90% of glucose reabsorption. Inhibition of SGLT2 leads to the decrease in blood glucose as a consequence of increased renal glucose excretion it has insulin-independent action, are effective in reducing HbA1c by 0.5%-1.5%, promote weight loss, have a low incidence of hypoglycemia . To study the effectiveness and safety of SGLT2 in emarati population during Ramadan
Materials and methods: We screened all Muslim patients with type 2 diabetes who had been were on, or started on treatment with SGLT2 inhibitors by March 30th, 2016 for eligibility for the trial. All prescriptions were compliant with DHA protocols and recommendations hence none was pregnant, all were > 18 years of age, and none of the patients was having an e-GFR of <45ml/min/m2. We looked at demographic data as well as lab results before Ramadan. Another set of Data was collected after Ramadan.
Results: 417 patients, the majority were females (58.5%). The mean age was 54+ 11.6. At baseline, the mean duration of diabetes was 13.4+6.6 years, and the duration ranged between 3months to 37 years. The mean glycated hemoglobin level was 8.3 + 1.7%. Mean weight was 83.8+ 16.6kg.Out of 226 patients on SGLT2 inhibitors + oral hypoglycemic agents, 41 (18.3%) episodes of hypoglycemia were seen (36.3% of all hypoglycemic episodes seen during Ramadan), while 71 episodes (38.1%), (62.9% of all hypoglycemic episodes seen during Ramadan), were seen in those using insulin (N=191) the P=0.000 highly significant.The

mean glycated hemoglobin level was 8.3 + 1.7% before Ramadan that has significantly reduced to 7.8+ 1.3% (p=0.0001) after Ramadan.
Conclusion: SGLT2 found to be safe and effective in reducing HBA1C during Ramadan
Disclosure: **H.M. Omran:** None.

875

Tolerability of canagliflozin in patients with type 2 diabetes fasting during Ramadan: results of the Canagliflozin in RAmadan Tolerance Observational Study (CRATOS)

M. Hasanein[1], A. Echtay[2], A. Hassoun[3], M. Alarouj[4], B. Afandi[5], R. Poladian[6], A. Bennakhi[4], M. Nazar[7], P. Bergmans[8], S. Keim[9], G. Hamilton[10], S.T. Azar[11];
[1]Dubai Hospital, Dubai, UAE and Cardiff University, Cardiff, UK, [2]Lebanese University Medical School, Rafik Hariri University Hospital, Beirut, Lebanon, [3]Dubai Diabetes Center, Dubai, United Arab Emirates, [4]Dasman Diabetes Institute, Kuwait City, Kuwait, [5]Tawam Hospital in affiliation with Johns Hopkins Medicine, Al Ain, United Arab Emirates, [6]Mount Lebanon Hospital, Beirut, Lebanon, [7]Janssen-Cilag Poland, Warsaw, Poland, [8]Janssen-Cilag BV, Breda, Netherlands, [9]Janssen-Cilag Portugal, Barcarena, Portugal, [10]Janssen UK, High Wycombe, UK, [11]American University of Beirut Medical Centre, Beirut, Lebanon.

Background and aims: There is a large population of people with type 2 diabetes mellitus (T2DM) who are Muslims and fast during Ramadan. Changes in the pattern and amount of meal and fluid intake during Ramadan in addition to the long fasting hours, especially in Europe, may increase the risk of hypoglycaemia and dehydration in these individuals. The Canagliflozin in Ramadan Tolerance Observational Study (CRATOS) evaluated the tolerability of canagliflozin (CANA), an SGLT2 inhibitor, compared with sulphonylureas (SUs) among patients with T2DM who fast during Ramadan.
Materials and methods: This non-randomized, parallel-cohort, prospective, comparative, observational study was conducted in the Middle East (Lebanon, Kuwait, United Arab Emirates) during Ramadan (6 June-5 July 2016) and enrolled patients who were taking CANA (n = 162) or any SU (n = 159) added to metformin ± DPP-4 inhibitor for >12 weeks before enrolment and had HbA1c ≤8.5% within 8 weeks before Ramadan. The proportion of patients with hypoglycaemia events and volume depletion events were assessed; propensity score analysis was used to calculate adjusted odds ratios (ORs) and 95% confidence intervals (CIs). Other assessments included medication and fasting adherence and adverse events (AEs).
Results: During Ramadan, fewer fasting patients experienced hypoglycaemia events with CANA versus SU (adjusted OR [95% CI]: 0.273 [0.104, 0.719]). Of hypoglycaemia events where blood glucose was measured at the time of the event, 2 of 6 with CANA and 27 of 37 with SU were confirmed by blood glucose <3.9 mmol/L. No severe hypoglycaemia events were reported in either group. More patients experienced volume depletion events (mostly dehydration) with CANA versus SU (adjusted OR [95% CI]: 3.5 [1.3, 9.2]). 82.1% and 78.0% of patients reported completing 30 days of fasting with CANA and SU, respectively. The most common reason for breaking fast among CANA patients (n = 29) was symptoms of excessive dehydration (24.1%) and among SU patients (n = 35) was symptoms of low blood sugar (34.3%). 98.8% and 96.2% of patients reported no missed doses of CANA and SU, respectively. One dose of CANA was missed due to excessive dehydration and 1 because the patient forgot; 4 doses of SU were missed to prevent hypoglycaemia, 1 as a precaution, and 1 because the patient forgot. CANA and SU were generally well tolerated, with low rates of AEs and no serious AEs (including hypoglycaemia and volume depletion-related AEs).
Conclusion: Among patients with T2DM fasting for Ramadan, the risk of a hypoglycaemia event was lower and the risk of a volume depletion event was higher with CANA versus SU. Overall, these findings support the use of CANA for the treatment of adults with T2DM who fast during Ramadan.
Clinical Trial Registration Number: NCT02737657

876

Complications of type 2 diabetes after SGLT2 inhibitor administration for 18 months: examination using two risk engines

A. Teshima, R. Ito, T. Ishikawa, J. Shikuma, A. Miwa, A. Kanazwa, M. Odawara;
Tokyo medical University Hospital, Tokyo, Japan.

Background and aims: Sodium-glucose cotransporter-2 (SGLT2) inhibitors became available in Japan in April 2014. In recent years, several studies have shown SGLT2 inhibitors' preventive effects on diabetic complications, but the effects of long-term administration remain unknown. To examine the risk of diabetic complications among patients with type 2 diabetes mellitus (T2DM) 5 and 10 years after 18-month administration of an SGLT2 inhibitor, we used the Japan Diabetes Complications Study /the Japanese Elderly Diabetes Intervention Trial risk engine (JJ risk engine) and examined retrospectively. The risk engine uses an algorithm to calculate the risk of complications based on Japanese patient data , a large clinical study involving 59 diabetes centers. We also used the UK Prospective Diabetes Study (UKPDS) risk engine.
Materials and methods: Participants were 205 Japanese T2DM outpatients (age, 53.8±11.3years; BMI, 30.77±5.44 kg/m^2; DM duration, 8.1 ±5.7 years; HbA1c, 8.63±1.46%) who started to receive an SGLT2 inhibitor between April 2014 and September 2015 from our Medical University Hospital. Taking into account ethnical and racial differences, we used the JJ risk engine to examine the risk of CHD, stroke, death from non-cardiovascular disease, overt nephropathy, and progression of retinopathy 5 and 10 years after an 18-month administration of an SGLT2 inhibitor. We also used the UKPDS risk engine to examine the risk of fatal and non-fatal CHD, and fatal and non-fatal stroke 5 and 10 years after an 18-month administration of an SGLT2 inhibitor. Where applicable, we compared the two engines' estimates between pre- and post-18-month administrations of SGLT2 inhibitors.
Results: After the 18-month administration of an SGLT2 inhibitor, HbA1c, BMI, systolic blood pressure, and cholinesterase significantly decreased (8.63±1.46 to 7.57±1.20, 30.77±5.44 to 29.6±4.80, 136.7±14.6 to 130.2 ±15.2, 402.3±82.9 to 384.0±91.9, respectively), but HDL cholesterol significantly increased (46.5±10.6 to 48.7±11.5). Total cholesterol showed no significant differences. Compared with pre-administration risk, post-administration risk estimated with the JJ risk engine was significantly lower in CHD (5 years post treatment: 2.00±2.92 to 1.40±1.29, p<0.01; 10 years post treatment: 5.55±3.90 to 4.59±2.61, p<0.001), stroke (5 years: 2.82±2.87 to 2.25±2.30, p<0.01; 10 years: 4.41±3.72 to 3.61±3.25, p<0.01), and overt nephropathy (5 years: 5.20±3.56 to 3.88±2.42, p<0.001; 10 years: 9.53±4.82 to 7.60±4.27, p<0.001). The risk was significantly higher for death from non-cardiovascular disease (5 years: 1.13±1.53 to 1.30±1.94, p<0.05; 10 years: 2.33±3.53 to 2.65±4.04, p=0.001), and no significant differences in the risk of progression of retinopathy were detected. Thirty-six patients discontinued receiving an SGLT2 inhibitor due to side effects or other reasons including: discontinuation of hospital visits (14 patients); polyuria (3 patients); genital infection (2 patients); rash, hypoglycemia, dizziness, muscle pain, transient ischemic attack (1 patient each); and others (12 patients).
Conclusion: This study shows that SGLT2 inhibitors potentially decrease the risk of CHD, stroke, and overt nephropathy 5 and 10 years after 18-month administration. We found that some estimates were different between the JJ and UKPDS risk engines, which may be attributed to Japanese people's higher morbidity of stroke and lower morbidity of CHD than Europeans.

PS 070 SGLT2 inhibitors: new class members and combinations

877

Sustained 52 week efficacy and safety of triple therapy with dapagliflozin + saxagliptin vs dual therapy with sitagliptin as add-on to metformin in uncontrolled type 2 diabetes

Y. Handelsman[1], C. Mathieu[2], S. Del Prato[3], E. Johnsson[4], R. Kurlyandskaya[4], N. Iqbal[5], R. Garcia-Sanchez[5], J. Rosenstock[6];
[1]Metabolic Institute of America, Tarzana, USA, [2]University Hospital Gasthuisberg, Leuven, Belgium, [3]University of Pisa, Pisa, Italy, [4]AstraZeneca Gothenburg, Mölndal, Sweden, [5]AstraZeneca, Gaithersburg, [6]Dallas Diabetes Research Center at Medical City, Dallas, USA.

Background and aims: Adding a single antidiabetes agent to metformin (MET) often fails to improve glycaemic control meaningfully in type 2 diabetes mellitus (T2DM) patients with high glycated haemoglobin (HbA_{1c}) levels. The efficacy and safety of triple therapy using dapagliflozin (DAPA) plus saxagliptin (SAXA) added to MET vs dual therapy with sitagliptin (SITA) added to MET were evaluated in a randomized, double-blind, double-dummy, 26-week trial in patients with T2DM. Safety and tolerability profiles were assessed in an extension to 52 weeks.

Materials and methods: Patients with HbA_{1c} 8.0%—10.5% on stable MET (≥1500 mg/day) were randomized (1:1) to once-daily add-on oral therapy with DAPA 10 mg/day plus SAXA 5 mg/day or SITA 100 mg/day. The primary end point was change in HbA_{1c} from baseline to week 26. Exploratory end points assessed at 52 weeks included change in HbA_{1c} from baseline, proportion of patients achieving a therapeutic glycaemic response (HbA_{1c} <7.0%), changes in body weight and fasting plasma glucose (FPG), and proportion of patients requiring rescue therapy or discontinuation for lack of glycaemic control. Incidences of adverse events (AEs) and hypoglycaemia were also assessed.

Results: Of 461 randomized patients, 411 (89%) completed the 26-week study, and 402 (87%) entered the extension phase. Mean±SD baseline data at randomization were similar between groups (age, 56 ±9.2 years; HbA_{1c}, 8.8±0.9%; T2DM duration, 8.0±5.4 years; BMI, 33.1±6.2 kg/m^2). Overall, efficacy outcomes achieved at week 26 were maintained up to week 52. Reduction from baseline to week 52 in HbA_{1c} was greater with DAPA+SAXA+MET vs SITA+MET (−1.3% vs −0.8%) (Table). Reductions in body weight (−2.3 kg vs −0.8 kg) and FPG (−25.5 mg/dL vs −3.6 mg/dL) were greater, and more patients achieved HbA_{1c} <7.0% (33.0% vs 19.5%) with DAPA+SAXA+MET vs SITA+MET. Fewer patients required rescue or discontinuation with triple vs dual therapy (19% vs 32%). Incidences of AEs of interest with DAPA+SAXA+MET vs SITA+MET were confirmed hypoglycaemia, 5.2% vs 3.9%; urinary tract infections, 6.5% vs 3.5%; and genital infections, 3.4% vs 2.2%. Fewer patients discontinued owing to AEs with triple vs dual therapy (1.7% vs 4.4%). Safety and tolerability profiles were consistent with 26-week data.

Conclusion: After 52 weeks of treatment, adding DAPA+SAXA to MET provided sustained greater improvements in glycaemic control, greater weight reductions, no increased hypoglycaemic risk, and a reduced need for rescue/discontinuation compared with SITA+MET, consistent with week 26 results. Safety and tolerability of both regimens were similar to previous findings.

Table. Results for efficacy end points at week 52

Study end point	DAPA+SAXA+MET N=232	SITA+MET N=229	Difference (95% CI)
Mean±SD HbA_{1c} (%) at baseline	n=224 8.8±0.8	n=219 8.9±0.9	–
Change in HbA_{1c} from baseline (%)			
Week 26	n=206 −1.4±0.1	n=184 −1.1±0.1	−0.3 (−0.5, −0.1)
Week 52	n=156 −1.3±0.1	n=112 −0.8±0.1	−0.5 (−0.7, −0.3)
Proportion of patients with HbA_{1c} <7.0% (%)	n=224 33.0±3.1	n=219 19.5±2.6	13.5 (5.6, 21.4)
Change in body weight from baseline (kg)	n=157 −2.3±0.3	n=112 −0.8±0.3	−1.6 (−2.4, −0.8)
Change in FPG from baseline (mg/dL)	n=156 −25.5±3.3	n=111 −3.6±3.7	−22.0 (−31.7, −12.3)
Proportion of patients discontinued owing to lack of glycaemic control or rescued for not achieving pre-specified glycaemic targets (%)	n=42* 18.6±2.5	n=75* 32.3±3.1	−13.8 (−21.4, −6.1)

All data are adjusted mean±SE unless otherwise specified.
A mixed statistical model was used to analyse between-group differences.
n is the number of randomized patients with non-missing baseline and week 26 or week 52 values (last observation carried forward), except for mean baseline and week 26 or week 52 HbA_{1c}, where n is the number of randomized patients with non-missing baseline value and at least one post-baseline value.
*number of responders.
CI, confidence interval; DAPA, dapagliflozin; FPG, fasting plasma glucose; HbA_{1c}, glycated haemoglobin; MET, metformin; SAXA, saxagliptin; SITA, sitagliptin.

Efficacy and safety of ertugliflozin in patients with type 2 diabetes inadequately controlled with metformin monotherapy: VERTIS MET trial

B. Charbonnel[1], R. Pascu[2], J. Frias[3], D. Páll[4], D. Saur[2], A. Darekar[5], S. Huyck[6], H. Shi[7], B. Lauring[6], S. Terra[8], J. Rosenstock[9];
[1]University of Nantes, Nantes, [2]Pfizer, Paris, France, [3]National Research Institute, Los Angeles, USA, [4]University of Debrecen, Debrecen, Hungary, [5]Pfizer, Tadworth, UK, [6]Merck & Co, Inc., Kenilworth, [7]Pfizer, New York, [8]Pfizer, Andover, [9]Dallas Diabetes Research Center at Medical City, Dallas, USA.

Background and aims: Ertugliflozin (ERTU) is an oral sodium-glucose cotransporter 2 inhibitor in development for treatment of patients with T2DM. This Phase 3, randomised, double-blind, 26-wk, multicenter study with an ongoing 78-wk extension evaluated the efficacy and safety of ERTU vs placebo (PBO) in adults with T2DM inadequately controlled (HbA1c 7.0-10.5%) on metformin (MET) monotherapy (≥1500 mg/day for ≥8 wks).

Materials and methods: Patients (N=621) with baseline mean ± SD age 56.6 ± 8.8 y, T2DM duration 8.0 ± 6.0 y, BMI 30.9 ± 4.7 kg/m^2 and HbA1c 8.1 ± 0.9% received PBO, ERTU 5 mg/day or ERTU 15 mg/day in a 1:1:1 ratio. Changes from baseline in efficacy endpoints (HbA1c [primary endpoint], fasting plasma glucose [FPG], body weight and BP), and proportion of subjects with HbA1c <7% at Wk 26 were tested for each ERTU group vs PBO. All efficacy analyses were based on the full analysis set, excluding data after initiation of glycaemic rescue therapy. A constrained longitudinal data analysis model with fixed effects for treatment, time, prior

antihyperglycaemic agent, baseline estimated glomerular filtration rate, menopausal status (men, premenopausal women, women perimenopausal or <3 y postmenopausal, women ≥3 y postmenopausal) and interaction of time by treatment was used to assess the endpoints. To control the overall Type I error rate at 0.05, a sequential testing approach was used across efficacy endpoints. Pre-specified adverse events (AEs) of special interest were subject to inferential testing without multiplicity control (p-values provided if <0.05). Percent changes from baseline in bone mineral density (BMD) were also assessed for ERTU vs PBO at Wk 26.

Results: At Wk 26, ERTU groups had significantly reduced HbA1c, FPG, body weight and BP vs PBO (Table). Patients in ERTU groups were significantly more likely to have HbA1c <7% at Wk 26 vs PBO (5 mg, 35%; 15 mg, 40%; vs PBO, 16%; p<0.001 for both ERTU groups). The incidence of AEs was 45.0%, 42.5%, and 50.2% in the PBO, ERTU 5 mg and ERTU 15 mg groups, respectively. The incidence of genital mycotic infections increased in ERTU groups vs PBO (females: PBO, 0.9%; ERTU 5 mg, 5.5%; ERTU 15 mg, 6.3% [p=0.032 vs PBO]; males: PBO, 0; ERTU 5 mg, 3.1%; ERTU 15 mg, 3.2%). The incidence of urinary tract infections was 1.0%, 2.9% and 3.4% in the PBO, ERTU 5 mg and ERTU 15 mg groups, respectively. The incidence of symptomatic hypoglycaemia and hypovolaemia AEs was similar between groups. ERTU had no adverse impact on BMD at Wk 26 (Table).

Conclusion: ERTU added to MET in patients with inadequately controlled T2DM improved glycaemic control, reduced body weight and BP without impacting BMD, but with an increased incidence of GMIs.

Safety and efficacy of ertugliflozin plus sitagliptin vs either treatment alone after 52 wks in patients with type 2 diabetes poorly controlled on metformin: VERTIS FACTORIAL extension

R.E. Pratley[1], A. Raji[2], R. Eldor[2], S. Sunga[2], Y. Qiu[3], J. Johnson[2], S. Huyck[2], G. Golm[2], S.G. Terra[4], J.P. Mancuso[5], S.S. Engel[2], B. Lauring[2]; [1]Florida Hospital Translational Research Institute, Orlando, [2]Merck & Co., Inc., Kenilworth, USA, [3]MSD R&D (China) Co., Ltd, Beijing, China, [4]Pfizer, Inc., Andover, [5]Pfizer, Inc., Groton, USA.

Background and aims: Ertugliflozin (ERTU) is an oral sodium/glucose cotransporter 2 (SGLT2) inhibitor in development for treatment of type 2 diabetes mellitus (T2DM). This study compared the safety and efficacy of co-administration of ERTU 5 mg or 15 mg plus sitagliptin (SITA) 100 mg compared with either treatment alone over 52 weeks.

Materials and methods: In a double-blind Phase 3 trial, 1233 patients with HbA1c 7.5-11.0% on stable metformin monotherapy ≥1500 mg/day were randomised into 5 groups (Table). ERTU + SITA combinations were compared with corresponding ERTU doses (5 or 15 mg) or SITA alone. The primary outcome was at Week 26; treatment was continued in a double-blind 26-week extension phase.

Results: Mean HbA1c at baseline was 8.6%. After 52 weeks in the ERTU+SITA groups, greater reductions in HbA1c, fasting plasma glucose (FPG) (vs ERTU or SITA alone), body weight and systolic BP (vs SITA alone) were observed (Table). The odds of having an HbA1c <7.0% were greater for ERTU+SITA versus ERTU or SITA alone. Administration of ERTU alone or with SITA was well tolerated overall. Rates of genital mycotic infections with ERTU+SITA were similar to those observed with ERTU alone, and significantly higher than those observed with SITA alone (p<0.05, except ERTU 5 mg+SITA in females). Symptomatic hypoglycaemia rates were not significantly different among groups but were highest in the ERTU 15 mg+SITA group. Overall the incidences of urinary tract infection and hypovolaemia were similar across groups.

Conclusion: Co-administration of ERTU+SITA resulted in effective glycaemic control sustained over 52 weeks and was generally well-tolerated.

Table. Summary of key efficacy endpoints at Week 52 (excluding rescue approach)

Safety and efficacy of ertugliflozin in combination with sitagliptin in patients with type 2 diabetes inadequately controlled on diet and exercise: the VERTIS SITA trial

B. Lauring[1], S.S. Miller[2], T. Krumins[1], H.J. Zhou[3], S. Huyck[1], J. Johnson[1], G. Golm[1], S.G. Terra[4], J.P. Mancuso[5], S.S. Engel[1]; [1]Merck & Co., Inc., Kenilworth, [2]SAM Clinical Research Center, San Antonio, USA, [3]MSD R&D (China) Co., Ltd, Beijing, China, [4]Pfizer, Inc., Andover, [5]Pfizer, Inc., Groton, USA.

Background and aims: Ertugliflozin (ERTU) is an oral sodium/glucose cotransporter 2 (SGLT2) inhibitor in development for the treatment of type 2 diabetes mellitus (T2DM). The efficacy and safety of initial combination therapy of ERTU and sitagliptin (SITA) was compared to that of placebo (PBO) in a 26-week, double-blind, randomised Phase 3 trial.

Materials and methods: Patients (n=291) with HbA1c 8.0-10.5% on diet and exercise were randomised 1:1:1 to ERTU 5 mg + SITA 100 mg (E5/S100), ERTU 15 mg + SITA 100 mg (E15/S100), or PBO.

Results: Baseline characteristics were generally comparable among groups (mean age 55.6 years, HbA1c 8.9%, T2DM duration 6.3 years, eGFR 90.7 mL/min/1.73m^2). After 26 weeks, significantly greater reductions from baseline were observed in HbA1c, fasting plasma glucose (FPG), 2-hour post meal glucose (PMG), body weight, and systolic blood pressure (SBP) in patients receiving E5/S100 and E15/S100 compared with PBO (Table). Observed reductions in diastolic BP were not significant (p>0.05). The odds of having an HbA1c <7.0% were significantly higher in E5/S100 and E15/S100 groups than PBO. The incidence of adverse events (AEs) was generally similar across groups. Pre-specified AEs of urinary tract infections, genital mycotic infections by gender, symptomatic hypoglycaemia and hypovolaemia were subjected to inferential testing: incidence rates were low and not significantly different across groups.

Conclusion: Initial co-administration of ERTU with SITA provided effective glycaemic control over 26 weeks and was generally well-tolerated.

Long-term efficacy and safety of ertugliflozin monotherapy in patients with inadequately controlled type 2 diabetes despite diet and exercise: the 52-week VERTIS MONO study

S. Terra[1], J. Frias[2], A. Goldman[1], R. Aronson[3], A. Darekar[4], S. Huyck[5], B. Lauring[5];
[1]Pfizer, Andover, [2]National Research Institute, Los Angeles, USA, [3]LMC Diabetes & Endocrinology, Toronto, Canada, [4]Pfizer, Tadworth, UK, [5]Merck & Co, Inc., Kenilworth, USA.

Background and aims: Ertugliflozin (ERTU) is an oral sodium-glucose cotransporter 2 inhibitor that is in development for the treatment of patients with T2DM. This Phase 3, multicenter, randomised study in adults with T2DM and HbA1c 7.0-10.5% despite diet and exercise comprised a 26-week, double-blind, placebo (PBO)-controlled period followed by a 26-week, active-controlled period in which patients in the PBO arm who had not received glycaemic rescue therapy had metformin (MET) added. Efficacy and safety of ERTU through Week 52 are reported.
Materials and methods: Patients (N=461) with baseline mean (± SD) age 56.4 (± 11.0) years, T2DM duration 5.0 (± 5.1) years, BMI 33.0 (± 6.7) kg/m^2 and HbA1c 8.2 (± 1.0)% were randomized to PBO, ERTU 5 mg/day or ERTU 15 mg/day in a 1:1:1 ratio. Least square (LS) mean (95% CI) changes from baseline in efficacy endpoints, and the proportion of subjects with HbA1c <7% at Week 52 were assessed for the ERTU groups. Genital mycotic infection (GMI), urinary tract infection (UTI), symptomatic hypoglycaemia and hypovolaemia adverse events (AEs) were subject to inferential testing without multiplicity control (p-values provided if <0.05).
Results: At Week 52, clinically meaningful reductions from baseline in HbA1c, fasting plasma glucose (FPG), body weight and systolic blood pressure (SBP) were observed in both ERTU groups. Approximately one-third of patients who received ERTU had HbA1c at goal (Table). Incidence of GMIs in females was significantly higher for ERTU 5 mg (26.9%; p=0.010) and ERTU 15 mg (29.0%; p=0.005) vs PBO/MET (9.9%) and in males, was higher for ERTU 5 mg (3.4%) and significantly higher for ERTU 15 mg (7.8%; p=0.042) vs PBO/MET (1.2%). The majority of GMIs occurred in the first 6 months of treatment. Incidence of UTIs was lower for ERTU 5 mg (10.9%) and ERTU 15 mg (6.6%; p=0.039) vs PBO/MET (13.7%). ERTU did not increase the incidence of symptomatic hypoglycaemia or hypovolaemia compared with PBO/MET.
Conclusion: ERTU, given over 52 weeks to adults with inadequately controlled T2DM despite diet and exercise, improved glycaemic control, reduced body weight and SBP, but increased the incidence of GMIs.

	Endpoint	ERTU 5 mg	ERTU 15 mg
Change from baseline at Week 52 [LS mean (95% CI)][a]	HbA1c (%)	-0.74 (-0.89, -0.58)	-0.89 (-1.05, -0.74)
	FPG (mmol/L)	-1.67 (-2.06, -1.28)	-2.08 (-2.46, -1.71)
	Body weight (kg)	-3.23 (-3.91, -2.55)	-3.38 (-4.06, -2.71)
	SBP (mmHg)	-3.27 (-5.57, -0.97)	-2.24 (-4.42, -0.05)
	DBP (mmHg)	-0.73 (-2.14, 0.67)	0.18 (-1.15, 1.51)
Percentage of patients with HbA1c <7% at Week 52[b]		29.5	33.1

All efficacy analyses are based on the full analysis set, excluding data after initiation of glycaemic rescue therapy. Patients initially randomised to PBO and not rescued during the first 26-week period switched to MET in the active-controlled period; therefore, there were no formal comparisons for efficacy between the PBO/MET and ERTU treatment arms at Week 52.
[a]LS means obtained from a cLDA model with fixed effects for treatment, time, prior antihyperglycaemic medication (yes, no), baseline eGFR (continuous) and the interaction of time (categorical variable) by treatment. Time was treated as a categorical variable.
[b]Missing data at Week 52 imputed using the cLDA model fitted with fixed effects as in the primary analysis.
cLDA, constrained longitudinal data analysis; DBP, diastolic blood pressure; eGFR, estimated glomerular filtration rate.

Glycaemic control and beta cell function in type 2 diabetes on SGLT2i and GLP-1RA combination therapy

R. Martinez, H. Al-Jobory, J. Adams, A. Chavez-Velasquez, C. Triplitt, R.A. DeFronzo, E. Cersosimo;
Medicine/Diabetes, University of Texas, San Antonio, USA.

Background and aims: To examine whether SGLT2 inhibition plus GLP-1RA combination therapy provides superior clinical and metabolic benefit compared to monotherapy with each agent,
Materials and methods: We randomized 24 inadequately controlled (A1c=8.3+/-0.35) T2D patients treated with met +/- SU to receive either canagliflozin (300 mg/d; n=8, CANA), liraglutide (1.8 mg/d; n=8, LIRA) or both (n=8, COMBO). Baseline characteristics were similar across all groups. After a baseline OGTT and measurements of systolic blood pressure [SBP], body weight [BW], A1c & fasting plasma glucose [FPG], a 16-wk treatment period was started. Clinical parameters & OGTT were repeated at study end. Matsuda [MI]* for insulin sensitivity, insulinogenic index [ΔI/ΔG] & insulin secretion/insulin resistance [disposition] index [IS/IR=ΔI/ΔG **X** MI*] were calculated.
Conclusion: Combination therapy with canagliflozin and liraglutide is accompanied by a greater than additive effect on body weight and systolic blood pressure, and an additive effect on glycemic control and beta cell function. These findings provide strong rationale for the use of SGLT2i and GLP-1RA in poorly controlled T2D patients to decrease A1c, improve beta-cell function, and promote body weight reduction.

Background and aims: Recent clinical studies have indicated that sodium-glucose cotransporter 2 (SGLT2) inhibitors may reduce not only fat mass but also lean body mass. It is important to elucidate the factors contribute to change in body composition and glucose-lowering effect of SGLT2 inhibitors. Our aim was to evaluate the changes in soft lean mass (SLM), representative of muscle volume, and metabolic parameters in relation with food intake and physical activity during tofogliflozin treatment in Japanese patients with type 2 diabetes (T2DM).
Materials and methods: This was a prospective observational study, enrolled 20 obese patients with T2DM (10 males, 10 females, age 58.6 ± 9.8 years, body weight 72.9 ± 14.1 kg, HbA1c 8.0 ± 0.4%). Patients received tofogliflozin 20 mg once daily for 24 weeks. Body composition assessed by bioelectrical impedance analysis, metabolic parameters, dietary intake, and physical activity score were evaluated at baseline, 4, 12, and 24 weeks. The primary endpoint was change in SLM from baseline to week 24. To examine the influence of dietary intakes, we examined the correlation between changes in HbA1c or loss of SLM and change in food intake.
Results: SLM significantly decreased by -1.46 kg (95% confidence interval (CI): -1.96, -0.98, $p < 0.001$) at 24 weeks with the change in body weight by -1.89 kg (95% CI: -2.50, -1.22, $p < 0.001$). Fasting plasma glucose and HbA1c decreased significantly at 24 weeks (167.6 ± 38.6 to 128.1 ± 25.2 mg/dl, $p<0.001$, and 8.11 ± 0.38 to 7.30 ± 0.44%, $p<0.001$, respectively). Daily total energy and carbohydrate intake did not differ significantly at 12, 24weeks compared with baseline. However, changes in HbA1c showed significant positive correlation with changes in carbohydrate intake ($r = 0.70$, $p = 0.004$), while changes in total energy intake did not show correlation with changes in HbA1c ($r = 0.35$, $p = 0.18$). Physical activity score at baseline and 24weeks showed negative correlation with SLM reduction ($r=0.65$, $p=0.016$, and $r=0.56$, $p=0.045$, respectively). Fasting plasma C-peptide (CPR) decreased significantly after 24 weeks of treatment (2.56 ± 1.21 to 2.24 ± 0.86 ng/ml, $p=0.016$), and the decrease in CPR was correlated with SLM reduction ($r = 0.62$, $p = 0.026$).
Conclusion: Tofogliflozin significantly decreased SLM, and the loss of SLM might be caused by increased energy loss through enhanced urinary glucose excretion with decrease in insulin secretion and low physical activity. In addition, increase in carbohydrate intake attenuated HbA1c reduction suggesting that adequate diet therapy is necessary to retain glucose-lowering effect of SGLT2 inhibitors.

A 12-week dose-ranging study of sotagliflozin, a dual SGLT1 and SGLT2 inhibitor, as adjunct therapy to insulin in type 1 diabetes (inTandem4)

C. Baker[1], S. Wason[2], P. Banks[2], S. Sawhney[2], P. Strumph[2], The Sotagliflozin inTandem4 Writing Group;
[1]Diabetes & Endocrine Associates, P.C., Omaha, [2]Lexicon Pharmaceuticals, Inc., The Woodlands, USA.

Background and aims: Sotagliflozin (SOTA) is a dual SGLT1 and SGLT2 inhibitor in Phase 3 development for type 2 diabetes (T2D) and as adjunct to insulin in type 1 diabetes (T1D). Inhibition of SGLT1 delays and reduces glucose absorption in the proximal intestine, improving postprandial glycemic control. SGLT2 inhibition reduces renal glucose reabsorption.
Materials and methods: In a double-blind Phase 2 dose-ranging trial, 141 adults with T1D treated with MDI or pump and A1C 7.0-10.0% at screening were randomly assigned 1:1:1:1 to once-daily SOTA (75, 200, 400 mg) or placebo, and stable insulin dosing for 12 weeks.
Results: Baseline characteristics (expressed as range of means for the arms) were comparable among groups; age: 42-48 yrs, duration of T1D: 22-27 yrs, BMI: 27-32 kg/m^2, total daily insulin: 0.65 -0.77 U/kg, A1C at randomization: 7.95-8.07%. After 12 weeks, adjunctive SOTA 200 and 400 mg were more effective than placebo in reducing A1C. All dosages of SOTA reduced body weight and increased UGE vs. placebo. SOTA 400 mg was more effective than placebo in decreasing 2-hour PPG, and decreasing SBP in those with SBP ≥130 mm Hg at baseline. The overall incidence of TEAEs was lower in the SOTA arms. Incidences of DKA, SH, nausea, diarrhea and genital mycotic infections, were low.
Conclusion: These results support the use of SOTA 200 mg and 400 mg as Phase 3 doses in the T1D development program.

24-week efficacy and safety of sotagliflozin, a dual SGLT1 and SGLT2 inhibitor, as adjunct therapy to insulin in type 1 diabetes (inTandem1)

J.B. Buse[1], S. Garg[2], J. Rosenstock[3], P. Banks[4], S. Sawhney[4], P. Strumph[4], The Sotagliflozin inTandem1 Writing Group;
[1]Endocrinology and Metabolism, University of North Carolina School of Medicine, Chapel Hill, [2]Barbara Davis Center for Diabetes, Aurora, [3]Dallas Diabetes Research Center at Medical City, Dallas, [4]Lexicon Pharmaceuticals, Inc., The Woodlands, USA.

Background and aims: Sotagliflozin (SOTA) is a dual SGLT1 and SGLT2 inhibitor in Phase 3 development for type 2 diabetes (T2D) and as adjunct to insulin in type 1 diabetes (T1D). Inhibition of SGLT1 delays and reduces glucose absorption in the proximal intestine, improving postprandial glycemic control. SGLT2 inhibition reduces renal glucose reabsorption.
Materials and methods: In a double-blind Phase 3 trial, 793 adults with T1D, treated with multiple daily injection or pump therapy, with A1C 7.0-11.0% at Screening were randomized 1:1:1 to placebo or SOTA 200 or 400 mg after a 6-week insulin optimization period.
Results: Baseline characteristics were comparable among groups. Total mean (SD); age: 46.1 (13.1) yrs, T1D duration: 24.4 (12.8) yrs, BMI: 29.7 (5.4) kg/m^2, Total daily insulin dose: 0.73 (0.36) U/kg, Baseline A1C: 7.58 (0.73) %. After 24 weeks, adjunctive SOTA 200 and 400 mg resulted in greater A1C reduction than placebo with more patients achieving the prespecified "net benefit" composite endpoint of A1C <7.0% and no severe hypoglycemia (SH) and no DKA (Table). Incidences of treatment-emergent adverse events were similar across groups. There was more SH in the placebo arm and more genital mycotic infections, diarrhea, and DKA in the SOTA arms.
Conclusion: In this study, SOTA adjunct therapy to insulin in T1D, improved glycemic control with a safety profile supporting further clinical development.

PS 071 SGLT2 inhibitors: glucagon and liver issues

886

Glucagon levels during short-term SGLT2 inhibition are largely regulated by plasma glucose changes

P. Lundkvist[1], M.J. Pereira[1], P. Kamble[1], P. Katsogiannos[1], R. Esterline[2], A.M. Langkilde[2], E. Johnsson[2], J.W. Eriksson[1];
[1]Department of Medical Sciences, Uppsala University, Uppsala, [2]AstraZeneca, Mölndal, Sweden.

Background and aims: Sodium glucose cotransporter 2 (SGLT2) inhibitors have been reported to increase glucagon (glg) secretion, but it is not known to what extent this is mediated via direct islet effects or plasma glucose (PG) lowering. We assessed the impact of PG changes following acute SGLT2 inhibition on circulating levels of glg and lipid-derived energy substrates.
Materials and methods: In a randomized 3-way crossover open-label study, 15 metformin-treated T2D patients (12 M, age 67±6y, BMI 27.1 ±2.9 kg/m^2, HbA1c 56±6 mmol/L; mean±SD) were investigated after overnight fast. A single oral dose of dapagliflozin (Dapa) 10mg was given at the start of all investigations, directly followed by a 5h variable infusion of 10% glucose to maintain glucose at the ambient baseline level (ΔAUC for PG 0 ±1%; mean±SEM; **visit G**) or isotonic NaCl allowing PG to drop (-16±1%; **visit N**). Glg, insulin (ins) and energy substrates were measured repeatedly during infusion periods and urinary glucose excretion was assessed. The 5h infusions were followed by 2h OGTTs, and in addition oral saxagliptin 5mg was co-administered with Dapa at one visit (not reported here).
Results: Plasma glucagon, the primary endpoint measure, was significantly lower during visit **G** vs **N**, but fell from baseline in both cases. Insulin and C-peptide were decreased in visit **N** but not in **G**. Glg/ins ratio markedly rose in visit **N** and fell during visit **G**. NEFA, glycerol and β-OH-ketones increased during visit **N** and levels were higher than in visit **G**. UGE correlated to glucose infusion rate during visit **G** (R^2 0.60, $p<0.05$), but it did not differ significantly between visit **G** and **N** (17±2.6 vs 13±1.1 g/5h). In multivariate regression analyses, change in PG during **G** and **N** visits was the only significant predictor of change in glg (R^2 0.28, $p<0.01$) following adjustments for age, sex, BMI and HbA1c. Fasting PG, ins and glg as well as ins changes and UGE were not significantly associated with glg changes. Glycerol, NEFA and β-OH-ketones were all lower during **G** vs **N**.
Conclusion: In T2D patients given a single dose Dapa, short-term glucagon regulation is largely mediated by glycemic changes. Direct α-cell effects by SGLT2 inhibition may be of less importance. In this study, no short-term rise in glucagon was seen after Dapa administration. Glucose lowering can also contribute to increased lipolysis, lipid oxidation and ketogenesis following SGLT2 inhibition.

Percent change from baseline with dapa 10 mg; 5 h glucose vs NaCl infusion

Dapagliflozin increases glucagon secretion via direct effect on electrical activity in pancreatic A cells

M.F. El Hachmane, S.O. Göpel;
Astrazeneca, Mölndal, Sweden.

Background and aims: Glucagon (gcg) is one of the major regulators of blood glucose levels and its physiological role is to protect against hypoglycemia via stimulation of hepatic glucose output. Recently it has been shown that Na^+/glucose co-transporter2 inhibitors (SGLT2i) used for the treatment of diabetes increase glucagon levels in man. As for most neuroendocrine cells glucagon release from A-cells is regulated by electrical activity and we thus investigate if SGLT2i affect glucagon release via its electrogenic effects. Basal glucagon levels are elevated in all types of diabetes which contributes to diabetic hyperglycemia. In addition, diabetics lack proper glucagon response at low glucose, increasing the risk for dangerous hypoglycemia. Therefore it is important to understand the regulation of glucagon release and how it is affected by Dapagliflozin.
Materials and methods: Glucagon secretion was measured by ELISA assays. Dapagliflozin sensitive currents were recorded from A-cells by using the standard whole cell patch clamp configuration.
Results: Pancreatic A-cells were functionally identified by the inactivation properties of a TEA-resistant K+- and voltage sensitive Na+-currents. Resting conductance was measured by applying 10 mV pulses before and after addition of 10 nM Dapagliflozin. In A-cells Dapagliflozin reduced the resting conductance by 57.5 ± 24.9 pS (n = 7) but only by 8.6 ± 11.3 pS in non A-cells (n = 16), $p < 0.05$. We and other have previously shown that application of increasing doses of the KATP-channel opener diazoxide at high (11 mM) glucose results in a bell shaped dose response curve in glucagon secretion. SGLT2 transporters can be viewed as a background conductance giving rise to an inward depolarizing current. Blocking SGLT2 with dapagliflozin should thus be equivalent to activating outward, hyperpolarizing KATP-currents with diazoxide. Dapagliflozin should therefore produce a leftward shift of the diazoxide dose response curve. Our experimental data of secretion measurements confirmed this hypothesis. Dapagliflozin shifted the peak of the diazoxide dose response curve from 10 to 3 μM. whereas the fold stimulation was not affected (1.9 ± 0.3 at 3uM diazoxide + dapagliflozin ($p < 0.05$, n = 13) and 2.1 ± 0.3 at 10uM diazoxide, ($p < 0.05$, n = 13) compared to 11 mM glucose alone. Dapagliflozin did not affect insulin secretion making it unlikely that SGLT2 inhibition affects glucagon release via a paracrine mechanism.
Conclusion: Dapagliflozin reduces inward currents and increases glucagon secretion at high glucose via a direct effect on pancreatic A-cell electrical activity. The absence of any effect on insulin secretion makes it unlikely that dapagliflozin affects glucagon release paracrine via modulation of insulin or somatostatin since somatostatin inhibits both insulin and glucagon secretion. Blood glucose reduction achieved with SGLT2 inhibitors is similar to other treatments. It is thus unlikely that the increase in glucagon levels seen in patients treated with SGLT2 inhibitors is due to reduced blood sugar but rather due to a direct interference with A-cell electrical activity.

The GLP1R agonist liraglutide inhibits hyperglucagonaemia induced by the SGLT2 inhibitor dapagliflozin

C. Bonner[1,2], C. Saponaro[2], V. Gmyr[2], E. Moerman[2], J. Thevent[2], N. Delalleau[2], G. Pasquetti[2], A. Quenon[2], J. Kerr-Conte[2], F. Pattou[2];
[1]Institute Pasteur, Lille, Lille Cedex, [2]Inserm U1190: Translational Research for Diabetes, Lille, France.

Background and aims: The newest pharmacologic treatments for type 2 diabetes (T2D) include glucagon-like peptide-1 receptor agonists (GLP1R-A) and sodium-glucose cotransporter 2 inhibitors (SGLT2-I). A recent clinical study in patients with T2D has demonstrated that the dual therapy with GLP1R-A and SGLT2-I reduced HbA1c levels more effectively than therapy with a GLP1R-A alone. However, there are currently no studies evaluating GLP1R-A, SGLT2-I, or the combination therapy, simultaneously. The aim of the current study was to determine the efficacy and the mechanism of action of the SGLT2-I, dapagliflozin, and GLP1R-A liraglutide, as mono-therapies or in combination for the treatment of T2D.
Materials and methods: Human pancreatic tissue, islets and plasma from healthy and diabetic mice were studied. GLP1R expression in the human pancreas was assessed by histology and qPCR analysis. Drug treatments with dapagliflozin and liraglutide were assessed for glycemia and pancreatic hormone secretion.
Results: Here we demonstrate that GLP1R is localized in alpha, beta and delta cells of human pancreatic islets. We also found that GLP1R gene expression was induced in the islets of obese normoglycemic and T2D individuals. Consistent with our previous data, SGLT2 inhibition by dapagliflozin induces glucagon secretion in human islet cultures, an effect that was markedly reduced by co-treatment with liraglutide. In healthy mice, we found that liraglutide alone or in the combination therapy significantly reduced glycemia and glucagon induced by dapagliflozin after an intra-peritoneal (IP) injection of glucose. However, acute (single administration) and chronic treatment (45 days) of db/db (diabetic) mice with the combination therapy markedly improved glycemic control compared to dapagliflozin or liraglutide treatments alone. Moreover, liraglutide significantly reduced hyperglucagonemia induced by dapagliflozin during fasting and after an IP injection of glucose.
Conclusion: Our results suggest that the combination of dapagliflozin and liraglutide needs to be studied in a prospective clinical trial because the effect of each of the molecules is synergistically enhanced by the addition of the partner drug.

Enlarged islet size, altered insulin$^+$ and glucagon$^+$ cell frequencies and modified blood-values for GLP-1, insulin and glucagon in Sglt1 knockout mice

M. Muehlemann[1], D. Zdzieblo[1], A. Friedrich[2], M. Hofmann[3], C. Otto[3], H. Koepsell[2], H. Walles[1,4], M. Metzger[1,4];
[1]Chair Tissue Engineering and Regenarative Medicine, University Hospital Wuerzburg, [2]Institute of Anatomy and Cell Biology, University Wuerzburg, [3]Department of General, Visceral, Vascular and Pediatric Surgery, University Hospital Wuerzburg, [4]Fraunhofer-Institute

Interfacial Engineering and Biotechnology IGB Translational Centre, Wuerzburg, Germany.

Background and aims: Inhibition of the sodium dependent glucose transporter (Sglt) 2 is a promising strategy in the treatment of diabetes leading to diminished glucose reabsorption from the kidney thereby contributing to glycemic control. Recently, also Sglt1 gained much attention in this context. Sglt1 is predominantly expressed in enterocytes of the small intestine regulating intestinal glucose uptake. So far, it was shown that Sglt1 inhibition contributes to the regulation of glucose homeostasis by reducing intestinal glucose absorption and upregulation of integrin secretion. However, if Sglt1 inhibition has additional effects of on other organs in terms of structural or functional changes still needs to be further investigated. Therefore, the aim of this study was to investigate if the loss of Sglt1 function in mice impacts on structure, cellular composition or function of pancreatic islets.
Materials and methods: Pancreatic islets were analyzed in Sglt1 knockout mice fed with a sugar-free, high fat diet ($Sglt1^{-/-}$). C57Bl/6 wildtype mice fed with standard chow (WTND) or fed with sugar-free, high fat diet (WTSD) served as controls. *Sglt1* expression was determined by qRT-PCR. Quantification of islet size was performed on hematoxylin & eosin (H&E)-stained pancreas sections. Immunohistochemical (IHC) stainings for insulin (INS) and glucagon (GCG) were used to investigate cellular composition of islets regarding the two most frequent cell types. Glucose-stimulated insulin secretion was performed on pancreatic islets *in vitro.* Furthermore, effects on INS, GCG or glucagon-like peptide 1 (GLP-1) levels in blood were analyzed by enzyme-linked immunosorbent assays (ELISA).
Results: In comparison to WTND and WTSD controls, pancreatic islets of Sglt1-/- mice displayed a significantly enlarged mean islet area. Additionally, Sglt1-/- islets showed increased frequencies for GCG+ cells while INS+ cells are less frequent in comparison to WTND or WTSD controls. Further, data obtained by glucose-stimulated insulin secretion assay revealed no response of Sglt1-/- islets and a delayed response of islets isolated from WTSD mice in comparison to the WTND control. Finally, basal blood-values for GLP-1 were increased in WTSD mice compared to the WTND or Sglt1-/- group while INS or GCG levels were similar in all three groups.
Conclusion: Our data show that Sglt1 knockout in mice impacts on size, cellular composition and function of pancreatic islets. Taken together, these findings suggest that further intense research is necessary to understand short and long term associated impacts of pharmacological Sglt1 inhibition on other organs to define its role as therapeutic option for the treatment of diabetes.

Effect of dapagliflozin, saxagliptin, and the combination of both on glucagon, endogenous glucose production (EGP) and glycerol in patients with type 2 diabetes

S. Sach-Friedl[1], T. Augustin[2], C. Magnes[2], E. Ekardt[1], A. Eberl[2], S. Narath[3], M. Brunner[1], S. Korsatko[1], E. Svehlikova[1], G. Treiber[1], T.R. Pieber[1,2];
[1]Medical University of Graz, [2]HEALTH - Institute of Biomedicine and Health Sciences, Joanneum Research, [3]CBmed - Center for Biomarker Research in Medicine, Graz, Austria.

Background and aims: In recent investigations, the use of the SGLT-2 inhibitors has been associated with an increased risk of glucagon-induced diabetic ketoacidosis (DKA). The aim of this trial was to investigate the role of glucagon on EGP and glycerol rate of appearance (Ra glycerol) during treatment with either the SGLT-2i dapagliflozin and/or the DPP-4i saxagliptin in metformin only treated T2DM.
Materials and methods: In this randomized, double-blind crossover trial, 17 patients (age 53 ± 6 ys, diabetes duration 7.6 ± 5.8 ys, BMI 29.4 ± 3.5 kg/m², HbA1c 60.6 ± 10.3 mmol/mol (7.7 ± 3.1 %)) underwent a stepwise eu- (5.5 mmol/L, ambient insulin level), hyper- (11.1 mmol/L, no insulin), and high insulin (2.5mU/kg/min) hypoglycaemic clamp (5.5, 3.5, 2.5 mmol/L) with primed tracer infusion of [6,6-$2H_2$]glucose (prime: 9.6mg/kg, constant: 0.08mg/kg/min) and [1,1,2,3,3-$2H_5$]glycerol (prime: 1.5μmol/kg, constant: 0.1μmol/kg/min) at baseline and on day 7 of once daily treatment with dapagliflozin, or saxagliptin, or dapagliflozin+ saxagliptin. Glucagon was measured by specific double sandwich ELISA (Mercodia AB, Sweden). Isotopic glucose and glycerol were measured with gas-chromatography mass spectrometry.
Results: Dapagliflozin (with and without saxagliptin) did not increase glucagon during eu-, hyper-, and hypoglycaemia compared to no treatment. All 3 treatments significantly reduced EGP during hyper- (p=0.003-0.044), but not during hypoglycaemia. Compared to no treatment or saxagliptin, dapagliflozin did not increase Ra glycerol during eu-, hyper-, and hypoglycaemia. NEFA concentrations were significantly reduced during hyperglycaemia in saxagliptin (p=0.0041) and saxagliptin+dapagliflozin (p=0.046) treatment compared to no treatment. Ketone bodies were not significantly different. Insulin level was comparable for all treatment groups. C-Peptide was significantly higher during hyper- and hypoglycaemia (p=0.0084-0.0004) for dapagliflozin+saxagliptin compared to no treatment. No significant differences were observed for counterregulatory hormones adrenalin, human growth hormone (HGH) and cortisol. Saxagliptin reduced noradrenalin concentration significantly during euglycaemia at ambient insulin levels compared to no treatment (p=0.0497) and dapagliflozin (p=0.0126) and euglycaemia at high insulin levels compared to dapagliflozin (p=0.0135).
Conclusion: Dapagliflozin did not increase overall glucagon levels, Ra glycerol and EGP in metformin treated T2DM patients. Our data suggest that the risk of DKA during treatment with SGLT-2 inhibitor dapagliflozin is not mediated via glucagon associated fuel shift.

Effect of canagliflozin on liver function tests in patients with type 2 diabetes and presumed liver fibrosis suggestive of non-alcoholic steatohepatitis

G. Meininger[1], D. Polidori[2];
[1]Janssen Research & Development, LLC, Raritan, [2]Janssen Research & Development, LLC, San Diego, USA.

Background and aims: Type 2 diabetes mellitus (T2DM) and obesity are risk factors for non-alcoholic fatty liver disease (NAFLD), including its more severe form, non-alcoholic steatohepatitis (NASH). Non-invasive liver fibrosis risk scores, such as Fibrosis (FIB)-4, have been used in lieu of liver biopsy to identify patients with presumed liver fibrosis suggestive

of NASH. Canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor, has been previously shown to improve glycaemic control, body weight (BW), and liver function tests (LFTs; eg, alanine aminotransferase [ALT], aspartate aminotransferase [AST], gamma glutamyl transferase [GGT]) across a broad array of T2DM patients in Phase 3 studies. Whether CANA improves LFTs in patients with T2DM and presumed liver fibrosis suggestive of NASH is unknown.

Materials and methods: This post hoc analysis used pooled data from the 4 placebo (PBO)-controlled, Phase 3 studies in a general population of patients with T2DM with an elevated FIB-4 score (≥1.3) consistent with liver fibrosis (~20% of the total population, N = 501; mean (SD) baseline BW = 89 (21) kg, HbA1C = 7.9 (0.9) %, ALT = 31 (20) U/L, AST = 30 (18) U/L, GGT = 49 (63) U/L, total bilirubin = 10 (5) μmol/L).

Results: At 26 weeks, both ALT and GGT were reduced with CANA 100 and 300 mg compared with PBO (Table).

Conclusion: In summary, in patients with T2DM and presumed liver fibrosis suggestive of NASH, both CANA 100 and 300 mg reduced liver enzymes compared with PBO.

Table. Changes in LFTs with CANA at Week 26.

	PBO	CANA 100 mg	CANA 300 mg

Intra- and inter-subject variability for increases in plasma ketone bodies in patients with type 2 diabetes treated with the SGLT2 inhibitor canagliflozin

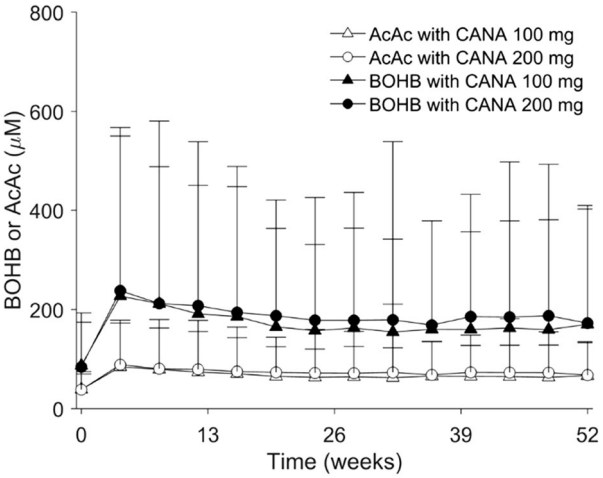
D. Polidori[1], P. Crawford[2];
[1]Janssen Research & Development, LLC, San Diego, [2]Sanford Burnham Prebys Medical Discovery Institute, Orlando, USA.

Background and aims: Overnight-fasted plasma ketone body concentrations are typically ~50-200 μM. Dramatic increases occurring during prolonged fasting or diabetic ketoacidosis have been well characterized, but the effects of modest changes in ketones occurring under different conditions are less understood. Recent findings indicate that failing hearts increasingly rely on ketones for energy, and that sodium glucose co-transporter 2 inhibitors (SGLT2i) modestly increase plasma ketones in most patients. These observations have stimulated a hypothesis that increases in ketones may contribute to SGLT2i-associated reductions in adverse cardiovascular and renal outcomes.

Materials and methods: Data from SGLT2i trials indicate that mean plasma ketone concentrations approximately double, with high between-subject variability. Here, we analyse data from a Phase 3 study with the SGLT2i canagliflozin. Overnight-fasted ketone concentrations were measured every 4 weeks for 52 weeks in 1,278 Japanese subjects treated with canagliflozin 100 or 200 mg.

Results: Mean plasma acetoacetate and β-hydroxybutyrate concentrations were increased at all post baseline visits, with similar increases seen with both canagliflozin doses (Figure). Median (interquartile range) percent change from baseline was 62% (180) for acetoacetate and 78% (234) for β-hydroxybutyrate. Approximately 2/3 of the variability in each measure was attributed to within-subject variability. Within-subject variability for plasma ketones is higher than that for other metabolites, and accounted for only 9%-17% of total variability for plasma glucose and HbA1c. Subjects in the lowest-response tertile exhibited no mean increase in ketones at any visit. Those in the highest-response tertile tended to be male and have the largest decrease in fasting glucose. Moreover, changes in plasma ketones were not fully explained by changes in plasma fatty acids, suggesting downstream effects of SGLT2i on hepatic metabolism that favour ketogenesis.

Conclusion: Canagliflozin treatment increases plasma ketone bodies in Japanese patients with T2DM, with high intra-patient variability. The increase in plasma ketone bodies is greater in magnitude and more variable than changes in other metabolic measures.



AcAc, acetoacetate; CANA, canagliflozin; BOHB, β-hydroxybutyrate.

Effects of canagliflozin versus glimepiride on adipokines, inflammatory biomarkers, and chemokines in patients with type 2 diabetes

L. Van Gaal[1], W.T. Garvey[2], L.A. Leiter[3], U. Vijapurkar[4], J. List[4], R. Cuddihy[5], J. Ren[6], M.J. Davies[6];
[1]Department of Endocrinology, Diabetology and Metabolism, Antwerp University Hospital, Antwerp, Belgium, [2]UAB Diabetes Research Center, University of Alabama at Birmingham, Birmingham, USA, [3]Division of Endocrinology & Metabolism, Li Ka Shing Knowledge Institute and Keenan Research Centre for Biomedical Science, St. Michael's Hospital, University of Toronto, Toronto, Canada, [4]Janssen Research & Development, LLC, Raritan, USA, [5]Janssen Global Services, LLC, Raritan, USA, [6]Janssen Scientific Affairs, LLC, Titusville, USA.

Background and aims: Type 2 diabetes mellitus (T2DM) and obesity are pro-inflammatory states that are associated with an increased risk of cardiovascular disease (CVD). Canagliflozin (CANA), a sodium glucose co-

transporter 2 (SGLT2) inhibitor, demonstrated superiority in lowering HbA1c versus glimepiride (GLIM) and greater body weight reduction via loss of fat mass in a 52-week, Phase 3 trial of patients with T2DM on metformin. This post hoc analysis assessed the effects of CANA versus GLIM on select adipokines, inflammatory markers, and chemokines that have been associated with impaired adipose tissue function, insulin resistance, and CVD.

Materials and methods: Serum samples were from randomly selected patients receiving CANA 300 mg (n = 100) or GLIM (n = 100) in the overall study. Change from baseline to Week 52 in serum leptin, adiponectin, CRP, PAI-1, VCAM-1, and MCP-1 was measured using a multiplex assay (Myriad RBM). Change in serum IL-6 and TNFα was measured with ultra high-sensitivity assays (Simoa-Quanterix). Change in leptin, adiponectin, and IL-6 was correlated with change in HbA1c, body weight, and lipids (HDL-C, LDL-C, triglycerides) within each group.

Results: At Week 52, the least squares mean (LSM) change in HbA1c was -0.99% with CANA and -0.91% with GLIM (baseline, 7.7-7.8%). LSM change in body weight was -4.1 kg with CANA and 0.7 kg with GLIM (baseline, 90-91 kg). At Week 52, median serum leptin was decreased 25% with CANA versus GLIM (-1.1 vs 1.0 ng/mL; difference [95% CI] of -2.8 ng/mL [-4.0, -1.6]). Median serum adiponectin was increased 17% with CANA versus GLIM (0.6 vs 0.0 μg/mL; difference [95% CI] of 0.5 μg/mL [0.3, 0.7]). There was a 22% reduction in median serum IL-6 (-0.3 vs 0.2 pg/mL; difference [95% CI] of -0.5 [-0.7, -0.2]) and a 7% increase in median serum TNFα (0.1 vs -0.1 pg/mL; difference [95% CI] of 0.2 pg/mL [0.0, 0.3]) with CANA versus GLIM. No between-group differences were observed with CRP, PAI-1, VCAM-1, or MCP-1. Change in leptin was correlated with change in body weight ($r \geq 0.35$) only; change in adiponectin and IL-6 was not correlated with change in HbA1c, body weight, or lipids.

Conclusion: CANA 300 mg demonstrated reductions in serum leptin and IL-6, and an increase in adiponectin versus GLIM in patients with T2DM; CANA was also associated with a small increase in TNFα and had neutral effects on other biomarkers. The CANA-related changes in leptin, adiponectin, and IL-6 were independent of glycaemic benefit, and the changes in adiponectin and IL-6 were independent of weight loss in this analysis. These collective results suggest that CANA may improve adipose tissue function, which may have positive effects on cardiometabolic health.

SGLT2 inhibition by empagliflozin attenuates ectopic fat accumulation and improves cardiac index in parallel to ketone bodies production: the EMPAFAT study

F. Maurice[1], P. Ancel[1], E. Mayoux[2], I. Abdesselam[1], F. Kober[3], P. Darmon[1,4], M. Grino[1], B. Gaborit[1,4], M. Bernard[1], A. Dutour[1,4];
[1]Aix Marseille Univ, INSERM 1062, INRA, NORT, Marseille, France, [2]Boehringer-Ingelheim, Department of Cardiometabolic Diseases Research, Biberach, Germany, [3]Aix Marseille Univ, CNRS 7339, CRMBM, Marseille, [4]Endocrinology and Metabolic Diseases Department, AP-HM, Marseille, France.

Background and aims: Ectopic fat deposition including myocardial, hepatic and skeletal muscle steatoses leads to insulin-resistance, cardiomyocytes dysfunction through lipotoxicity. Empagliflozin (EMPA) a specific inhibitor of sodium-glucose co-transporter 2 (SGLT-2), is a novel antihypergylcemic agent which reduced cardiovascular deaths in type 2 diabetic patients. The mechanisms underlying this improvement are yet unknown. Therefore, we set-up in mice a multimodal MR protocol to analyze the early effect of EMPA on cardiac function and ectopic fat deposition.

Materials and methods: C57BL6J/R mice were fed with high-fat (35%)-high-sucrose (34%) diet (HFHS) or standard diet (SD). After 1 month (M0), 30mg/kg EMPA or placebo treatment was initiated orally in the HFHS group. 4.7T MRI examinations were performed at baseline (M0) and after 1month (M1) and 3 month (M3) of treatment to assess cardiac function with cine cardiac MR (CMR) according to the hemisphere cylinder model and myocardial (MTGC), hepatic (HTGC) and muscular (MuTGC) triglyceride contents using ^{1}H-spectroscopy. Intraperitoneal glucose tolerance test (IPGTT) and fasting ketone bodies were assessed at M1 and M3.

Results: EMPA attenuated weight gain, ameliorated glucose homeostasis in mice under HFHS. EMPA decreased significantly ($p<0.05$) glucose AUC during IPGTT (EMPA 332 ± 28 vs HFHS 565± 30; SD 268± 13), HOMA-IR (EMPA 51.5 ± 8.01 vs HFHS 101.3 ± 16.8; SD 10.6 ± 2.7), insulin/glucagon ratio (EMPA 62.3 ± 10.4 vs HFHS 223.4 ± 63.5; SD 35.6 ± 12.7) and EMPA increased ketone bodies levels (β-hydroxybutyrate: 0.14 ±0.01 mM vs 0.09±0.01 mM, p=0.02). HFHS diet increased the three ectopic fat, Muscular triglyceride content (MuTGC), hepatic triglyceride content (HTGC), and myocardial triglyceride content (MTGC), After 1 month of treatment (M1), Empa greatly decreased MuTGC (EMPA 2.09±1.08%, vs HFHS 4.88±1.49%, p=0.004; SD 1.09±0.19%), and HTGC (EMPA 7.6 ±2.4% vs HFHS 33.2±8.5%, p=0.002; SD 2.3±0.7%). A similar effect of EMPA was found at M3. By contrast, the increase in MTGC with HFHS was not prevented by EMPA (EMPA 0.6±0.13% vs HFHS 0.6±0.07%, NS; SD 0.17±0.04). As expected, HOMA-IR was correlated to both MuTGC and HTGC. Cardiac index (CI) was reduced in HFHS mice (HFHS 0.47 ±0.03 vs SD 0.73±0.07 μL/min/g) and EMPA improved cardiac index (0.60 ±0.05, p=0.04) at M1 and M3. In the two HFHS group, Cardiac index was interestingly, positively correlated with ketone levels at M1 (r=0.54, p=0.007) but not with Glycaemia, HOMA-IR, HTGC and MuTGC.

Conclusion: Empagliflozin induced a drastic decrease of ectopic fat in liver and muscle, promoting insulin-sensitivity. Empaglifozin prevented the deleterious effect of HFHS diet on cardiac function that seems correlated to a shift in myocardial fuel source involving ketones.

Dapagliflozin for treatment of prednisone induced hyperglycaemia: a double-blind randomised clinical trial

M.C. Gerards[1], T.M. Vriesendorp[2], J.B.L. Hoekstra[3], V.E.A. Gerdes[1], B.J. Potter van Loon[4];
[1]Internal Medicine, MC Slotervaart, Amsterdam, [2]Internal Medicine, Isala, Zwolle, [3]Internal Medicine, Academic Medical Center, Amsterdam, [4]Internal Medicine, OLVG-West, Amsterdam, Netherlands.

Background and aims: Prednisone treatment for acute exacerbation of chronic obstructive pulmonary disease (COPD) is complicated by hyperglycemia in patients with and without pre-existent diabetes mellitus. Hyperglycemia is associated is with longer hospitalization and higher mortality. Treatment can be challenging because of severe insulin resistance. SGLT-2 inhibitors are an interesting treatment option because they are beta-cell independent and because of the quick onset of action. We therefore performed a double-blind randomized placebo controlled study to compare the effectiveness of dapagliflozin to placebo.

Materials and methods: We enrolled 46 subjects hospitalized for COPD exacerbation who were treated with prednisone, ≥ 30 mg daily for 5-14 days and had either a known history of type 2 diabetes or a random blood glucose > 10 mmol/L at admission. Subjects were treated with dapagliflozin 10 mg or placebo as add-on to their routine diabetes medication during their course of prednisone therapy. Subjects continued study medication as long as they were treated with prednisone. Glycemic control was evaluated using a blinded continuous glucose monitor.

Results: Glucose values were in the target range (3.9-10 mmol/L) 54.0 % of the time in the dapagliflozin group and 53.7 % in the placebo group.

There was no difference in mean glucose concentration (dapagliflozin 10.1 mmol/L, placebo 10.4 mmol/L). There were no severe hypoglycemic events. Five subjects in the dapagliflozin group had a non-severe hypoglycemic event versus 6 subjects who were treated with placebo. There was no difference in incidence of urogenital events between the groups.

Conclusion: Once daily dapagliflozin as add-on to routine diabetes medication did not result in better glycemic control in patients with prednisone-induced hyperglycemia during COPD exacerbation. There was no difference in incidence of hypoglycemic events. The glucose lowering efficacy of a short course of dapagliflozin is probably not strong enough to counter hyperglycemic effects of prednisone therapy.

Population pharmacokinetic-pharmacodynamic analysis to characterise the effect of empagliflozin on renal glucose threshold in patients with type 1 diabetes

J. Mondick[1], M. Riggs[1], S. Kaspers[2], N. Soleymanlou[3], J. Marquard[2], V. Nock[4];

[1]Metrum Research Group, Tariffville, USA, [2]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, [3]Boehringer Ingelheim Canada Ltd./Ltee, Burlington, Canada, [4]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany.

Background and aims: Empagliflozin is a sodium glucose cotransporter 2 (SGLT2) inhibitor that increases urinary glucose excretion (UGE) by lowering the renal threshold for glucose (RT_G). The objectives of this analysis were to quantify the effect of the SGLT2 inhibitor empagliflozin on renal glucose reabsorption in patients with type 1 diabetes (T1DM) using a mechanistic population pharmacokinetic-pharmacodynamic (PK-PD) model, and to compare results with analyses in patients with type 2 diabetes (T2DM).

Materials and methods: The PK-PD model was developed using data from a randomized Phase II study in which patients with T1DM received oral placebo or empagliflozin 2.5 mg, 10 mg, or 25 mg QD as adjunct to insulin. The PK-PD data set was comprised of 75 T1DM subjects contributing 1814 plasma empagliflozin concentrations and 895 urine glucose observations

Results: Empagliflozin pharmacokinetics were described using a two-compartment model with sequential zero and first-order absorption and a lag time. The pharmacodynamic model assumed that UGE was dependent on plasma glucose and renal function (accounting for UGE before saturation of reabsorption) and that empagliflozin lowered RT_G. Calculated RT_G with placebo was 181 mg/dL, and with empagliflozin (steady state) 1 mg and 2.5 mg was 53.4 mg/dL and 12.5 mg/dL, respectively. Empagliflozin 10 mg and 25 mg yielded minimal RT_G values. The final model was evaluated using visual predictive checks and found to be consistent with observed data.

Conclusion: Although estimated PK-PD parameters were generally comparable between patients with T1DM and patients with T2DM, population PK-PD simulations demonstrated that the lower RT_G in T1DM patients yielded a higher UGE compared with patients with T2DM.

Exposure to SGLT-2 inhibitors can reverse stearic acid-induced lipotoxicity in human endothelial progenitor cells

V. Spigoni[1], F. Fantuzzi[1], G. Taddei[1], F. Coltellacci[1], E. Derlindati[1], I. Zavaroni[2], A. Solini[3], R.C. Bonadonna[2], A. Dei Cas[2];

[1]University of Parma, [2]University of Parma and AOU of Parma, Parma, [3]University of Pisa, Pisa, Italy.

Background and aims: Lipotoxicity is implicated in the association among insulin resistance, type 2 diabetes, endothelial dysfunction and increased cardiovascular (CV) risk. In a previous research of ours, lipotoxicity impaired the function of key players in the process of endothelial repair, i.e. the human circulating angiogenic cells (CACs, also known as "early" endothelial progenitor cells), the bioavailability of

which predicts CV mortality in humans. Specifically, we showed that in CACs stearic acid (SA) induced a JNK-mediated pro-inflammatory response and lipoapoptosis, through the activation of endoplasmic reticulum (ER) stress. The SGLT-2 inhibitor (SGLT-2i) empagliflozin (EMPA) reduces the risk of CV mortality in people with type 2 diabetes, apparently beyond glucose control, perhaps by impairing Na^+/H^+ exchanger (NHE) flux in target cells, in an cariporide-like fashion. Goal of our study was to test the hypothesis that SGLT2-i can restrain SA-induced lipotoxicity in human CACs.

Materials and methods: CACs were isolated after culturing lymphomonocytes obtained from healthy subjects on fibronectin-coated dishes in endothelial medium (EGM-2) for 7 days. Digital PCR technology was used to test the expression of SGLTs in CACs. CACs were incubated with physiological concentrations of stearic acid (SA) (100 μmol/L) with/without SGLT-2i [EMPA and dapagliflozin (DAPA)] from 1 to 100 μmol/L over time to assess the effects on a) apoptosis (activation of caspases 3/7) b) pro-inflammatory cytokine [interleukin(IL)-1β, IL-6, IL-8, monocyte chemoattractant protein (MCP)-1 and tumor necrosis factor (TNF)-α] and oxidative stress marker [superoxide dismutase 2 (SOD2), thioredoxin (TXN) and heme oxygenase-1 (HO-1)] gene expression by qPCR c) activation of JNK by western blotting. The potential NHE involvement was assessed by adding amiloride and cariporide (both NHE inhibitors) in SA-treated CACs. Statistical analysis: differences between groups were identified using repeated measure ANOVA (followed by Bonferroni post-hoc).

Results: SGLT-2 expression in human CACs was not detected. Both EMPA and DAPA (at 100 μmol/L) inhibited SA-stimulated expression of IL-1β, IL-8, TNF-α and MCP-1 ($p<0.005$ *vs* SA), but, unexpectedly, not via JNK de-activation. Expression of oxidative stress markers (SOD2, TXN, HO-1) was reduced by EMPA and DAPA as strongly as by the antioxidant N-acetyl-cysteine ($p<0.05$ *vs* SA). Amiloride -a non-specific NHE blocker- but not cariporide (a NHE1 specific inhibitor), mimicked the anti-inflammatory effects of EMPA ($p<0.05$).

Conclusion: EMPA and DAPA can curb SA-induced inflammation and oxidative stress in human CACs, probably through SGLT2-independent mechanism(s), of which NHE-inhibition is a viable candidate. This study may be instrumental in disclosing at least some of the mechanisms involved in EMPA- (and possibly DAPA)-mediated CV protection.

Effects of empagliflozin on day-to-day variability of home blood pressure and heart rate in patients with type 2 diabetes

T. Misawa[1], Y. Kawagoe[2], F. Oda[2], M. Ogata[2], F. Sato[3], Y. Takahashi[3];
[1]Department of Internal Medicine, Yamagata Prefectural Kahoku Hospital, [2]Department of Pharmacy, Yamagata Prefectural Kahoku Hospital, [3]Department of Nutrition, Yamagata Prefectural Kahoku Hospital, Yamagata, Japan.

Background and aims: Recent evidence suggests that day-to-day variability of self-measured home blood pressure is strongly associated with cardiovascular and stroke mortality, and the EMPA-REG OUTCOM study documented impressive benefits with empagliflozin on cardiovascular and all-cause mortality and hospitalization for heart failure. However, the effects of empagliflozin in addition to standard care, on day-to-day variability of self-measured home blood pressure (BP) and heart rate (HR) at home in patients with type 2 diabetes (T2DM) at high cardiovascular risk are not known.

Materials and methods: We followed twenty-three consecutive T2DM patients (mean age: 69 years old, 12 men, mean BMI: 29.0 kg/m^2, mean HbA1c: 7.1%) with cardiovascular risk (CHD: 13 patients(pts), hypertension: 17 pts, atrial fibrillation: 5 pts, cardiac failure: 5 pts, stroke: 1 pt) to add 10 mg of empagliflozin once daily for three months. Home BP and HR were measured once every morning at home, using an oscillometric device. The variability of BP and HR were defined as the standard deviations (SD) of measurements which were performed on seven consecutive days.

Results: For home BP, empagliflozin significantly reduced systolic blood pressure (SBP) from 130±11 mmHg at baseline to 126±11 mmHg at the first week(1W) of the administration ($P<0.05$). SBP achieved the target home BP goal (125±11 mmHg) at the second week(2W) and was maintained during the study (4W: 124±10 mmHg, 8W: 125±8 mmHg, 12W: 124±10 mmHg, $P<0.01$). As regards day-to-day variability of SBP, SD mmHg and coefficient of variation (CV: SD/mean) % decreased from 7.3 ±3.5 mmHg and 5.6±2.7 % at baseline to 6.7±2.5 mmHg and 5.4±1.9 %, respectively, at 1W (4W: 5.8±2.3 mmHg and 4.6±1.9 %, 8W: 5.2 ±2.3 mmHg and 4.2±1.9 %, $P<0.05$). In diastolic blood pressure (DBP), there was a significant reduction of SD and CV compared with that at baseline (baseline: 4.9±1.6 mmHg and 6.9±2.3 %, 4W: 4.3 ±1.6 mmHg and 6.3±2.3 %, 8W: 3.9±1.8 mmHg and 5.5±2.5 %, 12W: 4.4±1.6 mmHg and 6.2±2.3 %, $P<0.05$); however, there was no change of DPB (baseline: 71±10 mmHg, 4W: 68±8 mmHg, 8W: 71±9 mmHg, 12W: 71±8 mmHg). Similarly, there was a decreasing trend in SD and CV of HR (baseline: 3.9±1.2 beats per minute (bpm) and 6.3±1.9 %, 1W: 4.3±2.6 bpm and 6.9±4.1%, 4W: 3.3±1.3 bpm and 5.4±2.1 %, 8W:3.5 ±1.8 bpm and 5.7±3.0 %, 12W: 3.1±1.3 bpm and 5.0±2.2 %, $P<0.1$), although there was no significant change in HR (baseline: 62±13 bpm, 1W: 63±11 bpm, 4W: 61±11 bpm, 8W: 61±11 bpm, 12W: 61±12 bpm).

Conclusion: *1,* Empagliflozin significantly reduced systolic home BP, without increasing HR in T2DM patients. *2,* Empagliflozin tended to reduce the day-to-day variability of self-measured morning home BP and HR in T2DM patients.

Empagliflozin (EMPA) reduces heart failure outcomes irrespective of blood pressure (BP), low density lipoprotein cholesterol (LDL-C) and HbA_{1c} control

J. McKnight[1], D. Fitchett[2], J. Lee[3], J.T. George[3], M. Mattheus[3], H.J. Woerle[3], S.E. Inzucchi[4];
[1]Western General Hospital, Edinburgh, UK, [2]St Michael's Hospital, Division of Cardiology, University of Toronto, Toronto, Canada, [3]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, [4]Section of Endocrinology, Yale University School of Medicine, New Haven, USA.

Background and aims: In EMPA-REG OUTCOME, EMPA given in addition to standard of care reduced the risk of hospitalisation for heart failure (HHF) (HR 0.65 [95% CI 0.50, 0.85]) and the composite of HHF or cardiovascular (CV) death (0.66 [0.55, 0.79]) vs placebo (PBO) in patients with type 2 diabetes and established CV disease. We investigated the effects of controlling BP, LDL-C and HbA1c on treatment differences in HF outcomes.

Materials and methods: Patients were randomised to EMPA 10 mg, EMPA 25 mg, or PBO. HHF and the composite of HHF or CV death were assessed in the pooled EMPA group vs PBO adjusting for control of BP, LDL-C and HbA1c at baseline and during the study as time-dependent covariates. Control was defined as systolic BP (SBP)

<140 mmHg and diastolic BP (DBP) <90 mmHg, LDL-C <100 mg/dL, and HbA1c <7.5%.

Results: Adjusting for control of BP, LDL-C or HbA1c at baseline and during the study, HRs for HHF with EMPA vs PBO ranged from 0.64 to 0.67, and HRs for HHF or CV death ranged from 0.65 to 0.66 (Figure). Adjusting for control of all 3 parameters, the HR (95% CI) for HHF was 0.66 (0.50, 0.86) and for HHF or CV death was 0.66 (0.55, 0.79) (Figure).

Conclusion: EMPA reduced HHF and HHF or CV death to the same extent when analyses were adjusted for control of BP, LDL-C and HbA1c over time, suggesting that these risk reductions were preserved irrespective of control of conventional risk factors during the study.

Effects of the SGLT-2 inhibitor empagliflozin on vascular function and central haemodynamics in patients with type 2 diabetes

R.E. Schmieder, K. Striepe, A. Jumar, M.V. Karg, D. Kannenkeril, M.P. Schneider, C. Ott;
University of Erlangen-Nürnberg, Erlangen, Germany.

Background and aims: Empagliflozin is a selective sodium-glucose cotransporter 2 (SGLT-2) inhibitor indicated for the treatment of type 2 diabetes. Its application leads to improved cardiovascular, renal and heart failure outcome in secondary prevention. To better understand these effects, we examined vascular function and central hemodynamics in patients with type 2 diabetes.

Materials and methods: In this prospective, double blind, randomized, placebo-controlled, crossover, interventional single center study 76 patients with untreated type 2 diabetes were randomized to empagliflozin 25 mg orally once daily or placebo. After 6 weeks of treatment with either empagliflozin or placebo and 1 week wash-out-phase, patients received the other compound for another 6 weeks (cross-over). We analyzed the effects of empagliflozin on central hemodynamics and vascular function as assessed by central systolic blood pressure (BP) (primary endpoint), central pulse pressure, forward and backward wave amplitude and augmentation index under office (Sphygmocor, AtCor, Australia) as well as ambulatory conditions (Mobilograph, IEM, Aachen).

Results: After 6 weeks of therapy fasting plasma glucose, HbA1c, body weight (all p<0.001) and office systolic (p<0.001) and diastolic (p<0.021) BP were significantly lower with empagliflozin than with placebo. Treatment with empagliflozin reduced central systolic BP (114 ± 12 vs 119 ± 14 mmHg, p<0.001), central diastolic BP (74.4 ± 6.9 vs 76.8 ± 8.2 mmHg, p=0.004) and central pulse pressure (39.5 ± 9.9 vs 42.2 ± 11 mmHg, p=0.012) compared to placebo. Forward (p=0.006) and backward (p=0.026) reflection amplitude, assessed under office conditions, were also significantly lower with empagliflozin than with placebo. Under ambulatory conditions over 24 hours we also observed lower central systolic (117 ± 9 vs 119 ± 9 mmHg, p=0.059) and diastolic (79 ± 7 vs 81 ± 7 mmHg, p=0.011) BP after 6 weeks treatment with empagliflozin compared to placebo. Pulse wave velocity under ambulatory conditions was also reduced after 6 weeks with empagliflozin (p=0.016).

Conclusion: Our study demonstrated consistent significant improvements of vascular function and central hemodynamics with empagliflozin under office and ambulatory conditions. Our data support the concept that empagliflozin exerts beneficial effects on cardiovascular and heart failure outcome via improved vascular function.

Renal protective effect of sodium dependent glucose transporter 2 inhibitor in combination with the renin angiotensin system blockers in early stage of diabetic nephropathy

D. Kukidome, N. Kajihara, S. Hanatani, J. Kawashima, T. Matumura, E. Araki;
Metabolic Medicine, Kumamoto University, Kumamoto, Japan.

Background and aims: The secondary analysis of the Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients showed that subjects treated with empagliflozin, an inhibitor of sodium-dependent glucose transporter 2 (SGLT2), had a significantly lower risk for the progression macroalbuminuria, even though empagliflozin did not prevent incident albuminuria. However, the effects of combined SGLT2 and the renin-angiotensin system (RAS) inhibition on microalbuminuria have not been well-established. Our aim of this retrospective study was to determine the renoprotective effects of combined SGLT2 and RAS inhibition, using urine albumin/creatine ratio (UACR) and estimated glomerular filtration rate (eGFR) as indicators, in subjects with type 2 diabetes (T2D) with early nephropathy (defined as UACR less than 300mg/g).

Materials and methods: Thirty-seven subjects with T2D of outpatients (the mean age: 54.0 years, BMI: 28.1, duration of diabetes: 12.2 years) who have continued to use SGLT2 inhibitor for six months or longer at our University Hospital were selected, and were divided into two groups. One group was already treated with RAS inhibitor (SGLT2i+RASi, n=12), the other group was treated without RAS inhibitor (SGLT2i, n=25). The changes of UACR, eGFR, and metabolic parameters after treatment with SGLT2 inhibitor were compared with the changes of those parameters before treatment using paired Student's *t*-test or Chi square test. Multiple linear regression analysis was performed to evaluate the effects of covariates on albuminuria reduction.

Results: The mean body weight and HbA1c were improved from baseline to six months after the treatment with SGLT2 inhibitor (75.6kg to 73.7kg, 8.1% to 7.8%, respectively, p<0.05). However, UACR or eGFR was not changed six months after treatment with SGLT2 inhibitor compared with baseline (51.0 ± 61.8 vs 54.3 ± 73.3 mg/g, 85.3 ± 21.4 vs 86.1 ± 21.8, respectively). In the subgroup analysis, the mean UACR was decreased 27.5 ± 18.4mg/g in the SGLT2i+RASi group, while it was

increased 13.0 ± 8.9mg/g in the SGLT2i group ($p < 0.05$). Similarly, the proportion of subjects who recognized UACR reduction was significantly higher in the SGLT2i +RASi group than that in the SGLT2i group (66.7% vs 32.0%, $p < 0.05$). However, there was no difference in body weight, HbA1c, eGFR or hematocrit between SGLT2i+RASi group and SGLT2i group. On multiple linear regression analysis, a reduction of eGFR ($p<0.001$), a baseline of UACR($p=0.004$) and the combination with RAS inhibitors ($p=0.002$) were independent predictors to explain the reduction of UACR according to SGLT2i treatment.

Conclusion: Administration of SGLT2 inhibitor reduces urine albumin excretion in T2D subjects who had been prescribed RAS inhibitors. This finding supports the potential use of SGLT2 inhibitor in combination with RAS blockers in patients with type 2 diabetes at high risk of progression of nephropathy.

SGLT-2 inhibitors affect on plasma renin activity and aldosterone concentration with the alteration of urinary sodium excretion and haematocrit in type 2 diabetes

T. Ishizuka, I. Mori, K. Fujioka, M. Fuwa, M. Tangiku, D. Andoh, T. Maruyama, K. Yamada;
Center of General Internal Medicine and Rheumatology, Gifu Municipal Hospital, Gifu, Japan.

Background and aims: SGLT-2 inhibitors (SGLT-2i) have shown that an inhibition of sodium glucose cotansporter-2 in the renal tubule results in an excretion of urinary glucose and Na. The purpose of this study is to examine alterations of plasma renin activity (PRA) and aldosterone concentration (PAC) after treatment with SGLT-2 inhibitor in type 2 diabetes mellitus (T2D).

Materials and methods: We measured PRA and PAC after resting at supine position for 30 minutes in 18 T2D patients (age 68±18 years old, men: female = 12:6) after treatment with SGLT-2 inhibitors (tofogliflozin: 9 cases, empagliflozin: 4cases, canagliflozin: 4cases dapagliflozin: 1case) for more than 1 months, and also selected as control 18 non-diabetic patients adjusted for age and sex from 2014 to 2016. Moreover, we could measured each metabolic parameters such as blood glucose, HbA1c, serum lipids level, urinary Na/creatinine and blood pressure, and PRA and PAC before and after treatment with SGLT-2 inhibitors (SGLT-2i) for 1month in 7 T2D patients. We analyzed these results with paired and unpaired *t* test using JMP12.2.0.

Results: SGLT-2i significantly increased PRA and decreased PAC levels compared with control as follows; PRA in control group and SGLT-2i group 0.9±0.5 ng/ml/h and 5.8±8.9 ng/ml/h, $p<0.04$, PAC in control group and SGLT-2i group 99±44 pg/ml and 72±36 pg/ml, $p<0.05$. Moreover, when we examined each metabolic parameter before and after treatment with SGLT-2i for 1 month in 7 T2D patients, each body weight, blood pressure, and HbA1c was significantly decreased compared with before treatment in 6 T2D patients ($p<0.04$). PRA value after treatment with SGLT-2i was significantly increased compared with before (before 3.25±3.13, after 5.98±4.78, $p<0.05$), but not PAC. Moreover, correlation between the alteration of PRA and PAC and urinary Na/creatinine and hematocrit were measured. Each alteration of PRA and PAC significantly correlated with alteration of urinary Na/creatinine and hematocrit, respectively ($P<0.05$).

Conclusion: SGLT-2i increases urinary sodium excretion, which affects macula densa in juxta-glomerular apparatus, and finally stimulates secretion of renin, but the alteration of aldosterone and hematocrit was correlated. SGLT-2i-induced increases in urinary sodium excretion affect stimulation of renin secretion and SGLT-2i-induced increase in urinary glucose excretion may affect on osmotic diuresis and aldosterone secretion.

The effects of the SGLT2 inhibitors on the Japanese type 2 diabetes patients with chronic kidney disease

K. Kobayashi[1], K. Sato[1], N. Hatori[1], M. Miyakawa[1], M. Toyoda[2];
[1]Committee of Hyperetension and Kidney disease, Kanagawa Physicians Association, Yokohama, [2]Division of Nephrology, Endocrinology and Metabolism, Department of Internal Medicine, Tokai University School of Medicine, Isehara, Japan.

Background and aims: Some large-scale clinical trials with the sodium-glucose cotransporter-2 inhibitors (SGLT2i) have revealed significant improvements in cardiovascular events and even diabetic nephropathy in patients with type 2 diabetes mellitus(T2DM). The frequency of SGLT2i use by general practitioners is expected to increase; however, it is not clear whether similar results are observed in Japanese patients with T2DM. This study is aimed to clarify the renal effects of the SGLT2i in the Japanese T2DM patients with chronic kidney disease (CKD).

Materials and methods: Data from T2DM patients with CKD who are visiting members of the Kanagawa Physicians Association, and who were taking SGLT2i administration were extracted. Clinical findings at the time of the survey and the beginning of SGLT2i administration were examined.

Results: Among 863 registered cases, 761 cases were analysed (male: female = 491: 270, age 59.6±13.0 years). The administration period was 14.4 months on average. The distribution of eGFR (mL/min/1.73m^2) was as follows: ≥ 60 is 74.2%; 30-59, 25.8%; and <30, 0.3%. Six SGLT2i were used: ipragliflozin (n=236), empagliflozin (n=123), tofogliflozin (n=144), dapagliflozin (n=112), canagliflozin (n=88), and luseogliflozin (n=54). Seventy-seven patients (10.1%) were administered SGLT2i alone, while 434 (57.0%) were also treated with metformin. DPP4 inhibitors were administered to 423 patients (55.6%), sulfonylureas to 260 (34.2%), insulin to 195 (25.6%), and GLP1 analogues to 101 patients (13.3%). Clinical findings at the beginning of administration versus at the time of the survey are shown as mean ± SD. Body weight (kg), 76.8±16.4 vs. 74.6±16.0 ($p<0.01$); Hemoglobin A1c (HbA1c, %), 8.1±1.5 vs. 7.4±1.2 ($p<0.01$); blood pressure (BP) at the hospital (mmHg), 138.3 ± 19.7/79.2 ± 12.7 vs. 132.7 ± 17.0/77.5 ± 11.3 ($p<0.01$); BP in the morning at home (n=71; mmHg), 129.5 ± 13.9/76.3 ± 13.6 vs. 128.5 ± 13.5/74.8 ± 11.2 ($p=0.55$). Improvements in both weight loss and HbA1c were found in 62.8% of cases. eGFR decreased from 78.1 ± 24.1 to 75.4 ± 24.3 mL/min/1.73m^2 ($p<0.01$), and logarithmic value of albumin-creatinine ratio (ACR) was significantly decreased from 4.13 ± 1.56 to 3.94 ± 1.55 ($p<0.01$). The changes of logarithmic value of ACR based on the presence (+) or absence (-) of concomitant medications were; DPP4 inhibitors (+/-), -0.24 ± 1.03 vs. -0.12 ± 0.92 ($p=0.11$); GLP1 analogue (+/-), -0.14 ± 1.04 vs. -0.20 ± 0.97 ($p=0.57$); Renin-angiotensin system inhibitors(+/-), -0.26 ± 1.06 vs. -0.12 ± 0.89 ($p=0.06$). In this study, the degree of adherence with dietary treatment of each patients was divided into four groups ("good" (n=17), "fair" (n=117), "a little bad" (n=291), and "bad" (n=77)). The change of logarithmic value of ACR were -0.56 ± 0.85, -0.17 ± 0.89, -0.22 ± 0.96, and 0.02 ± 0.88, respectively, which was considered to be related to adherence with dietary treatment.

Conclusion: Although the use of concomitant drugs varies between Japan and other countries, this retrospective study confirmed that the results of large-scale clinical trials were also observed in the real world in Japan. The importance of dietary therapy was also partially observed, and further discussion on the relationship with background factors or differences between each SGLT2i should be considered in the future.

Empagliflozin and incidence of events consistent with acute renal failure, including acute kidney injury: pooled safety analysis in >12,000 individuals

R. Agarwal[1], D. Wheeler[2], K. Doi[3], A. Koitka-Weber[4], S. Hauske[5], C. Zeller[4], S. Kohler[5], M. von Eynatten[5], C. Wanner[6];

[1]Indiana University, Indianapolis, USA, [2]Centre for Nephrology, University College London, London, UK, [3]Dept of Emergency and Critical Care Medicine, University of Tokyo, Tokyo, Japan, [4]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, [5]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, [6]Dept of Medicine, Würzburg Univ Clinic, Würzburg, Germany.

Background and aims: SGLT2 inhibitors may alter renal hemodynamics, often reflected as a modest decrease in renal function shortly after drug initiation. Although GFR generally stabilizes during chronic treatment, reports of acute kidney injury (AKI) have emerged, representing an important safety consideration.
Materials and methods: To investigate events consistent with acute renal failure (ARF) including AKI with empagliflozin (EMPA), we analyzed pooled safety data from >12,000 patients with T2D who were randomized (1:1:1) to EMPA 10 mg, 25 mg, or PBO in 15 Phase I-III trials (including EMPA-REG OUTCOME) plus 4 extension studies. ARF incidence was assessed using investigator-reported adverse events (without adjudication) coded according to the narrow standardized MedDRA query. AKI was captured by the MedDRA preferred term 'AKI'.
Results: Total exposure (patient-years) was 7782, 7754 and 7369 for EMPA 10 mg, 25 mg and PBO, respectively. The incidence rates of either ARF (table) or AKI were similar for the two EMPA doses and PBO. As expected, ARF and AKI events increased with decreasing renal function, yet the overall risk with EMPA was similar to PBO across all subgroups of baseline eGFR.
Conclusion: This large pooled analysis of >12,000 patients with T2D does not suggest an increased risk for acute renal events with EMPA in the setting of controlled clinical trials. When initiating EMPA, careful monitoring of renal function according to local prescribing information is recommended.

Safety update on dapagliflozin across the phase 2b/3 clinical trial programme

A.J.L. Scheen[1], S. Jabbour[2], J. Seufert[3], C.J. Bailey[4], C. Karup[5], A.M. Langkilde[5];
[1]University of Liège, Liège, Belgium, [2]Sidney Kimmel Medical College at Thomas Jefferson University, Philadelphia, USA, [3]University Hospital of Freiburg, Freiburg, Germany, [4]Aston University, Birmingham, UK, [5]AstraZeneca Gothenburg, Mölndal, Sweden.

Background and aims: Safety and tolerability of sodium-glucose cotransporter-2 inhibitors (SGLT2i) are of interest. Dapagliflozin is a highly selective SGLT2i for the treatment of type 2 diabetes.
Materials and methods: Data were pooled from 13 placebo-controlled trials of up to 24 weeks' duration (Table). To detect rare adverse events (AEs), larger placebo/comparator-controlled pools of 21 trials (≤208 weeks; dapagliflozin, n=5936; control, n=3403) and 30 trials (≥12 weeks; dapagliflozin, n=9195; control, n=4629) assessed diabetic ketoacidosis and lower-limb amputations, respectively.
Results: Over 24 weeks, AE and serious AE rates were similar for dapagliflozin vs placebo; 60 vs 56% and 5 vs 5%, respectively. Rates of hypoglycaemia, volume depletion AEs and urinary tract infection were balanced between groups (Table). Genital infections were more frequent with dapagliflozin vs placebo (6 vs 1%), fractures were balanced between groups (0.3 vs 0.7%) and renal function AEs occurred in 3 vs 2% of patients (most common was decreased creatinine clearance; 1.1 vs 0.7%). In the 21-study pool, 1 serious event of diabetic ketoacidosis and 3 events of ketonuria/metabolic acidosis occurred with dapagliflozin; estimated incidence for any of these events was 0.03 (95% CI: 0.010, 0.089). In the 30-study pool, lower-limb amputations occurred in 8 (0.1%) dapagliflozin vs 7 (0.2%) control patients.
Conclusion: In summary, dapagliflozin was well tolerated across the clinical trial programme. AE rates were generally balanced for dapagliflozin vs placebo/control, including special interest AEs such as hypoglycaemia, fractures, amputations and diabetic ketoacidosis.

Factors associated with the discontinuation of metformin therapy: results from 11,539 patients in the global DISCOVER study

K. Khunti[1], J. Cid-Ruzafa[2], P. Fenici[3], M.B. Gomes[4], N. Hammar[5], M. Kosiborod[6], A. Nicolucci[7], S. Pocock[8], W. Rathmann[9], M.V. Shestakova[10], H. Watada[11], I. Shimomura[12], F. Tang[6], L. Ji[13], DISCOVER;
[1]Diabetes Research Unit, University of Leicester, Leicester, UK, [2]Evidera, Barcelona, Spain, [3]AstraZeneca, Cambridge, UK, [4]Rio de Janeiro State University, Rio de Janeiro, Brazil, [5]AstraZeneca Gothenburg, Mölndal, Sweden, [6]Saint Luke's Mid America Heart Institute, Kansas City, USA, [7]Center for Outcomes Research and Clinical Epidemiology, Pescara, Italy, [8]London School of Hygiene and Tropical Medicine, London, UK, [9]Leibniz Center for Diabetes Research, Heinrich Heine University, Düsseldorf, Germany, [10]Endocrinology Research Centre, Moscow, Russian Federation, [11]Graduate School of Medicine, Juntendo University, Tokyo, [12]Graduate School of Medicine, Osaka University, Osaka, Japan, [13]Peking University People's Hospital, Beijing, China.

Background and aims: Clinical guidelines recommend metformin as first-line glucose-lowering therapy in patients with type 2 diabetes mellitus (T2DM), with the addition of a second agent if HbA_{1c} levels remain uncontrolled. Some patients may discontinue metformin, most often because of intolerance. However, the frequency of, and factors associated with, metformin discontinuation have not been well described on a global scale.
Materials and methods: DISCOVER is a 3-year observational study of patients with T2DM initiating a second-line therapy. Treatment patterns, reasons for treatment changes, and clinical variables were recorded at baseline using a standardized electronic case report form. A multivariate hierarchical logistic regression model, with country as a random effect, was used to assess factors associated with metformin discontinuation.
Results: Data were assessed from a total of 13 245 patents across 32 countries. Of these, 11 539 (87.1%) used metformin as first-line therapy, either as monotherapy (7977 patients, 69.1%) or as part of a combination (3562 patients, 30.9%). Among these, 4083 (35.4%) discontinued metformin when initiating second-line therapy (37.2% of those who used initial metformin monotherapy; 31.3% of those who used metformin as part of a combination). The rate of metformin discontinuation varied greatly across countries (9.7-98.0%). Factors associated with the likelihood of discontinuing metformin are shown in the Figure. Patients with chronic kidney disease (relative to without) and those without health insurance (relative to with) were more likely to discontinue metformin. Patients with $HbA_{1c} \geq 7.0\%$ were less likely to discontinue metformin than those with $HbA_{1c} < 7.0\%$. When compared with those aged < 75 years, patients aged ≥ 75 years had an OR for discontinuation of 1.38 (95% CI 1.00-1.90).
Conclusion: Metformin was discontinued in more than one-third of patients initiating a second-line therapy. Although discontinuation may be appropriate in some patients, this rate is considerably higher than would be expected. Adverse effects may be the reason for discontinuation in patients with $HbA_{1c} < 7.0\%$.

Figure. Likelihood of discontinuing metformin when initiating a second-line glucose-lowering therapy. ORs were calculated using a hierarchical logistic regression model, with country as a random effect and adjusted for all variables in the figure.

Small intestine as the main site of blood glucose-lowering effect during an early response to single dose of metformin

O. Horakova, P. Kucharikova, J. Kopecky, M. Rossmeisl;
Department of Adipose Tissue Biology, Institute of Physiology of the Czech Academy of Sciences, Praha, Czech Republic.

Background and aims: Metformin is the most prescribed drug for the treatment of type 2 diabetes. During long-term treatment, metformin inhibits hepatic gluconeogenesis while enhancing glucose uptake in skeletal muscle. Although it is known that the gut has an important role in the effects of metformin, its precise involvement is still not fully understood, especially in the context of acute metformin administration. Thus, we studied acute effects of metformin on glucose uptake in tissues as well as glucose transport across intestinal epithelium in dietary obese mice.
Materials and methods: Adult C57BL/6J mice were fed a corn oil-based high-fat diet (HF; lipids ~35% wt/wt) for 8 weeks. Thereafter overnight fasted mice were given a single dose of metformin (Met; 400 mg/kg body

weight) or saline (Sal) by oral gavage. After 30 minutes mice were subjected to either oral glucose tolerance test (OGTT) or the analysis of glucose uptake using ^{18}F-fluorodeoxyglucose and PET/μCT or radiolabeled assays using [^{3}H]2-deoxyglucose. The same experimental setup was used to measure *ex vivo* glucose transport across intestinal epithelium, when mice were sacrificed 30 min after metformin gavage and two segments of jejunum and ileum were used to prepare everted gut sacs. Data are presented as means ± SE. Data were analyzed with *t*-test at the significance level $p = 0.05$.

Results: Incremental area under the glycaemic curve during OGTT (as a marker of glucose intolerance) was decreased in Met when compared to Sal group (Met, 587±79 vs. Sal, 1713±109 mmol/180 min), while plasma insulin levels did not differ between the Met and Sal group 30 min after glucose administration. The analysis using PET/μCT did not reveal any differences in radioisotope accumulation between Met and Sal group one hour after ^{18}F-FDG gavage. Glucose uptake using [^{3}H]2-deoxyglucose was unchanged in skeletal muscle, adipose tissue or kidney of Met vs. Sal group. On the contrary, decreased glucose uptake was observed in the livers of mice from Met group (Met, 61±6 vs. Sal, 98±13 dpm/mg tissue; $p<0.05$). Furthermore, glucose transport across intestinal epithelium was reduced in proximal jejunum (Met, 0.4±0.2 vs. Sal, 1.7±0.2 mmol), and in both proximal (Met, 1.3±0.3 vs. Sal, 4.1±0.4 mmol) and distal (Met, 2.9 ±0.3 vs. Sal, 4.6±0.6 mmol) ileum in the Met group.

Conclusion: Together our results support the idea that the inhibition of transepithelial glucose transport in the intestine is responsible for blood glucose-lowering during an early response to single dose of metformin.

Changes in metabolites in response to metformin during the 18-month Copenhagen Insulin and Metformin Therapy (CIMT) Trial

N. Safai[1], A. Ali[1], T.R.L. Suvitaival[1], P. Spegel[2], M. Al-Majdoub[2], B. Carstensen[1], H. Vestergaard[3], M. Ridderstråle[4], CIMT Trial Group;
[1]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [2]Lund University, Malmö, Sweden, [3]Copenhagen University, Copenhagen, [4]Novo Nordisk A/S, Søborg, Denmark.

Background and aims: Metformin is the first-line treatment in type 2 diabetes. However, not all patients benefit from treatment. Our aim was (1) to investigate the effects of metformin on the plasma metabolome, of which e.g. increased levels of branched chain and aromatic amino acids are known to be associated with type 2 diabetes, giving molecular insight into its known HbA_{1c}-lowering effect, and (2) to find out, whether metabolomic profile can predict the HbA_{1c}-outcome of the treatment.

Materials and methods: The CIMT trial was a multicenter trial from May 2008 to December 2012. Participants were randomized to 18 months of treatment with metformin/placebo and to three different insulin regimens. In total, 87 metabolites were analyzed in all participants (n=371) with LC/MS at baseline and follow-up. Metabolite levels were standardized and analyzed with a linear mixed effect model in R, adjusting for age, sex, BMI, and previous insulin treatment. Associations between metabolites and HbA_{1c} were analyzed with a linear regression model with the same adjustments. Variables with a multiple testing-corrected $p<0.1$ are reported.

Results: At baseline, subjects who were treated with metformin before the trial (n=313) had higher levels of leucine/isoleucine (one peak) and five lysophosphatidylethanolamines (LPEs C16:0, C18:1, C20:4, 20:5 and C22:6), and lower levels of carnitine and valine, when compared to metformin-naïve subjects (n=58). As an effect of metformin treatment in the trial at follow-up, again, leucine/isoleucine was elevated and carnitine and valine were reduced compared to baseline. In addition to these confirmatory findings, we found lower levels of hydroxycinnamic acid, cinnamic acid, phenylacetamide and tyrosine. We did not find significant associations between baseline metabolites and follow-up HbA_{1c} in the randomized population ($p>0.16$). However, we found an association to HbA_{1c} at baseline between those that had been on metformin before the trial and the metformin-naïve patients: The levels of carnitine C10:1 ($p_{interaction}$=0.025), carnitine C12:1 ($p_{interaction}$=0.067) and leucine/isoleucine ($p_{interaction}$=0.027) were negatively associated with HbA_{1c} at baseline in the metformin treated group compared to the metformin-naïve group.

Conclusion: Contrary to what might have been expected, in this exploratory analysis of changes in the plasma metabolome associated with metformin use, our results indicate that metformin is associated with increased levels of LPEs and leucine/isoleucine which are known to be associated with diabetes and insulin resistance. Meanwhile, there were improvements in the levels of valine, tyrosine and carnitine which are also associated with insulin resistance and mitochondrial dysfunction. This differential response deserves further study. Because of the small number of metformin-naïve patients in this study, we were not able to identify metabolites that can predict a favourable HbA_{1c}-response to metformin.

Metformin exposure in diabetic subjects is similar to patients without diabetes

E.I.O. Sundelin[1], L.C. Gormsen[2], S. Heebøll[3], M.H. Vendelbo[2], S.B. Pedersen[4], S. Jakobsen[2], J. Frøkiær[2], H. Grønbæk[3], N. Jessen[1,5];
[1]Department of Clinical Medicine, Aarhus University Hospital, [2]Department of Nuclear Medicine & PET-center, Aarhus University Hospital, [3]Department of Hepatology and Gastroenterology, Aarhus University Hospital, [4]Department of Endocrinology and Internal Medicine, Aarhus University Hospital, [5]Department of Biomedicine, Aarhus University Hospital, Aarhus C, Denmark.

Background and aims: The effectiveness, low cost and favorable side effect profile of metformin, has made it first-line anti-diabetic treatment in type 2 Diabetes Mellitus (T2DM) worldwide. A study has demonstrated a 80-fold difference in steady state plasma metformin concentrations in patients with T2DM with no correlation to decrease in HbA1c after adjusting for baseline HbA1c. Plasma metformin concentration is therefore considered a poor surrogate marker of the glucose lowering effect of metformin. It is well accepted that the anti-hyperglycaemic effect of metformin involves reduction of hepatic glucose production and thus requires hepatic uptake of the drug. Under physiological pH metformin is an organic cation and relies on the membrane transporters, OCT1 and MATE1, for hepatic uptake. To determine hepatic exposure to metformin in diabetic subjects *in vivo*, we have used ^{11}C-metformin Positron Emission Tomography (PET) to investigate diabetic and non-diabetic patients with non-alcoholic steatohepatitis (NASH) or simple steatosis. As secondary endpoint, mRNA expression of OCT1 and MATE1 was investigated under the hypothesis that the level of metformin exposure was associated to their level of expression.

Materials and methods: Diabetic subjects with NASH (n=4), non-diabetic subjects with NASH (n=7) or simple steatosis (n=7) where liver biopsies had been obtained for diagnostic purposes, were studied using PET after intravenous injection of ~167 MBq ^{11}C-metformin. Volume of distribution (Vd) was evaluated using Pmod (PMOD Technologies LLC). Liver biopsies were analyzed using qPCR and normalized to 40S ribosomal protein S18.

Results: Hepatic exposure to metformin in diabetic patients with NASH (Vd 1.91 ± 0.09) is similar to non-diabetic patients with NASH (Vd 2.27 ± 0.15) and simple steatosis (Vd 2.39 ± 0.25) p=0.32, One-Way ANOVA. Preliminary data from qPCR analysis on liver biopsies show no significant difference in mRNA expression of OCT1 and MATE1 among

diabetic and non-diabetic patients (p=0.17 and p=0.18 respectively), nor was there an apparent correlation between transporter expression and Vd.
Conclusion: This study demonstrates that metformin exposure *in vivo* is stable in diabetic and non-diabetic human subjects with non-alcoholic fatty liver disease (NAFLD). Approximately 70% of patients with T2DM have NAFLD as part of the metabolic syndrome, and their hepatic disease does not influence metformin distribution.

Differences in the correlation of HbA_{1c} versus fasting plasma glucose in large cohorts of drug-naive versus metformin treated patients

B. Ahrén[1], J.E. Foley[2];
[1]Lund University, Lund, Sweden, [2]Novartis Pharmaceuticals Corporation, East Hanover, USA.

Background and aims: We previously tested the relative contribution of fasting plasma glucose (FPG) and postprandial glucose (PPG) to HbA1c using an algorithm developed by the A1c-Derived Average Glucose (ADAG) study group. The algorithm estimates average glucose exposure to calculate apparent PPG by subtracting FPG. The ADAG algorithm predicted 24 hour PPG exposure in drug-naive patients but was not robust enough to assess this PPG exposure in metformin treated patients. The current analysis was carried out in an attempt to further investigate the difference between drug-naive and metformin treated patients.
Materials and methods: The baseline data (before treatment) of drug-naive (n=2445) and of metformin treated patients (n=2727) from the pooled vildagliptin database were utilised. The slope of HbA1c versus FPG for the overall population and for the groups with HbA1c <8% (drug-naive, n=933 and metformin, n=1634) and ≥8% (drug-naive, n=1512 and metformin, n=1093) were calculated.
Results: The overall population slopes of HbA1c versus FPG were 0.21 ±0.007, R^2=0.44 in drug-naive and 0.21±0.005, R^2=0.58 in metformin from the same intercept of 6.5%. In patients with HbA1c <8%, the slopes were 0.06±0.007, R^2=0.56, intercept=7.0% in drug-naive and 0.10 ±0.006, R^2=0.29, intercept=6.7% in metformin treated patients. The HbA1c ≥8% slopes were 0.13±0.007, R^2=0.20, intercept=7.7% in drug-naive and 0.13±0.008, R^2=0.30, intercept=7.6% in metformin. Thus, there was no difference in overall population or in patients with HbA1c ≥8% between drug-naive and metformin, although the slope was lower and the intercept was higher in patients with HbA1c ≥8%. However, in patients with HbA1c <8% the slopes were lower and from a lower intercept than in patients with HbA1c ≥8%. Furthermore, in patients with HbA1c <8% from a 0.3% higher intercept the drug-naive slope was lower than the metformin slope (figure). We assume that a lower slope (adjusted for intercept) of HbA1c versus FPG is due to a greater contribution of PPG to the total glucose exposure.
Conclusion: Thus, the data are consistent with a greater PPG contribution to HbA1c in patients with HbA1c <8% in both drug-naive and metformin treated patients. The apparent higher PPG contribution in drug-naive than in metformin treated patients with HbA1c <8% may explain why the ADAG algorithm predicted 24 hour PPG exposure in drug-naive patients but was not robust enough to assess this PPG exposure in metformin treated patients. Furthermore, the apparent higher PPG contribution in metformin treated patients with HbA1c <8% is greater than that in metformin treated patients with HbA1c >8%, suggesting that metformin may reduce PPG independent of its baseline effect to inhibit hepatic glucose production and that this contributes to its reduction in HbA1c.

Figure: Baseline HbA1c versus baseline FPG in patients with type 2 diabetes mellitus with baseline HbA1c levels <8%

Comparative assessment of glycaemic achievements with second line anti diabetes therapy intensification: real world evidence based choices for patients and providers

O. Montvida[1], J. Shaw[2], S. Paul[3];
[1]School of Biomedical Sciences, Queensland University of Technology, Brisbane, [2]Baker IDI, Melbourne, [3]University of Melbvourne, Melbourne, Australia.

Background and aims: There are multiple options for second-line anti-diabetic drugs (ADDs), but little is known about their effects on glycaemia in clinical practice. The aim of this real-world study was to inform clinicians and patients about the likelihood of achieving desired glycaemic control with each of the major second line ADDs when added to metformin.
Materials and methods: Centricity Electronic Medical records contains extensive primary and ambulatory care clinical data from the USA. A cohort of patients with T2DM on metformin, who added and continued a second line ADD for at least 6 months, and without history of cardiovascular, renal or malignant diseases, was identified with: DPP-4 inhibitor (DPP-4i, n=22,085), GLP-1 receptor agonist (GLP-1RA, n=5,491), sulfonylurea (SU, n=67,291), thiazolidinedione (TZD, n=11,696), and insulin (INS, n=15,957). Adjusted change in HbA1c, the probability of reducing HbA1c below 7% or by at least 1.5% were evaluated over 6, 12 and 24 months of continued therapy - stratified by HbA1c categories of 7-8%, 8-9%, 9-12% and > 12% at therapy intensification (baseline).
Results: The 5 treatment groups had similar mean follow-up of 4 years and variable baseline characteristics: age (mean: 53-59 years), gender (male: 35-53%), weight (mean: 98-110 kg), and HbA1c (mean: 7.8-9.3%). Mean unadjusted HbA1c changes at 6 months were 0.8/ 0.8/ 0.7/ 1.0/ 0.8 % in SU/ DPP-4i/ GLP-1RA/ INS/ TZD groups respectively. In the 8-9% baseline HbA1c group, adjusted HbA1c reductions were consistent over 2 years and were similar in the GLP-1RA, TZD and DPP-4i groups, while SU and INS users experienced significantly smaller reductions (6- and 12-month HbA1c changes in Table 1). Patients in the

DPP-4i, GLP-1RA and TZD groups had a significantly higher probability of reducing HbA1c by at least 1.5% or below 7% at 6 months and over 2 years (probability range: 35 - 50%) compared to SU or INS groups. The SU group had a higher probability of reducing HbA1c by at least 1.5% (probability range: 27 - 32%) compared to the INS group (probability range: 20 - 30%) over 2 years. In the 9-12% baseline HbA1c group, HbA1c reductions were similar in GLP-1RA, TZD, DPP-4i and SU groups at 6 months (mean: 1.9 - 2.2%). While the probability of reducing HbA1c by at least 1.5% was similar in all ADD groups at 6 months (probability range: 57-70%), the likelihood of better glycaemic achievements was significantly higher at 12 and 24 months in the incretins and TZD groups (Table 1).

Conclusion: In metformin treated patients with T2DM, intensification with SU or INS offers relatively lower probability of short- and long-term glycaemic achievements, in comparison to incretins or TZDs.

Table 1: Adjusted reduction in HbA1c (95% CI), probability to reduce HbA1c for at least 1.5% (95% CI), and probability to reduce HbA1c below 7% (95% CI) at 6 and 12 months post second-line initiation by baseline HbA1c category and by second-line drug class in type 2 diabetes patients with no history of cardiovascular, chronic kidney disease or cancer.

Clinical and economic outcomes in type 2 diabetes patients treated with fixed-dose versus loose-dose combination anti-hyperglycaemic therapies

A. Vlahiotis[1], E. Wittbrodt[2], J. Patel[2], K.F. Bell[2], E. Riehle[1];
[1]Truven Health Analytics, an IBM Company, Cambridge, [2]AstraZeneca, Wilmington, USA.

Background and aims: Medication adherence is required for successful type 2 diabetes (T2D) treatment and adequate A1C reduction. Prior research has demonstrated that fixed-dose combination (FDC) regimens lead to greater patient adherence than loose-dose combination (LDC) regimens. Given the new entrants into the FDC market, this study aimed to compare adherence and clinical and economic outcomes between patients initiating FDC and LDC anti-hyperglycemic regimens in a contemporary, real-world setting.

Materials and methods: his retrospective, observational study used claims data from *Truven Health* MarketScan Commercial and Medicare Supplemental Databases (2013-2015) to identify and compare T2D patients initiating metformin-containing FDC or LDC oral anti-hyperglycemic regimens. Outcomes were measured in the 12 months following initiation. Adherence was defined as the proportion of days covered (PDC) by the initiated regimen derived from the days' supply of pharmacy claims for regimen medication(s); patients with PDC ≥80% were deemed adherent. A logistic model was fit to determine the odds of being adherent for the FDC versus LDC cohort, adjusted for key baseline characteristics, including index-regimen non-metformin class. The highest recorded A1C values in the year before and after initiation were used for analysis among the subset of patients with laboratory data available. Annual T2D-related costs were summed using all claims with a primary diagnosis of T2D or claims for anti-hyperglycemic medications.

Results: The identified cohorts of 22,456 FDC patients and 21,172 LDC patients were well balanced on key baseline characteristics, including mean age (both cohorts: 55.2 years) and sex (women: FDC = 40.8%, LDC = 41.8%). Additionally, among the subset of patients with laboratory data (FDC N=842; LDC N=873), the proportion of patients with baseline A1C values <7.0 were not significantly different between the cohorts (FDC: 17.3% vs. LDC: 16.7%; p=0.735). A majority of the FDC cohort initiated on a metformin+dipeptidyl peptidase-4 (DPP-4) inhibitor regimen (77%), while metformin+sodium glucose cotransporter-2 (SGLT2) inhibitor regimens were rare (1.3%). Among the LDC cohort, the most frequently initiated regimen was metformin+sulfonylurea (73%). Nearly 80% of FDC medications were brand-named, versus only 23% of LDC regimens. In the year following initiation, FDC patients were significantly more likely to be adherent compared with LDC patients (41% vs. 29%; p<0.001). In the adjusted logistic model, the odds of being adherent were 1.69 times greater for the FDC cohort compared with the LDC cohort (p<0.001). The proportion of patients achieving an A1C value <7.0 during the year following initiation was 7% higher among the FDC cohort (37% vs. 30%, p=0.001). Compared with the LDC cohort, the mean T2D-related pharmacy costs were higher among FDC patients (FDC: $2,142 vs. LDC: $917; p<0.001); however, T2D-related medical costs were significantly lower (FDC: $1,483 vs. LDC: $1,717; p<0.001).

Conclusion: This study provides real-world evidence that FDC anti-hyperglycemic regimens are associated with higher adherence, lower T2D-related medical costs, and improved A1C outcomes compared with LDC regimens. These findings strengthen evidence for prescribing FDC medications to achieve significant clinical improvements in patients with T2D requiring combination therapy.

Effects of canagliflozin on biomarkers of cardiovascular stress in older patients with type 2 diabetes

N. Sattar[1], J.L. Januzzi[2], J. Butler[3], P. Jarolim[4], U. Vijapurkar[5], K.W. Merton[6], J. Ren[6], W. Canovatchel[5], M. Desai[5], M.J. Davies[6];
[1]BHF Glasgow Cardiovascular Research Centre, University of Glasgow, Glasgow, UK, [2]Massachusetts General Hospital, Harvard Medical School, Boston, [3]Cardiology Division, Stony Brook University, Stony Brook, [4]Brigham and Women's Hospital, Harvard Medical School, Boston, [5]Janssen Research & Development, LLC, Raritan, [6]Janssen Scientific Affairs, LLC, Titusville, USA.

Background and aims: Sodium glucose co-transporter 2 (SGLT2) inhibitors may reduce cardiovascular (CV) risk in patients with type 2 diabetes mellitus (T2DM). We examined the effects of canagliflozin (CANA) on the CV stress biomarkers N-terminal pro-B type natriuretic peptide (NT-proBNP) and high sensitivity troponin I (hsTnI) in older patients with T2DM.
Materials and methods: In this exploratory analysis of a subset of T2DM patients (age 55-80 y, mean = 64 y; 56% male, T2DM duration = 12 y) randomized to placebo (PBO; N = 216), CANA 100 mg/d (N = 229), or CANA 300 mg/d (N = 221) for 104 weeks, serum levels of NT-proBNP (Roche) and hsTnI (Abbott) were measured. Median percent change from baseline was compared at weeks 26, 52, and 104. For these analyses, CANA groups were pooled.
Results: Baseline characteristics were similar between groups. From a baseline median of ≈50 pg/mL, NT-proBNP increased with PBO, but changed minimally with CANA over 104 weeks (Table). From a baseline median of ≈3.3 pg/mL, hsTnI also increased with PBO, but was reduced or unchanged with CANA. Hodges-Lehmann estimates (95% confidence interval) of the median percent differences between CANA and PBO at weeks 26, 52, and 104, respectively, were -13.2% (-25.4, -1.7), -16.3% (-28.9, -4.0), and -27.6% (-43.2, -11.5) for NT-proBNP; and -8.3% (-14.0, -2.5), -11.9% (-18.0, -5.6), and -10.0% (-17.3, -2.6) for hsTnI ($p<0.05$ for each between-group difference).
Conclusion: CANA delayed rise in NT-proBNP and hsTnI over 2 years compared with PBO in older T2DM patients. These results suggest attenuation in CV stress with CANA, consistent with the anticipated CV protective effect of SGLT2 inhibitors.

Table. Median percent change in NT-proBNP and hsTnI from baseline to 26, 52, and 104 weeks.

Parameter*,†	PBO	Pooled CANA	Difference vs PBO (95% CI)
NT-proBNP			
Week 26	17.5 (11.8)	−3.6 (8.6)	−13.2 (−25.4, −1.7)‡
Week 52	13.2 (8.1)	−1.2 (8.0)	−16.3 (−28.9, −4.0)§
Week 104	39.1 (10.9)	8.7 (8.7)	−27.6 (−43.2, −11.5)§
hsTnI			
Week 26	4.5 (3.6)	−5.8 (4.0)	−8.3 (−14.0, −2.5)§
Week 52	3.2 (3.8)	−6.9 (4.0)	−11.9 (−18.0, −5.6)§
Week 104	11.5 (4.4)	0.0 (4.6)	−10.0 (−17.3, −2.6)§

CI, confidence interval; SE, standard error. *Data are median percent change (SE) unless otherwise indicated. †Results are data as observed for patients with values at baseline and at each specific time point (NT-proBNP: n = 180, 156, and 148 for PBO and n = 379, 368, and 318 for CANA at weeks 26, 52, and 104, respectively. hsTnI: n = 172, 145, and 140 for PBO and n = 344, 329, and 294 for CANA at weeks 26, 52, and 104, respectively). ‡Nominal p<0.05. §Nominal p<0.01. Nominal p values for the difference in median percent change between the CANA and PBO groups are based on the Wilcoxon rank sum test. SEs for the median percent change were estimated using the bootstrap technique by simulated repeated samples for each biomarker and treatment group.

The sodium-dependent glucose transporters (SGLT) as a new promising pharmacological target in human ischaemic hearts

A. Di Franco, G. Cantini, L. Raimondi, E. Mannucci, M. Luconi;
University of Florence, Florence, Italy.

Background and aims: Recently, EMPAREG OUTCOME trial has shown that empagliflozin reduces cardiovascular mortality and the rate of hospitalization for heart failure, in patients with type 2 diabetes with previous cardiovascular events. The mechanisms underlying the cardioprotective effects of this sodium/glucose transporter 2 (SGT2) inhibitor are still unknown, though a direct action of the drug on the cardiomyocytes could be hypothesized.
Materials and methods: We evaluated the expression of SGLT1 and SGLT2 by quantitative-real time-RT-PCR and western blot analyses, in tissue biopsies of healthy, ischemic and hypertrophic human hearts.
Results: In this study, we evaluated the relative expression of SGLT2 and SGLT1, the two most relevant members of the SGLT family being potentially responsive to empagliflozin, in tissue biopsies of healthy (n=9), ischemic (n=9) and hypertrophic (n=6) human hearts. We found no expression of SGLT2 in either normal or pathological conditions, whereas SGLT1 was expressed in normal myocardial tissue and was significantly upregulated in ischemia and hypertrophy, in association with increased phosphorylation in activating domains of the intracellular second messengers AMP-activated protein kinase (AMPK), extracellular-signal regulated kinase 1 and 2 (ERK-1/2) and mammalian target of rapamycin (mTOR).
Conclusion: Our findings suggest that the hyper-expression of SGLT1 in cardiomyocytes may represent a potential pharmacological target for cardioprotection.

An SGLT-2 inhibitor reverses impaired ventricular repolarisation in patients with type 2 diabetes

T. Sato[1,2], T. Miki[1], H. Ohnishi[1,3], T. Yamashita[1], A. Takada[4], T. Yano[1], M. Tanno[1], A. Tsuchida[5], T. Miura[1];
[1]Department of Cardiovascular, Renal and Metabolic Medicine, Sapporo Medical University School of Medicine, [2]Department of Cellular Physiology and Signal Transduction, Sapporo Medical University School of Medicine, [3]Department of Public Health, Sapporo Medical University School of Medicine, Sapporo, [4]Department of Cardiology, Steel Memorial Muroran Hospital, Muroran, [5]Department of Cardiology, JR Sapporo Hospital, Sapporo, Japan.

Background and aims: EMPA-REG OUTCOME trial demonstrated that empagliflozin, an SGLT-2 inhibitor, reduced cardiovascular events, including sudden cardiac death and heart failure, in patients with type 2 diabetes mellitus (T2DM), but its mechanisms remain unclear. It has been shown that increased ventricular repolarization heterogeneity is associated with the risk of ventricular arrhythmias and sudden cardiac death and that ventricular repolarization heterogeneity is often observed in patients with T2DM. In the present study, we hypothesized that treatment with an SGLT-2 inhibitor reverses ventricular repolarization heterogeneity in patients with T2DM.
Materials and methods: We retrospectively analyzed data for consecutive patients with T2DM in whom a 12-lead electrocardiogram was recorded before and after treatment with an SGLT2 inhibitor at outpatient clinics from April 2014 to October 2016. The changes in corrected QT

dispersion (QTcd: the difference between the maximum and minimum of the QTc intervals) and Tpeak-Tend interval at V5 lead (Tpeak-Tend), indices of ventricular repolarization heterogeneity, after treatment with an SGLT-2 inhibitor were calculated.

Results: Forty-six patients enrolled in this study; thirty-three (72%) were men, age was 60.4±10.7 (SD) years, and median duration of diabetes was 10.5 years. Six SGLT-2 inhibitors were used for treatment in the study subjects (ipragliflozin, n=17; dapagliflozin, n=16; empagliflozin, n=7; canagliflozin, n =3; luseogliflozin, n=2; tofogliflozin, n=1). Duration of treatment with an SGLT-2 inhibitor was 241.5±170.5 days. Treatment with SGLT-2 inhibitors reduced HbA1c (7.7±1.2 vs. 7.5±1.4%), body weight (77.8±13.9 vs. 74.7±12.5 kg) and systolic blood pressure (132.8 ±17.9 vs. 125.8±11.9 mmHg). QTcd was significantly reduced after treatment with an SGLT-2 inhibitor (51.9±19.2 vs. 45.5±11.6 msec, p<0.01), though heart rate and mean QTc interval were not altered. Interestingly, improvement in QTcd was clearly evident in patients with prolonged QTcd before the treatment; when the patients were divided into two subgroups by the median of QTcd (48.8 msec), improvement of QTcd was seen in the high-QTcd subgroup but not in the low-QTcd subgroup. Similarly, improvement of Tpeak-Tend was observed (96.0±6.6 vs 90.1 ±8.3 msec, p<0.01) only in a subgroup with Tpeak-Tend being higher than the median value (84.0 msec). There was a weak but significant positive correlation between changes in QTcd and changes in systolic blood pressure (Spearman's ρ=0.32 p<0.05), while no correlation was found between changes in QTcd or Tpeak-Tend and changes in HbA1c.

Conclusion: These findings suggest that an SGLT-2 inhibitor reverses impaired ventricular repolarization heterogeneity in patients with T2DM, independent of its effect on glycemic control. The favorable effect on ventricular repolarization heterogeneity may be a potential mechanism of recently reported reduction of cardiovascular events by empaglifozin.

Does baseline HbA_{1c} or change in HbA_{1c} predict the reduction in cardiovascular (CV) death with empagliflozin? Results from EMPA-REG OUTCOME

S.E. Inzucchi[1], D. Fitchett[2], C. Wanner[3], M. Mattheus[4], J.T. George[5], H.J. Woerle[4], B. Zinman[6];

[1]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [2]St Michael's Hospital, Division of Cardiology, University of Toronto, Toronto, Canada, [3]Department of Medicine, Würzburg University Clinic, Würzburg, [4]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, [5]Boehringer Ingelheim Ltd, Bracknell, Berkshire, UK, [6]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Division of Endocrinology, University of Toronto, Toronto, Canada.

Background and aims: In the EMPA-REG OUTCOME trial, EMPA given in addition to standard of care significantly reduced CV death by 38% vs placebo (PBO) (HR 0.62; 95% CI 0.49, 0.77) in patients with type 2 diabetes (T2DM) and established CV disease. We investigated whether baseline HbA1c or change in HbA1c influenced the effect of EMPA on CV death.

Materials and methods: Patients were randomised to EMPA 10 mg, EMPA 25 mg, or PBO. Background glucose-lowering therapy was to remain unchanged for 12 weeks and then be adjusted to achieve glycaemic control according to local guidelines. CV death was analysed in the pooled EMPA group vs PBO in subgroups by (1) baseline HbA1c (<7.0%; 7.0 to <8.0%; 8.0 to <9.0%; ≥9.0%) and (2) reduction from baseline in HbA1c at week 12 (≥0.5%; <0.5%). Differences in risk between treatment groups were assessed using a Cox proportional hazards model.

Results: A total of 7020 patients were treated. Median observation time was 3.1 years. The benefit of EMPA vs PBO on CV death was consistent irrespective of baseline HbA1c or change in HbA1c from baseline at week 12 (Figure).

Conclusion: In patients with T2DM and established CV disease, the reduction in CV death with empagliflozin appeared to occur irrespective of either baseline HbA1c or the early glycaemic response to the medication.

EMPA-REG OUTCOME: consistent reduction in risk of cardiovascular (CV) outcomes and mortality with empagliflozin (EMPA) irrespective of sulphonylurea (SU) use at baseline

J.T. George[1], S.E. Inzucchi[2], D. Fitchett[3], M. Mattheus[4], C. Janista[4], B. Zinman[5];

[1]Boehringer Ingelheim Ltd, Bracknell, Berkshire, UK, [2]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [3]St Michael's Hospital, Division of Cardiology, University of Toronto, Toronto, Canada, [4]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, [5]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Division of Endocrinology, University of Toronto, Toronto, Canada.

Background and aims: In EMPA-REG OUTCOME, EMPA given in addition to standard of care significantly reduced CV death by 38% and all-cause mortality by 32% vs placebo (PBO) in patients with T2DM and established CV disease. We investigated CV outcomes and adverse events (AEs) by SU use at baseline.

Materials and methods: Patients were randomised to receive PBO, EMPA 10 mg, or EMPA 25 mg. Background glucose-lowering therapy was to remain unchanged for 12 weeks then be adjusted to achieve glycaemic control according to local guidelines. Differences in risk of CV outcomes between EMPA and PBO across subgroups by use of SU at baseline were assessed using a Cox proportional hazards model.

Results: In total, 2333, 2345 and 2342 patients received PBO, EMPA 10 mg and EMPA 25 mg, of whom 992 (42.5%), 985 (42.0%) and 1029 (43.9%), respectively, were taking SU (alone or with other glucose-lowering medications) at baseline. At week 164, the adjusted mean (SE) change from baseline in HbA1c was -0.33% (0.03) with EMPA pooled and 0.10% (0.05) with PBO in patients who were taking SU at baseline (adjusted mean [95% CI] difference: -0.43% [-0.54, -0.31]) and -0.36% (0.03) with EMPA and -0.03% (0.04) with PBO in patients who

were not taking SU at baseline (adjusted mean [95% CI] difference: -0.33% [-0.43, -0.22]). AEs were consistent with the known safety profile of EMPA. Confirmed hypoglycaemic AEs (plasma glucose ≤70 mg/dL and/or requiring assistance) were reported in 23.4%, 24.5% and 25.0% of patients in the PBO, EMPA 10 mg and EMPA 25 mg groups who were taking SU at baseline, and 31.2%, 30.5% and 29.7% of patients in these groups not taking SU at baseline, respectively. Hypoglycaemic AEs requiring assistance were reported in 1.1%, 1.2% and 1.0% of patients in the PBO, EMPA 10 mg and EMPA 25 mg groups who were taking SU at baseline and 1.9%, 1.5% and 1.5%, respectively, of patients in these groups not taking SU at baseline, respectively. Risk reductions in CV outcomes and all-cause mortality with EMPA pooled vs PBO were consistent irrespective of SU use at baseline (Figure).

Conclusion: In patients with T2DM and established CV disease, the proportion of patients with hypoglycaemic AEs was similar between the PBO and EMPA groups in patients who were and were not taking SU at baseline. EMPA reduced the risk of CV and all-cause mortality, 3-point major adverse CV events and heart failure irrespective of SU use at baseline.

Reduction in hospitalisation for heart failure with empagliflozin is consistent across categories of baseline HbA_{1c} and change in HbA_{1c}: results from EMPA-REG OUTCOME

H.J. Woerle[1], D. Fitchett[2], S.E. Inzucchi[3], C. Wanner[4], M. Mattheus[1], J.T. George[5], B. Zinman[6];
[1]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, [2]St Michael's Hospital, Division of Cardiology, University of Toronto, Toronto, Canada, [3]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [4]Department of Medicine, Würzburg University Clinic, Würzburg, Germany, [5]Boehringer Ingelheim Ltd, Bracknell, Berkshire, UK, [6]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Division of Endocrinology, University of Toronto, Toronto, Canada.

Background and aims: In the EMPA-REG OUTCOME trial, EMPA given in addition to standard of care significantly reduced the risk of hospitalisation for heart failure (HHF) vs placebo (PBO) (HR 0.65; 95% CI 0.50, 0.85) in patients with type 2 diabetes (T2DM) and established CV disease. We investigated whether baseline HbA1c or change in HbA1c influenced the effect of EMPA on HHF.

Materials and methods: Patients were randomised to receive EMPA 10 mg, EMPA 25 mg, or PBO. Background glucose-lowering therapy was to remain unchanged for 12 weeks and then be adjusted to achieve glycemic control according to local guidelines. HHF was analysed in the pooled EMPA group vs PBO by categories of (1) baseline HbA1c (<7.0%; 7.0 to <8.0%; 8.0 to <9.0%; ≥9.0%) and (2) reduction from baseline in HbA1c at week 12 (≥0.5%; <0.5%). Differences in risk between treatment groups were assessed using a Cox proportional hazards model.

Results: A total of 7020 patients were treated. Median observation time was 3.1 years. The benefit of EMPA vs PBO on HHF was consistent irrespective of baseline HbA1c or change in HbA1c from baseline at week 12 (Figure).

Conclusion: In patients with T2DM and established CV disease, the reduction in HHF with empagliflozin appeared to occur irrespective of either baseline HbA1c or the early glycaemic response to the medication.

EMPA-REG OUTCOME: empagliflozin (EMPA) reduced the risk of cardiovascular (CV) outcomes and mortality irrespective of metformin (MET) use at baseline

S. Hüttner[1], B. Zinman[2], D. Fitchett[3], V. Woo[4], M. Mattheus[1], C. Janista[1], J.T. George[5], S.E. Inzucchi[6];
[1]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, [2]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Division of Endocrinology, University of Toronto, [3]St Michael's Hospital, Division of Cardiology, University of Toronto, Toronto, [4]Section of Endocrinology and Metabolism, University of Manitoba, Winnipeg, Canada, [5]Boehringer Ingelheim Ltd, Bracknell, Berkshire, UK, [6]Section of Endocrinology, Yale University School of Medicine, New Haven, USA.

Background and aims: In the EMPA-REG OUTCOME trial, EMPA given in addition to standard of care significantly reduced CV outcomes and all-cause mortality vs placebo (PBO) in patients with T2DM and established CV disease. We investigated CV outcomes and adverse events (AEs) by use of MET at baseline.

Materials and methods: Patients were randomised to receive PBO, EMPA 10 mg, or EMPA 25 mg. Background glucose-lowering therapy was to remain unchanged for 12 weeks then be adjusted at the investigator's discretion to achieve glycemic control according to local guidelines. Differences in risk of CV outcomes between EMPA and PBO across subgroups by use of MET at baseline were assessed using a Cox proportional hazards model.

Results: In total, 2333, 2345 and 2342 patients received PBO, EMPA 10 mg and EMPA 25 mg, of whom 1734 (74.3%), 1729 (73.7%) and 1730 (73.9%), respectively, were taking MET (alone or with other glucose-lowering medications) at baseline. In patients who were and were not taking MET at baseline, risk reductions in CV outcomes and all-cause mortality with EMPA vs PBO were consistent (Figure). At week 164, the adjusted mean (SE) change from baseline in HbA1c was -0.32% (0.03) with EMPA pooled and 0.08% (0.04) with PBO in patients who were taking MET at baseline (adjusted mean [95% CI] difference: -0.40% [-0.49, -0.31]) and -0.41% (0.04) with EMPA and -0.14% (0.07) with PBO in patients who were not taking MET at baseline (adjusted mean [95% CI] difference: -0.27% [-0.42, -0.11]). AEs were consistent with the known safety profile of EMPA. Confirmed hypoglycaemic AEs (plasma glucose ≤70 mg/dL and/or requiring assistance) were reported in 26.1%, 26.5% and 27.3% of patients in the PBO, EMPA 10 mg and EMPA 25 mg groups who were taking MET at baseline, and 32.9%, 32.1% and 28.4% of patients not taking MET at baseline, respectively. Hypoglycaemic AEs requiring assistance were reported in 1.2%, 1.4% and 1.2% of patients in the PBO, EMPA 10 mg and EMPA 25 mg groups who were taking MET at baseline and 2.5%, 1.5% and 1.5% of patients not taking MET at baseline, respectively.

Conclusion: In patients with T2DM and established CV disease, EMPA reduced the risk of CV outcomes and all-cause mortality irrespective of MET use at baseline, The proportion of patients with hypoglycaemic AEs was similar between the PBO and EMPA groups in patients who were and were not using MET at baseline.

Empagliflozin decreases risk of kidney function decline in type 2 diabetes: slope analyses in patients with / without heart failure at baseline from the EMPA-REG OUTCOME trial

A.K. Cheung[1], D. Fitchett[2], B. Zinman[3], S.D. Anker[4], U.C. Broedl[5], A. Salsali[6], M. Mattheus[5], M. von Eynatten[5], C. Wanner[7];
[1]University of Utah, Salt Lake City, USA, [2]St Michael's Hospital, University of Toronto, [3]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, Canada, [4]Universitätsmedizin Göttingen, Göttingen, [5]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, [6]Boehringer Ingelheim Pharmaceuticals Inc., Ridgefield, USA, [7]Dept of Medicine, Würzburg Univ Clinic, Würzburg, Germany.

Background and aims: Progressive decline of kidney function is common in patients with diabetes, whether or not they have heart failure (HF). In the EMPA-REG OUTCOME trial, empagliflozin decreased the risk for the composite of CV death and hospitalization for HF (HR 0.66; 95% CI 0.55, 0.79; p<0.0001) in patients with type 2 diabetes and established cardiovascular risks. Empagliflozin also slowed the progression of kidney disease and decreased the risk of events indicative of kidney disease progression. Here, we report the rate of change in eGFR in patients with and without HF in the EMPA-REG OUTCOME trial.

Materials and methods: 7020 patients receiving standard care were randomized (1:1:1) to empagliflozin 10 mg, 25 mg or placebo. Treatment differences in the average rate of change in eGFR for pre-specified trial phases were assessed using a linear-regression, random-intercept and time-coefficient model and results are depicted for mean slopes. Patients with and without HF at baseline were assessed separately.

Results: Empagliflozin caused an acute drop in eGFR during the first 4 weeks, followed by a long-term stable eGFR during a median treatment time of 2.6 years (Figure), and a rapid return towards baseline after cessation of empagliflozin. In contrast, there was a steady decline in eGFR in the placebo group during the long-term treatment phase. The pattern of eGFR changes were similar in patients with (n=706) or without baseline (n=6314) HF.

Conclusion: Empagliflozin slowed eGFR decline in patients with type 2 diabetes, whether or not they were reported to have had HF at the start of treatment. Slope analyses using multiple eGFR readings from individual patients represent an emerging useful method to document changes in kidney function over time. The kidney effects of empagliflozin on patients with HF (with or without diabetes) is being further investigated in ongoing trials in patients with HFrEF (EMPEROR-reduced) and HFpEF (EMPEROR-preserved).

LRG1 as a predictive marker for pre-eclampsia in women with type 1 diabetes

A.H.Y. Cheung[1], A.J. Jenkins[2], K.F. Hanssen[3,4], S.K. Garg[5], J.Y. Yu[6], C.E. Aston[7], C.B. Kelly[1], T.J. Lyons[1], C.J. Watson[1];
[1]Centre for Experimental Medicine, Queen's University Belfast, Belfast, UK, [2]University of Sydney, NHMRC Clinical Trials Centre, Sydney, Australia, [3]Department of Endocrinology, Oslo University Hospital, [4]Institute of Clinical Medicine, University of Oslo, Oslo, Norway, [5]Barbara Davis Center for Childhood Diabetes, Aurora, [6]Division of Endocrinology, MUSC, Charleston, [7]Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, USA.

Background and aims: Pregnant women with type 1 diabetes (T1DM) have a 4-fold increased risk for pre-eclampsia (PE) vs. their non-diabetic counterparts. PE is characterised by new-onset hypertension (>140/90mmHg), with proteinuria (>300mg/24h) and/or organ damage developing after 20 wks gestation: it can be fatal to both mother and child. Currently, PE is hard to predict, and the only cure is delivery. Improved biomarkers and specific treatments are urgently needed. We aim to explore the utility of Leucine-Rich alpha-2-Glycoprotein-1 (LRG1), a marker of inflammation and angiogenesis, as a predictor of PE in pregnant type-1 diabetic (T1DM) women.
Materials and methods: This is a prospective study of 62 pregnant women: 23 with T1DM who developed PE, 21 with T1DM who remained normotensive, and 18 healthy non-diabetic women as reference controls. The two T1DM groups were matched for age, duration of diabetes, HbA1c and parity. Fasting plasma samples were collected during the second trimester (21.7±1.4 weeks of gestation) and analysed for LRG1 (ELISA, IBL). Samples were diluted at 1:2000 as determined by previous validation studies. sFlt, the current 'gold standard' anti-angiogenic biomarker for PE prediction, was previously measured in this cohort (ELISA, R&D Systems).
Results: LRG1 protein levels were significantly increased in women with T1DM who subsequently developed PE vs. those who did not (50.7 ± 2.4 vs 40.8 ± 2.5 μg/mL, $p<0.01$, mean ± SEM). This significant increase preceded the clinical signs and symptoms of PE. In comparison, sFlt did not predict PE at this gestational age.
Conclusion: Women with T1DM who later developed PE had significantly higher plasma LRG1 in the second trimester of pregnancy vs. those who remained normotensive. LRG1 may have utility as an early predictor of PE, and could provide novel insights into disease mechanisms for PE in diabetic women.

NMR-based metabolic phenotyping of serum in patients with gestational diabetes

L. Spanou[1], E. Anastasiou[1], C. Kostara[2], E. Bairaktari[2], V. Tsimihodimos[3];
[1]Department of Endocrinology -Diabetes Center, Alexandra General Hospital, Athens, [2]Laboratory of Clinical Chemistry, University of Ioannina, [3]Department of Internal Medicine, School of Medicine, University of Ioannina, Ioannina, Greece.

Background and aims: Gestational diabetes mellitus (GDM) is associated with adverse maternal and fetal outcomes and confers to the affected women a high lifetime risk for the development of type 2 diabetes. Because of the importance of early intervention in preventing these complications, there is still scope for devising improved first-trimester biomarker determination for the diagnosis and risk stratification of gestational diabetes. Metabolomic profiling, the systematic study of small-molecule products of biochemical pathways, has been used to predict, diagnose and monitor several metabolic disorders, including GDM. Proton nuclear magnetic resonance (^{1}H NMR) spectroscopy is one of the preferred tools for the metabolomic analysis of biological matrixes. It is a rapid and reproducible technique, requires minimum sample pretreatment, and provides an overall qualitative and quantitative metabolic assay, including detailed information on molecular structure. We employed NMR spectroscopy combined with Multivariate Data Analysis to characterize the metabolic signature of blood serum in a Caucasian cohort of 19 pregnant healthy women who developed GDM compared to 19 non-diabetic pregnant healthy women.
Materials and methods: The two groups studied were matched for age, BMI and serum lipid parameters. Blood samples were collected between the 26th and 30th week of pregnancy just before the OGTT test and before any therapeutic intervention was applied. The serum ^{1}H NMR spectra were recorded at 298 K on a 500 MHz Bruker Avance DRX NMR spectrometer operating at a field strength of 11.74 Tesla and running on TopSpin 2.1 suite. Orthogonal projection to Partial Least Squares Discriminant Analysis (OPLS-DA) was applied to construct statistical models of serum metabolic data.
Results: The two dimensional OPLS-DA scores plot revealed a distinct separation between pregnant women with and without GDM with minimal overlapping. The significance of the OPLS-DA metabolic models via cross-validated ANOVA test was calculated as a p value of 0.002 (significant <0.5). According to the OPLS-DA coefficient plot, the serum metabolic phenotype of pregnant women with GDM was characterized by lower concentrations of lactate, alanine, glutamine and glutamate and higher concentrations of 2-hydroxybutyrate, 3-hydroxybutyrate, and to a lesser extent of branched chain amino acids (leucine, valine and isoleucine). Of note, elevated branched chain amino acids that have been considered as a risk factor for type 2 diabetes were only marginally elevated in our study, a finding that is in consistent with previous studies in GDM.
Conclusion: Apart from hyperglycemia, GDM is associated with a characteristic metabolic profile that possibly reflects the disturbances in various metabolic pathways. The role of these alterations in the pathogenesis of the complications of GDM as well as their impact on the increased risk for the subsequent development of type 2 diabetes remain to be established.

Changes in lipid and amino acid levels during pregnancy and early postpartum period in gestational diabetes

A. Pleskacova[1], M. Skrutkova Langmajerova[2], J. Smutna[1], V. Bartakova[1], K. Chalasova[1], L. Pacal[1], J. Tomandl[1], K. Kankova[1];
[1]Department of Pathophysiology, Masaryk University, [2]Department of Biochemistry, Masaryk University, Brno, Czech Republic.

Background and aims: The increasing prevalence of gestational diabetes mellitus (GDM) poses a risk for permanent diabetes development in future life for both mother and child. We hypothesize that changes in non-esterified fatty acids (NEFAs) and amino acids (AAs) in plasma previously associated with type 2 diabetes development may reflect more serious abnormalities of insulin secretion and sensitivity reflected by more severe disturbances of glucose tolerance during pregnancy associated with higher *postpartum* metabolic risk. The aims of this study were to determine NEFAs (C12:0 to C22:6) and all proteinogenic and several nonessential AAs during pregnancy and *postpartum* period in women with GDM and those with physiological pregnancy and to study the relationships between selected metabolites and anthropometrical and biochemical data.
Materials and methods: A total of 40 women (20 GDM cases diagnosed according to WHO criteria and 20 healthy counterparts) were included in the study. All subjects underwent OGTT with 75g of glucose load between 24-28th week of pregnancy, moreover, women with GDM history underwent repeated *postpartum* OGTT up to 12 months after delivery. Plasma levels of NEFAs were determined by gas chromatography with flame ionization

detector. Plasma essential and several nonessential AAs were determined by capillary electrophoresis with subsequent MS detection.
Results: Decreased levels of dodecanoic and tetradecanoic acid were found in GDM group at 2nd trimester (P=0.02 a P=0.05, Mann-Whitney). There was a significant decrease in docosahexaenoic acid levels *postpartum* within GDM group (P=0.03, Wilxocon). Five NEFAs (C16:0, C17:0, C18:0, C18:1, C18:2) were positively correlated with age, two NEFAs (C16:1, C18:3) were negatively correlated with offspring birth weight, plasma levels of docosahexaenioc acid were positively correlated with systolic blood pressure in 2nd trimestr of pregnancy and C14:0, C16:1 and C18:1 levels during pregnancy were correlated with glycaemia levels (all P<0,05, Spearman). Decreased levels of several AAs (Ala, Asn, Gln, Glu, His, Lys, Ser, Trp and hydroxyproline) were found in GDM pregnancy (all P<0.05, Mann-Whitney). Levels of almost all analyzed AAs were decreased *postpartum* in GDM group compared to their levels during pregnancy (all P<0.04, Wilcoxon). Negative correlations between glutamic acid, histidine and hydroxyprolin levels and respective values of OGTT glucose levels and AUC during pregnancy were found (all P<0.05, Spearman).
Conclusion: Our data support a possible link between GDM and selected proteomic and lipidomic parameters. Pathophysiological relevance and predictive potential of altered metabolomic pattern in GDM for future maternal metabolism and/or offspring health remain to be studied.

Impact of maternal triglyceride and novel metabolic parameters on neonatal anthropometrics in Asians

S. Samsuddin[1], P. Arul[1], M. Md Amin[1], A. Yahya[2], N. Musa[1], L.L. Lim[1], S.S. Paramasivam[1], J. Ratnasingam[1], L. Ibrahim[1], K.C. Chooi[1], A.T.B. Tan[1], P.C. Tan[3], A. Ahmad Kamar[4], A. Anuar Zaini[4], S.R. Vethakkan[1];
[1]Medicine, University Malaya Medical Centre, [2]Social and Preventive Medicine, University Malaya Medical Centre, [3]Obstetric & Gynaecology, University Malaya Medical Centre, [4]Paediatrics, University Malaya Medical Centre, Kuala Lumpur, Malaysia.

Background and aims: In Caucasian populations, maternal obesity and triglyceride (Tg)(in addition to glucose) have been found to modulate neonatal anthropometrics via intrauterine fetal programming. Less is known of these associations during pregnancy in Asians, in whom strength of/ thresholds for correlation may differ given that visceral adiposity/insulin resistance in Asians is elevated at a lower BMI. Hence we aimed to determine the relationship between maternal BMI/metabolic variables (including Tg) and neonatal anthropometrics in Malaysian mother-offspring pairs.
Materials and methods: In this prospective observational study, we recruited both women with gestational diabetes mellitus(GDM) and normal glucose tolerance(NGT)(excluding pregestational diabetes) from a tertiary combined multidisciplinary antenatal clinic. Demographic, anthropometric and clinical data were obtained during an interview/examination using a structured questionnaire. Blood was drawn for insulin, C-peptide and Tg during 75g OGTT at 14-32 weeks gestation. At birth, neonatal anthropometrics were assessed and data such as maternal weight gain during pregnancy, mode of delivery etc. extracted from records.
Results: We recruited 470 women: 125 GDM, 225 lean NGT , 90 nonlean NGT(BMI>27.5 kg/m2). In the group as a whole (n=470), pregravid BMI, fasting Tg, fasting glucose and HOMA2-%S correlated significantly and independently with BW Ratio (r=0.193, 0.148, 0.222,-0.142 respectively). Total gestational weight gain in pregnancy was the strongest significant independent predictor of BW (r=0.219). Pregravid BMI, fasting Tg, fasting glucose, HOMA2-%S and total gestational wt gain in pregnancy were also independently predictive of BWR in the NGT mothers (p<0.05). Mean BW in this population of well-treated GDM mothers in a tertiary centre BW was nonsignificantly lower in GDM compared with Lean NGT offspring(2959g vs 3060g). 7 (4.7%) offspring fulfilled criteria for macrosomia, BW ≥ 4 kg. There were 10 LGA babies(2.1%) as defined by Fenton antenatal growth charts. Calculated 90th centile threshold in this Asian population(GDM+NGT) for BW was 3.6 kg. In the whole group,fasting Tg >3.6 mmol/l(95th centile)(OR 31.9) and gestational weight gain>10kg (OR 13.6)was independently predictive of LGA status. Tg >3.6 mmol/l (OR 16.2) and gestational wt gain > 20 kg (OR 4.7) were independently predictive of a sum of skinfold thickness >90th centile.
Conclusion: These findings indicate that maternal hypertriglyceridemia is an important risk factor for LGA status and increased neonatal adiposity in Asian offspring independent of glucose, in treated GDM and NGT mothers. Gestational weight gain and insulin resistance also adversely impact neonatal anthropometrics. Our findings indicate that in addition to maternal glycemia, hypertriglyceridemia and insulin resistance may prove to be important metabolic targets in pregnancy.

Inflammation is differently modulated in offspring of mothers with gestational diabetes as compared to offspring of NGT obese women

M. Fabrizi[1], G. Bedogni[2], G. Cinelli[1], C. Vallone[3], A. Severino[1], F. Signore[3], M. Manco[1];
[1]Research Unit for Multifactorial Disease, Bambino Gesù Children's Hospital, Rome, [2]Liver Research Center, Clinical Epidemiology Unit, Trieste, [3]Department of Obstetrics and Gyneacology, San Camillo Hospital, Rome, Italy.

Background and aims: Both pre-pregnancy obesity and gestational diabetes mellitus (GDM) confer, each independently, the offspring an increased metabolic risk. Aim of the present cohort study was to compare the inflammatory profile of normal weight controls (NWCs), GDM and normal glucose tolerant obese (NGT_Ob) mothers and its impact on the offspring's cytokine release and body weight at birth.
Materials and methods: Serum levels of leptin, adiponectin, their ratio (L/A) as estimate of insulin resistance, interleukin (IL) 6, IL8, IL10, tumor necrosis factor (TNF) alpha, TNFRII, Intercellular Adhesion Molecule 1 (ICAM1), sCD14 were assayed at birth in maternal and cord blood of 350 normal weight, 51 NGT obese and 42 GDM women from the "Feeding" cohort study. Cytokine values are reported after log transformation.
Results: Leptin (4.1 ± 0.7; 3.5 ± 1.0; 2.9 ± 0.9 ng/ml) was significantly increased in NGT_Ob and GDM vs. NWCs (p<0.001 for all). The L/A (21.2 ± 21.9; 10.8 ± 18.5) and ICAM1 (6.5 ± 1.0; 5.7 ± 0.9 ng/ml) were significantly increased only in NGT_Ob vs. NWC women (p<0.001), while TNFRII was significantly increased in GDM women vs. NWCs (6.8 ± 0.4; 6.6 ± 0.4 pg/ml; p<0.03). GDM offspring showed the highest leptin (2.8 ± 1.2; 2.3 ± 1.1; 2.1 ± 1.0 ng/ml), L/A (3.3 ± 7.7; 1.3 ± 2.0) and proinsulin levels (2.9 ± .9; 2.6 ± 0.7; 2.5 ± 0.7 pmol/L) (p<0.001 for all). The best predictors of child body weight z-score at birth were the child's proinsulin and leptin concentrations (β=0.334, p<0.0001), while maternal age, leptin, pre-pregnancy body mass index, and gestational weight gain were excluded variables. Comparison of offspring born with large for gestational age (LGA) demonstrated no difference in proinsulin levels, while confirmed significantly higher leptin (3.2 ± 1.2; 2.7 ± 1.2; 2.3 ± 0.9 ng/ml), L/A (7.0 ± 12.8; 2.0 ± 2.8; 1.1± 1.1) and sCD14 (1.8 ± 1.6; 0.7 v 0.4; 1.0 ± 0.8 μg/ml) levels in GDM (N=14) than in NGT_Ob (N=8) and NWCs offspring (N=46).
Conclusion: Newborns of GDM mothers exhibit increased proinsulin, leptin, L/A and sCD14 levels than offspring of obese NGT mothers. While proinsulin seems to explain the higher birth weight of the children, leptin and sCD14 might partially explain the risk of developing low-grade inflammation and metabolic disturbances in adult life.

Chemerin and omentin-1 circulating and gene expression levels in adipose tissue and placenta in women with gestational diabetes

P.C. Tsiotra[1], P. Halvatsiotis[2], K. Patsouras[3], E. Maratou[1], E. Salamalekis[3], S.A. Raptis[1], G. Dimitriadis[2], E. Boutati[2];
[1]Dept. of Basic Sciences, Mol. Biology Lab., Hellenic National Diabetes Center (HNDC), [2]2nd Department of Internal Medicine, University of Athens, Medical School, University General Hospital "Attikon", [3]3nd Dept of Obstetrics and Gynecology, University of Athens, Medical School, University General Hospital "Attikon", Athens, Greece.

Background and aims: Gestational diabetes mellitus (GDM) is defined as a state of glucose intolerance characterized by β-cell dysfunction and insulin resistance. Maternal adipose tissue and the placenta secrete various adipokines such as chemerin and omentin-1 that could play a role in the development of insulin resistance in human pregnancy. We examined whether chemerin and omentin-1 mRNA and protein production is altered in GDM women and whether this might relate to indices of insulin resistance.
Materials and methods: Maternal peripheral blood, visceral adipose tissue (VAT), subcutaneous adipose tissue (SAT) and placenta tissues were obtained from GDM women -with and without obesity- and normal glucose tolerant (NGT) pregnant women, at the time of the Cesarean section. We developed a real-time quantitative RT-PCR using fluorecently labelled hybridization probes to detect relative chemerin and omentin-1 mRNA levels in VAT, SAT and the placenta. Circulating chemerin and omentin-1 protein levels were measured in all women by use of standard commercial ELISAs. Fasting plasma glucose and insulin (RIA) levels were measured from maternal peripheral blood.
Results: Circulating chemerin was significantly higher in GDM-obese compared to NGT-non-obese women (Table) and correlated positively with BMI and HOMA-IR at delivery. Circulating omentin-1 was significantly lower in GDM (obese and non-obese) compared to NGT-non-obese women (Table) and was negatively correlated with BMI. Chemerin mRNA is expressed significantly higher in both fat depots (SAT and VAT) compared to placenta in all women (6-to 24-times, $p<0.05$) and its expression in VAT in GDM-obese was higher compared to NGT-non-obese women (Table). Omentin-1 is expressed significantly higher in VAT compared to SAT (50- to 100-times, $p<0.01$) and its expression in placenta was negligible in all women (Table)
Conclusion: Maternal adipose tissue and especially VAT is the main site of chemerin and omentin-1 mRNA expression in at term human pregnancy. Chemerin is elevated and omentin -1 protein production is decreased in GDM-obese women. This finding together with the positive association of chemerin with markers of insulin resistance, suggest a potential role of these adipokines and more especially of chemerin in the development of insulin resistance in these women.

Gestational diabetes modulates cholesterol homeostasis in human fetoplacental endothelium

Y. Sun[1], S. Kopp[2], C.C. Gali[1], M. Zandl[1], E. Fanaee-Danesh[1], I. Björkhem[3], G. Desoye[2], C. Wadsack[2], U. Panzenboeck[1];
[1]Medical University of Graz, [2]Department of Obstetrics and Gynecology, Medical University of Graz, Graz, Austria, [3]Division of Clinic Chemistry, Karolinska Institute, Stockholm, Sweden.

Background and aims: Gestational diabetes mellitus (GDM) is associated with hyperinsulinemia, hyperlipidemia and disordered cholesterol metabolism in the maternal circulation. Cholesterol can be efficiently delivered into the fetal circulation across human term fetoplacental endothelial cells (HPEC) via ABCA1 and ABCG1. The aim of this study was to investigate how GDM affects cholesterol metabolism in HPEC and to explore the underlying mechanism(s) of alteration.
Materials and methods: HPEC were isolated from fetal arterial vessels of term placentas from GDM or healthy subjects. Cholesterol biosynthesis and esterification were determined by TLC using cholesterol precursor [^{14}C]-acetate. HPEC were labeled with [^{3}H]-cholesterol or [^{3}H]-24S-hydroxycholesterol to perform sterol efflux assays, using fetal serum, HDL_3, or apoA-I as acceptors. Cellular ROS production was measured using H_2DCFDA dye. Oxysterol levels in HPEC and umbilical cord plasma were quantified by GC-MS.
Results: GDM promoted cholesterol biosynthesis in HPEC by up-regulating SREBP2 mRNA expression and HMGCR mRNA and protein levels. Total cellular cholesterol levels were maintained through that GDM significantly enhanced cholesterol release from HPEC as a result of up-regulation of ABCA1 and ABCG1. Similar results were obtained when control HPEC were incubated with LXR against TO901319, 27-hydroxycholesterol, 24(S)-hydroxycholesterol, 7-ketocholesterol, or 7β-hydroxycholesterol. GDM conditions further upregulated Cyp27A1 transcription and increased the production of reactive oxygen species (ROS). ROS generated oxysterols were significantly increased in GDM HPEC. 24(S)-hydroxycholesterol release to fetal serum was more efficient in GDM than in control HPEC.
Conclusion: The GDM environment modulates cholesterol homeostasis by enhancing cholesterol biosynthesis which is compensated by increasing cholesterol efflux in response to LXR activation due to increasing oxysterol presence in the fetoplacental endothelium.

Elucidating the role of novel angiogenesis-related proteins, FKBPL and SIR-1, in trophoblast cells exposed to diabetic stimuli: potential implications for preeclampsia

L. McClements[1,2], R. McNally[1], A. Alqudah[1], T. Robson[2], C.J. Watson[1], T.J. Lyons[1];
[1]Centre for Experimental Medicine, Queen's University Belfast, Belfast, UK, [2]Molecular and Cellular Therapeutics, Royal College of Surgeons in Ireland, Dublin, Ireland.

Background and aims: Diabetic vascular complications are closely related to irregular angiogenesis, oxidative stress and lipid peroxidation. Preeclampsia (PE) is a pregnancy condition characterised by high blood pressure, proteinuria and multi-organ dysfunction. PE occurs in 4-6% of pregnancies; however in women with diabetes the incidence of PE is increased four-fold. Furthermore, PE does not only have short-term risks, but long-term is associated with cardiovascular disease and/or Type 2 diabetes in both mothers and offspring. Despite research efforts in this area, currently there are no reliable early biomarkers, preventative or treatment strategies for PE, other than delivery. Moreover, paucity of mechanistic data is impeding the development of successful preventative

and curative therapies of PE, particularly in the context of diabetes. The novel angiogenesis-related protein, FKBPL, is a critical regulator of developmental and pathological angiogenesis and closely associated with nutrient-sensing protein, SIRT-1. Therefore, FKBPL may play a key role in the pathophysiology of PE associated with diabetes.

Materials and methods: Three different trophoblast cells lines (HTR8.SV.neo, BeWo and Jar) were exposed to diabetic stimuli: normal vs. high glucose (5.5 vs. 10, 20, 40 mM), native vs. highly oxidised, glycated low density lipoprotein (N- vs. HOG-LDL; 25 μg protein/ml), or hypoxia (1%); then FKBPL and SIRT-1 protein expression and mRNA levels were measured in cell lysates. FKBPL and SIRT-1 were also measured in placental extracts using western blotting.

Results: FKBPL and SIRT-1 protein expression differed across the three trophoblast cell lines, with Jar cells expressing the highest levels of FKBPL and SIRT-1, BeWo cells expressing the lowest level of SIRT-1 and HTR8.SV.neo cells expressing the lowest level of FKBPL. In BeWo cells treated with high vs. normal glucose (48 h), FKBPL mRNA levels were increased 1.3-fold (10mM; p=0.001; n=3), 1.21-fold (20mM; p=0.03; n=3) and 1.46-fold (40mM; p=0.007; n=3). In HTR8.SV.neo cells treated with HOG-LDL (24 h) a 2-fold increase of FKBPL protein was demonstrated compared to native LDL (p=0.048; n=4). No significant changes in FKBPL or SIRT-1 protein expression were observed in Jar cells treated with HOG-LDL, perhaps because of higher FKBPL protein expression in Jar vs. HTR8.SV.neo (p=0.03; n=3). Exposure of HTR8.SV.neo cells to hypoxia (1%) led to 2.4- and 3.8-fold reductions in FKBPL (p=0.003; n=3) and SIRT-1 (p=0.02; n=3) protein expressions, respectively. In concert, we have previously published that endothelial cells (HMEC-1) exposed to hypoxia (0.1%) exhibited reduced FKBPL secretion. FKBPL is also strongly expressed in placental extracts.

Conclusion: Our data suggest that FKBPL and SIRT-1 may have important regulatory and biomarker roles in the development of PE as a vascular complication of diabetes. Pregnancies complicated by both diabetes and PE might exhibit elevated levels of FKBPL/SIRT-1 in early gestation (hyperglycaemia, oxidative stress) and reduced levels in late gestation (placental hypoxia). We plan to investigate this in longitudinal plasma samples from patients with and without diabetes, and with and without PE.

Amino acid profile in metformin vs insulin treated women with gestational diabetes

M.S. Huhtala[1], K. Tertti[2], T. Rönnemaa[3];
[1]Department of Obstetrics and Gynecology, University of Turku, [2]Department of Obstetrics and Gynecology, Turku University Hospital, [3]Department of Medicine, University of Turku, Turku, Finland.

Background and aims: Gestational diabetes mellitus (GDM) is a growing health concern worldwide. While recent evidence is supporting the safety of metformin use in the treatment of GDM, the detailed data considering long term consequences and the effect on maternal and fetal metabolism is mostly lacking. Amino acids influence intermediary metabolism. Changes in aromatic and branched chain amino acids have been associated with insulin resistance and type 2 diabetes. This study was conducted to investigate whether metformin treatment of GDM affects the amino acid profile of the mother or the fetus and to find out if it causes adverse or favourable changes in the metabolome compared to conventional insulin treatment.

Materials and methods: 217 pregnant women diagnosed with GDM were randomized to receive either metformin (110) or insulin (107). Serum samples were available from 99 metformin and 91 insulin treated women at the time of GDM diagnosis (mean 30th week of pregnancy). Another serum sample was collected at 36th week of pregnancy. Cord blood samples were obtained from new-borns exposed to metformin (n=98) or insulin (n=98) during gestation. NMR spectroscopy was used to determine serum concentrations of 9 amino acids (alanine, glutamine, glycine, isoleucine, leucine, valine, histidine, phenylalanine and tyrosine), 3 ketone bodies (acetate, acetoacetate and 3-hydroxybutyrate), and 5 glycolysis related metabolites (glucose, lactate, pyruvate, citrate and glycerol). Student's t-test and Pearson correlations were used for statistical analysis.

Results: The rise in alanine (58.8 μmol/l vs. 31.5 μmol/l, p<0.0001) and isoleucine (6.69 μmol/l vs. 2.37 μmol/l, p=0.023) during the treatment was larger in the metformin group compared to insulin. Other branched chain, aromatic or other amino acids were not affected by metformin. Serum lactate (273 μmol/l vs. 119 μmol/l, p=0.015) and citrate (13.7 μmol/l vs. 8.22 μmol/l, p=0.017) increased slightly more in the metformin group. Alanine or isoleucine concentrations at 36th week of pregnancy or their changes were not associated with glycemic control (HbA1c) of the mothers, birth weight of the baby or maternal weight gain. In cord serum samples, the only difference was higher alanine in the metformin group (487 μmol/l vs. 446 μmol/l, p<0.001).

Conclusion: Metformin treatment of GDM causes a similar clearcut increase in serum alanine concentration as previously reported in non-pregnant, non-diabetic subjects. Alanine is a major source for liver gluconeogenesis. Its increase in serum in the metformin group may be a consequence of the suppressing effect of metformin on gluconeogenesis. Overall, the observed changes in the metabolome were small and the data are unlikely to raise health concerns in the mother or the fetus. However, the mechanism behind the altered amino acid profile as well as its clinical significance need yet further studies.

Exposome of placenta: the effect of maternal adipose tissue metabolism on the placenta

G. Medina-Gomez[1], M. Díez-Hochleitner[1,2], Y. Vivas[1], A. Izquierdo[1], P. Corrales-Cordón[1], J. Pita[2], J. Sevillano[2], M. Ros[1], M.P. Ramos[2];
[1]Ciencias Basicas de la Salud, Universidad Rey Juan Carlos, Alcorcon, [2]Universidad San Pablo CEU, Madrid, Spain.

Background and aims: The placenta is exposed to different environmental signals during pregnancy. The so-called exposome of the placenta can

alter the proper placental development and therefore affect the correct fetal development. Recently, preliminary studies have pointed to a possible communication between the placenta and the expandability of the adipose tissue during gestation. The aim of this work is to investigate the different effects of metabolic situations with alterations in the adipose tissue (increased or altered distribution) in placental metabolism in rodents.

Materials and methods: For the obese pregnant model, 8-weeks-old wistar rats were fed standard diet or moderated cafeteria diet (MFD). Body mass index (BMI), biochemical parameters and different cytokines were measured at day 30. After 35 days with the diet, rats were crossed and gestation was followed until day 20 (G20). For the model with alteration of adipose tissue, 3-month-old peroxisome proliferator-activated receptor gamma 2 knockout (PPARγ2KO) mice were crossed and sacrificed at day G18. We performed GTT (glucose 1g/kg BW) and ITT (insulin 0.75U/kg BW). Lipid metabolism gene expression, enzymatic activities and metabolomic analysis was measured in placenta form both models.

Results: Our data showed that a MFD significantly increased body weight (BW) of rats compared with rats fed control diet in the first week (227. 3± 2.3 g *vs.* 215.1 ± 3.2 g (P<0. 01), with significant differences during the 35 days with the diet. However, at G20, neither differences were detected in the BW nor the placental weight of rats fed MFD in comparison with rats fed control diet. Although fetuses number per litter was similar, the fetuses weight from obese mothers was significantly lower ($p<0.01$) compared with fetuses from control diet mothers. Only cholesterol content was significantly decreased ($p<0.05$) in placenta from obese rats; however, Glut 1 and lipin gene and protein expression was significantly increased in obese compared with control diet rats. Cystathionine was significantly increased in the metabolomic analysis in obese pregnant rats. Although pregnant PPARγ2KO mice showed increased BW at G18, no differences were found in placenta or fetuses weight. Deletion of PPARγ2 during gestation revealed different fat distribution, significant increased triglyceride content in liver, but not differences in lipid content in placenta, despite decreased lipropotein lipase gene expression. Of note, the placentas from PPARγ2KO mice presented some degree of inflammation, with significant increase of the ratio iNOS/Arginase.

Conclusion: Impairment of adipose tissue expandability during pregnancy has an effect on metabolic adaptations in the pregnant that can alter the placenta exposome. These adaptations are promoted in placental lipid and carbohydrate metabolism, with the purpose of normal gestation to term.

Pregnancy outcomes in women diagnosed with type 1 diabetes in childhood: a national electronic record-linked cohort study

L. Allen[1], R. Cannings-John[2], A. Evans[3], D. Thayer[4], S. Paranjothy[3], D. Fone[3], C. Dayan[1], J. Gregory[3];
[1]Diabetes Research Group, Cardiff University, [2]Centre for Trials Research, Cardiff University, [3]Division of Population Medicine, Cardiff University, Cardiff, [4]Centre for Health Information, Research and Evaluation, Swansea University, Swansea, UK.

Background and aims: The Brecon register is a near complete (98% ascertainment) community-based register of type 1 diabetes (T1D) diagnosed prior to age 15 in Wales since 1995 (n=3289.) This national approach means the Brecon Cohort is representative of all individuals with childhood onset T1D in Wales, and avoids the biases observed in previously published clinic-based studies. This study aims to utilise the Brecon register to compare pregnancy outcomes in young women (up to age 35) with childhood onset T1D and women without childhood onset T1D (general population.) We will also describe the relationship between pregnancy outcomes, maternal age and duration of T1D, which is not currently understood. This study forms part of a programme of work aimed at identifying individuals that develop early complications of T1D, who are likely to benefit from new interventions, such as immunotherapy to preserve beta cells. Since pregnancy outcomes are strongly influenced by glycaemic control at conception, they are especially likely to be influenced by beta cell function in the years after diagnosis.

Materials and methods: The Brecon register was linked to multiple national datasets in the Secure Anonymised Information Linkage (SAIL) databank, to conduct an electronic record-linked cohort study of pregnancy in women under 35 in Wales from 1995-2013. The outcome measures were pre-eclampsia, preterm birth (<37 weeks), low birth weight (≤2.5kg), small for gestational age (SGA) (≤10th centile), macrosomia (≥4kg), large for gestational age (LGA) (≥90th centile), congenital malformations, stillbirths and hospital admissions in the first year of life. Confounders including maternal age and socioeconomic status, parity, mode of delivery, gestation, birth weight, gender, smoking and breastfeeding were adjusted for as appropriate. Analysis involved logistic regression, with estimates of effects between groups reported as odds ratios (OR) with 95% confidence intervals (95%CI.)

Results: 197,796 births were eligible for inclusion. 330 births were to mothers with childhood onset T1D. Baseline characteristics were comparable, with the exception of mode of delivery (66% Caesarean section in mothers with childhood onset T1D vs 18.5% in the general population) and mean gestation at delivery (35.7 vs 39.7 weeks.). All adverse outcomes except SGA were more common in mothers with childhood onset T1D; pre-eclampsia crude OR 3.31 (95% CI 2.46, 4.46), preterm birth 11.30 (9.09, 14.06), macrosomia 1.80 (1.35, 2.40), LGA 2.28 (1.70, 3.05), low birth weight 2.45 (1.83, 3.28), stillbirths 10.50 (6.12, 18.01), congenital malformations 2.88 (1.99, 4.18), admissions during first year of life 3.35 (2.68, 4.19), SGA 0.18 (0.08, 0.37.) All except stillbirths and congenital malformations remained significant after adjusting for confounders.

Conclusion: Our study demonstrates that a record-linkage approach can be used to describe pregnancy outcomes in a community-based cohort. Pregnancy outcomes remain poor in mothers with childhood onset T1D, despite significant advances in obstetric and diabetes care. Measures to preserve beta cell function may improve outcomes, and further studies are required to explore this.

Risk factors for neonatal acidosis in women with type 1 diabetes

P. Gutaj[1], U. Mantaj[2], A. Zawiejska[1], E. Wender-Ożegowska[1];
[1]Division of Reproduction, Poznan University of Medical Sciences, [2]Obstetric Ward IV, Gynecologic and Obstetric University Hospital, Poznan, Poland.

Background and aims: Type 1 diabetes is associated with increased risk of adverse neonatal outcomes, including neonatal asphyxia. Low pH values in the umbilical artery have strong association with neonatal outcomes and have been widely adopted in clinical practice, especially in high-risk populations. The aim of this study was to identify factors associated with low arterial pH values (pH< 7.10) in infants of type 1 diabetic mothers.
Materials and methods: Clinical and laboratory data of 1069 women with type 1 diabetes and their infants from a period between 1993 and 2015 were extracted from clinical records of a tertiary care center of our university. Between 1993 and 2005 the recommended HbA1c in pregnancy was < 7.0 %, and from 2006 < 6.1%. Data of 280 women were excluded from the analysis due to: miscarriage (pregnancy loss < 22 weeks), multiple pregnancy and incomplete data. Finally, data of 789 women was included in the analysis. Based on pH values in the umbilical artery of their infants, women were divided into 2 groups: NORMAL pH- pH ≥ 7.10 and LOW pH- pH<7.10. Determinants of the LOW pH in umbilical artery were identified by logistic regression with data presented as odds ratios and 95% confidence intervals.
Results: 72 (9.1%) infants had LOW pH in the umbilical artery. LOW pH values were associated with decreased Apgar score at 1 minute (0.76 [0.70-0.82]) and 5 minute (0.77 [0.69-0.85]) after birth. Maternal age, age at diagnosis of diabetes and diabetes duration had no association with LOW umbilical artery pH. Maternal pre-pregnancy BMI, the presence of diabetic vascular complications, chronic hypertension, and gestational hypertension/preeclampsia had no impact on LOW umbilical artery pH. LOW pH values were not associated with gestational age at delivery and the degree of prematurity (late to moderate preterm 32-37 weeks, very preterm- 32-28 weeks and extremely preterm- < 28 weeks). There was association between maternal HbA1c [%] analyzed before delivery and LOW pH in the umbilical artery- 1.40 [1.11-1.78], P=0.005. Similar association was found for HbA1c analyzed between 20-24 weeks- 1.29 [1.03-1.63], P=0.026. There was no association between the first trimester HbA1c level as well as lack of preconception care and LOW pH in the umbilical artery. There was association between urgent cesarean section (N=53) and LOW pH in the umbilical artery 1.64 [1.11-2.44], P=0.01 and this association was independent of HbA1c analyzed before delivery. There was no association between both neonatal LGA (birthweight> 90 percentile) and SGA (birthweight < 10 percentile) and LOW pH in the umbilical artery.
Conclusion: Lack of efficient glycemic control after first trimester of pregnancy is the strongest predictor of neonatal acidosis in women with type 1 diabetes. However in the group of urgent cesarean sections for fetal distress, low umbilical artery pH values cannot be explained by maternal hyperglycemia.
Disclosure: **P. Gutaj:** None.

Maternal and perinatal outcomes in all diabetes pregnancies and controls in Kronoberg 2009-2012

A. Stogianni[1,2], L. Lendahls[3,4], M. Thunander[2,3];
[1]Department of Internal Medicine, Central Hospital, Kronoberg, Växjö, [2]Department of Clinical Sciences, Endocrinology and Diabetes, Lund University, Lund, [3]Deparment of Research and Development, Region Kronoberg, Växjö, [4]Department of Health and Caring Sciences, Linnaeus University, Kalmar, Sweden.

Background and aims: To compare maternal and perinatal outcomes in women with pregestational (PDM) type 1 (T1D) or type 2 diabetes (T2D) and gestational diabetes mellitus (GDM) and compare these to those of pregnancies not complicated with diabetes. In Kronoberg nurses take greater responsibility than is usual in prenatal diabetes care.
Materials and methods: Retrospective records review of 281 pregnancies during 2009-2012, including all 145 complicated by diabetes in the region. Rates of maternal (abortion, preeclampsia, pre-delivery, vaginal/cesarean sectio delivery, CS) and fetal outcomes (large for gestational age (LGA), macrosomia (> 4500g), congenital malformations) were assessed, and examined for potential predisposing or contributing factors such as maternal age, ethnicity, obesity, weight gain, parity, HbA1c levels and insulin doses.
Results: There were 48 (33%) PDM and 97 (67%) GDM pregnancies, that were compared to 136 pregnancies not complicated by diabetes. Among the PDM 37 women (77.1%) had T1D and 11 (22.9%) T2D. The PDM mothers were more physically active (p<0.01), and had normal pregestational BMI (p=0.05) but tended to gain more weight during pregnancy compared to the GDM mothers (p=0.06). Compared to GDM the PDM group rates of CS (24.7% and 41.7%, p=0.03), preterm deliveries (12.3% and 37.5%, p=0.0001) and LGA (13.4% and 53.2%, p=0.0001) were increased, and pregestational BMI was associated with macrosomia (p=0.028). In the GDM group, obesity was associated with LGA (p=0.038) while excessive weight gain tended to be associated (p=0.078). In comparison to T1D the T2D women had higher pregestational BMI (34.0 kg/m^2 vs 26.7 kg/m^2, p=0.01), tended to be older (33.5 vs 29.8, p=0.075) and a greater proportion were unemployed (81.8% vs 27.8%, p=0.02). HbA1c in the second (p=0.04) and third trimesters (p=0.08) of pregnancy was lower in T2D compared to in T1D. In T1D significantly more infants were LGA, 59.5% vs 27.3% in T2D (p=0.05). Among pregnant women with any diabetes type more were of non-Caucasian origin (p=0.0001), delivered by CS (p=0,042) and were smokers (p=0.001), compared to the non-diabetic women, while weight gain during pregnancy was higher (11.1 kg vs 13.1 kg, p=0.005) among the women without any diabetes. There was a tendency towards more LGA neonates in the diabetic pregnancies (p=0.059).
Conclusion: Obesity and excessive weight gain in pregnancies complicated by diabetes were found to be associated with increased risk of macrosomic and/or LGA neonates. That the weight gain during pregnancy was lower in the diabetic pregnancies, and that the frequency of LGA in GDM was not elevated indicates that this model of antenatal diabetes care is successful in those respects. The increased prevalence of LGA in Type 1 diabetes despite maternal BMI and mostly good glycemic control warrants both increased clinical attention and further investigation.

Is fasting plasma glucose in early pregnancy a better predictor of adverse obstetric outcomes than HbA_{1c}?

L. Mañé[1], J. Flores-Le Roux[1], D. Benaiges[1], L. Gortazar[1], M. Rodríguez[2], I. Marcelo[2], J. Chillarón[1], G. Llauradó[1], J. Pedro-Botet[1], A. Payà[3];
[1]Endocrinology, Hospital del Mar, [2]Department of Medicine, UAB University, [3]Ginecology, Hospital del Mar, Barcelona, Spain.

Background and aims: Emerging data sustains that an early pregnancy HbA1c ≥ 5.9% identifies a group of women at high risk for poorer pregnancy outcomes regardless of gestational diabetes mellitus (GDM) diagnosis. The usefulness of different HbA1c cut-off points has not been fully evaluated yet. Fasting plasma glucose (FPG) is an inexpensive parameter and previous studies have also reported significant graded associations between first trimester FPG levels below those diagnostic of diabetes and adverse pregnancy outcomes albeit without an obvious threshold at which

risk increased. Our aim is to determine, in a multi-ethnic cohort, the suitability of first-trimester FPG and HbA1C levels to identify women without diabetes at increased pregnancy risk.

Materials and methods: A prospective study was conducted between April 2013-September 2015. Universal testing for FPG and HbA1c levels at the first antenatal bloods was performed. All women were screened for GDM at 24-28 weeks' gestation using a two-step approach. Primary outcomes were macrosomia and preeclampsia. We assessed different FPG and HbA1c cut-off points for associations with primary outcomes. Odds ratios were adjusted by nulliparity, pre-pregnancy body mass index, previous macrosomia, ethnicity, pregnancy weight gain, GDM diagnosis and anemia.

Results: 1228 pregnancies were included for outcome analysis. Adjusted odds ratios for associations between different first trimester FPG and HbA1c cut-off values and primary outcomes are shown in the table. There was no association between FPG levels and the risk of developing macrosomia or preeclampsia. Women with HbA1c≥5.8% showed an increased risk of macrosomia. A HbA1c≥5.9% threshold was associated with a higher risk of preeclampsia.

Conclusion: In a multiethnic population, first-trimester FPG levels are not a better predictor of adverse pregnancy outcomes than HbA1c.

Adjusted odds ratios for associations between first trimester FPG and HbA1c cut-off values and primary outcomes

	Macrosomia (n) in each group (below vs above threshold)	OR (95% CI)	Preeclampsia (n) in each group (below vs above threshold)	OR (95% CI)
FPG 84 mg/dl	22/447 vs. 55/782	1.14 (0.63-2.08)	12/447 vs. 34/782	1.91 (0.87-4.2)
FPG 88 mg/dl	36/705 vs. 41/524	1.40 (0.80-2.47)	21/705 vs. 25/524	1.97 (0.99-3.9)
FPG 92 mg/dl	51/901 vs. 26/328	1.38 (0.76-2.53)	31/901 vs. 15/328	1.74 (0.87-3.5)
FPG 96 mg/dl	60/1049 vs. 17/180	1.54 (0.75-3.14)	39/1049 vs. 7/180	1.28 (0.53-3.1)
FPG 100 mg/dl	70/1134 vs. 7/95	0.95 (0.31-2.86)	44/1134 vs. 2/95	0.69 (0.15-3.1)
HbA1c 4.8%	9/120 vs. 68/1109	0.55 (0.23-1.30)	3/120 vs. 43/1109	1.63 (0.38-7.0)
HbA1c 5.0%	21/319 vs. 56/910	0.77 (0.41-1.42)	15/319 vs. 31/910	0.63 (0.3-1.28)
HbA1c 5.4%	57/872 vs. 20/357	0.80 (0.42-1.51)	35/872 vs. 11/357	0.95 (0.45-1.9)
HbA1c 5.8%	67/1145 vs. 10/84	**2.69 (1.16-6.24)**	42/1145 vs. 4/84	1.65 (0.54-4.9)

Study on pregnancy outcomes in patients with prepubertal onset of type 1 diabetes

L. Danyarova, A. Tashmanova;
Diabetology, Scientific-Research Institute of Cardiology and Internal Diseases, Almaty, Kazakhstan.

Background and aims: The work was initiated to study peculiarities of pregnancy in patients with prepubertal onset of type I diabetes mellitus (DMI).

Materials and methods: We examined 27 patients with prepubertal onset of DMI. Carbohydrate metabolism was assessed according to the level of glycemia (laboratory and self-monitoring with the Akki-check Nano swab) and glycated hemoglobin (HbaAc). DCA Vantage Siemens (USA) was used to measure glycated hemoglobin (HbA1c) by means of latex agglutination inhibition. Certified by the National Glycohemoglobin Standardization Program this method became the reference one. All patients were basally-bolus insulin therapy Detemir + Novorapid. All patients were examined in compliance with protocol of management for patients with pre-gestational diabetes.

Results: Mean age of the examinees, primagravidas, was 24.3 ± 4.9, the disease onset age and duration being 9.9 ± 3.9 and 11.2 ± 3.4, respectively. Pre-gestational, gestational and post-gestational HbA1c was 8.1 ± 1.1 %, 6.81 ± 1.5 % and 8.8 ±1.6 %, respectively, that is, as it can be seen, reduced through pregnancy. 27 patients received intensive basal-bolus therapy with recombinant human insulin, daily dose requirement changing by gestational age. Thus, daily doses in the first and second trimesters were 46.7 ± 11.0 and 51.6 ± 15.6 U/d, respectively, the one after delivery being 48.6 ± 9.7 U. Hypoglycemic episodes were registered almost in all examinees 3-4 times a week in the first half of pregnancy, severe hypoglycemia being observed in three patients, the severest one through coma being registered in one patient. As to vascular complications, diabetic retinopathy of various degrees was found in 11 patients (50 %), III-IV degree diabetic nephropathy being found in four. Diabetic nephropathy was found progressing, but transient and resolving in six months after delivery. As to pregnancy outcomes, therapeutic abortion was performed in three patients, due to morning sickness in one woman and to deterioration of the kidneys in two. Cesarean section was performed at various gestational ages in 17 (70.8%), at 34-35 week in five patients, at 36-37 week in six women, at 38-39 week in another six. Natural delivery was performed in seven patients at 38-39 week.

Conclusion: Prepubertal DM onset poses high risk of complications in pregnancy. Risk of unfavorable pregnancy outcome is the highest one upon prolongation of pregnancy with contraindications.

Contribution of telemedicine in the management of gestational diabetes: comparison of two remote follow-ups, using mydiabby platform or a h24 hotline

S.N. Ngambou, myDiabby;
Diabetologia Service, Douai Hospital, Douai, France.

Background and aims: Telemedical management of gestational diabetes (GD) can be more effective than the conventional or classical management by improving and simplifying the course, increasing patients and healthcare users satisfaction and enabling significant reductions in costs. We compared data from a center in the "Ile de France" using the myDiabby telemedical platform (TLM group), to those of a center in the "Hauts de France", carrying out a conventional monitoring, enriched with a hotline (HOT group).

Materials and methods: The available TLM / HOT data were collected for all 300 and 203 patients followed in the two centers respectively, during the year 2015. The main maternal characteristics, essential pregnancy data and major events of childbirth were compared. All data were entered into a computerized program. In addition, a satisfaction questionnaire was sent to the patients and the medical team of the TLM group. After an initial training workshop, patients in the TLM group were only followed by e-mails exchanged on a secure messaging system, which could also be used to send an electronic chart of self-monitoring of blood glucose. Those in the HOT group had episodic visits and could call the nurses by H24 hotline, communicate their blood glucose results, which were then reported manually. Specialised nurses assisted mothers in insulin dose adjustment, under the supervision of medical doctors.

Results: (TLM / HOT) For maternal characteristics, the mean age was 33 / 30.5 years, patients were less obese in the first group (BMI>25: 20/80%), and we found history of GD in 15/19% of the mothers. 42/21% of mothers were more than 35 years old; 5/8% have a history of foetal macrosomia and 46/40% had a family history of type 2 diabetes. GD was early diagnosed in 25/44%, insulin was needed in 32/48% of the cases. Mean term delivery were the same at 39wks, with 28/26% caesarean section. The average weight of the babies was the same, 3333/3314 grams, of which respectively 3 and 10% were > 4000 grams. In the TLM group, women were less obese but older, with more history of diabetes, less early diagnosis and less insulin, same term, caesarean sections, and the same mean weight of babies but less macrosomes. Differences between the two populations were moderate except for hospitalizations. While only 2.5% of women in the TLM group were hospitalized, this figure rose to 27% in the HOT group, an identical figure was

found at the national level. Time saving in decision making, improved overall visibility, catch-up of loss sight were advised as benefits by the TLM medical team and patients in this group all wished to recommend this follow-up for identical situations.

Conclusion: The HOT group has already benefited from improved support thanks to a dedicated team and hotline. "Mother-child" outcomes are of high quality in an area where medical facilities are lagging behind the national average. An orientation in this group towards telemedicine is an option, the results are equal or better with a major benefit at the level of hospitalizations whose drop close to disappearance is both an organizational benefit, an improvement in the quality of life of the Future mother and a very important minimization of the overall cost of care.

PS 077 Pregnancy and diabetes

937

Reported rates of pregnancy outcomes with Gla-100 and Gla-300: results from a post-marketing survey of pharmacovigilance data

D. Ozkaya[1], M. Bertolini[1], J. Pagan[2];
[1]Sanofi, Paris, France, [2]Sanofi, Bridgewater, USA.

Background and aims: Approximately 2-5% of pregnancies are complicated with diabetes, and hyperglycaemia has been associated with an increased risk of birth defects compared with the general population. Maintenance of normal glycaemic levels, including with use of exogenous insulin, is recommended to minimise the risks of foetal and maternal complications during pregnancy. Insulin glargine 100 U/ml (Gla-100) and 300 U/ml (Gla-300) are long-acting insulin analogues that have been shown to provide good glycaemic control with low risk of hypoglycaemia in people with diabetes; as such, they may offer beneficial treatment options in pregnancy. Currently, there are no randomised controlled trials specifically designed to investigate the rate of birth defects in pregnancies where insulin glargine is administered.

Materials and methods: Using Medical Dictionary for Regulatory Activities (MedDRA) terms, a cumulative search of Sanofi's global pharmacovigilance database was performed to identify pregnancy outcomes for women using insulin glargine.

Results: Post-marketing searches identified 2695 (574 solicited, 2121 unsolicited) cases of exposure to Gla-100 during pregnancy, and 43 (28 solicited, 15 unsolicited) for Gla-300. Cases were reviewed to remove non-relevant reports, leaving 2681 cases of Gla-100 use in pregnancy and 42 cases with Gla-300 (**Table**). Cumulative patient exposure was 90,860,252 and 572,677 patient-years for Gla-100 and Gla-300, respectively. Reporting rates for adverse events of specific interest were 29.5/1,000,000 patient-years with Gla-100 and 73.3/1,000,000 patient-years with Gla-300. Congenital, familial and genetic anomalies were rare with Gla-100 (82, 3.1%) and were mostly cardiac (42, 1.6%), limb (9, 0.3%) or gastrointestinal (6, 0.2%) malformations; no congenital, familial or genetic anomalies were observed with Gla-300 for the reporting period. The rates observed for Gla-100 were consistent with the rate of birth defects reported for the general population, being ~3% of all live births. Spontaneous abortions with insulin glargine were also rare (4.3% with Gla-100, 0.0% with Gla-300) and consistent with miscarriage rates observed in the general population (10%).

Conclusion: Rates of spontaneous abortions and congenital anomalies were low for Gla-100 and Gla-300 and consistent with rates in the general population. These results indicate the use of insulin glargine during pregnancy is not associated with any specific adverse effects on pregnancy and no specific foetal malformations or neonatal toxicity.

Table. Pregnancy events and reporting rates for Gla-100 and Gla-300

MedDRA search term	Gla-100		Gla-300	
	Number of events (%)[ac]	Reporting Rate[bd] (per 1,000,000 patient-years)	Number of events (%)[ac]	Reporting Rate[be] (per 1,000,000 patient-years)
Total number of pregnancy exposures	**2681 (N/A)**	**29.51**	**42 (N/A)**	**73.34**
Abortion induced	12 (0.4)	0.13	0 (0.0)	N/A
Abortion spontaneous	114 (4.3)	1.25	0 (0.0)	N/A
Congenital, familial, and genetic disorders	82 (3.1)	0.9	0 (0.0)	N/A
Ectopic pregnancy	5 (0.2)	0.06	0 (0.0)	N/A
Exposures via breast milk	78 (2.9)	0.86	2 (5.0)	3.49
Premature birth	82 (3.1)	0.9	1 (2.0)	1.75
Exposure via father	5 (0.2)	0.06	2 (5.0)	3.49
Stillbirth	19 (0.7)	0.21	0 (0.0)	N/A
Live birth/Unknown outcome	2284 (85.2)	25.14	37 (88.0)	64.61

[a] Some cases may be counted more than once owing to multiple events reported in one case
[b] The reporting rate is based on cumulative exposure as there are no data by gender
[c] Percentage calculation is based on total number of pregnancy/lactation related cases and events

The CONCEPTT-Diet study: an analysis of diet and glycaemia in UK women with type 1 diabetes before and during pregnancy

S. Neoh[1], J. Grisoni[2], Z.A. Stewart[1], D.S. Feig[3], H.R. Murphy[1,4];
[1]Institute of Metabolic Science, Cambridge, [2]Cambridge University NHS Foundation Trust, Cambridge, UK, [3]Mount Sinai Hospital, Toronto, Canada, [4]Norwich Medical School, Norwich, UK.

Background and aims: CONCEPTT is a multicentre randomised controlled trial evaluating the impact of real-time continuous glucose monitoring (RT-CGM) on maternal glycaemic control before and during pregnancy. CONCEPTT-Diet is a prospective observational study of UK participants aiming to investigate the relationship between maternal diet and glycaemia.
Materials and methods: Women with Type 1 diabetes, aged 18-40 years, using insulin pump therapy or multiple daily injections with baseline HbA1c 48-86 mmol/mol (6.5-10%) were eligible for the study. Participants were randomised to either RT-CGM or Home Glucose Monitoring (HGM) added to standard insulin delivery. UK participants who consented to be involved in the dietary study completed a 3-day food diary at run-in and at 24 weeks (pre-pregnant cohort) or at 34 weeks gestation (pregnant cohort). Dietary analysis was performed using validated software Dietplan 6.0.
Results: There were 54 participants in the pre-pregnant cohort. Baseline mean energy intake was 1577 kcal/day, of which 42% was derived from carbohydrates (mean 175 g/day) and 41% from fat (mean 71 g/day). 49% of mean daily carbohydrate intake was from recommended sources. In the HGM group (n=30), mean daily protein consumption increased between baseline and follow-up, due to increased consumption of meat, bread and cheese. Carbohydrate intake from confectionary increased in both HGM and CGM groups, with greater change observed in the CGM group (40% v. 25%). In the pregnant cohort (n=44), mean daily energy intake was 1764 kcal, of which 43% was from carbohydrates (mean 204 g/day) and 40% from fat (mean 78 g/day). 49% of mean carbohydrate intake was from recommended sources. At baseline, macronutrient intake was more evenly spread throughout the day with larger snacks and smaller meals compared to the pre-pregnant cohort. No significant change in macronutrient consumption was observed in the HGM group (n=25) between baseline and follow-up. In the CGM group (n=19), mean fat consumption decreased by 10 g/day, but baseline fat intake was high (mean 85 g/day). Carbohydrate intake from confectionary also decreased in both groups with greater change observed in the CGM group (40% v. 30%).
Conclusion: Participants in this study demonstrate increased energy consumption from fats and corresponding lower consumption from carbohydrates compared to the background UK population. More than half the carbohydrates consumed are from non-recommended sources. Mean daily protein consumption increased between baseline and follow-up in the women randomised to HGM before pregnancy but not during pregnancy. Mean carbohydrate intake from confectionary decreased in all groups with a greater change observed in the women receiving RT-CGM.
Clinical Trial Registration Number: NCT01788527

Are pregnancy outcomes different in women with IADPSG-diagnosed gestational diabetes treated with insulin compared to those receiving medical nutritional therapy only

D. Bogdanet, A. Egan, B. Kirwan, L. Carmody, F. Dunne;
Diabetes and Endocrinology, Galway Diabetes Research Centre, National University of Ireland Galway, Galway, Ireland.

Background and aims: Use of IADPSG diagnostic criteria for GDM diagnosis is now common in Europe. In Ireland, the prevalence of GDM using these criteria is 12.4%. The objective was to assess if women with GDM diagnosed using IADPSG criteria treated with insulin have comparable pregnancy outcomes to those treated with medical nutritional therapy (MNT) only.
Materials and methods: This retrospective cohort study included 752 GDM women on insulin (GDM-I) and 567 GDM women on MNT only (GDM-M). All women were managed within the Atlantic Diabetes in Pregnancy clinical network. Maternal outcomes examined were pregnancy-induced hypertension (PIH), preeclampsia (PET), antepartum (APH) postpartum hemorrhage (PPH), polyhydramnios, and cesarean delivery. Fetal outcomes examined were shoulder dystocia (SD), malformations, hypoglycemia, prematurity, mortality, neonatal intensive care unit admission (NICU), macrosomia (>4kg) and large and small for gestational age (LGA> 90th centile, SGA < 10th centile).
Results: GDM-I women were more obese (BMI>30kg/m^2) compared to GDM-M women (66.5% vs 49.2%; p<0.01) and more likely to have a family history of type 2 diabetes (68.1% vs 61.3%p=0.01). There were no differences in ethnicity, parity or smoking between groups. Systolic BP (121 vs 119 mm Hg; p<0.01) was greater in the GDM-I group at baseline. Results of the OGTT showed a higher fasting blood glucose (5.3 vs 4.9 mmol/l; p<0.01) and a higher 2-hour blood glucose (7.8 vs 7.4 mmol/l; p<0.01) in women with GDM-I compared to GDM-M. Women with GDM-I had a greater risk of polyhydramnios (aOR 2.33, 95%CI 1.31-4.14) and were more likely to deliver by cesarean section (aOR 1.67, 95%CI 1.25-2.23). There was no difference between the groups for rates of PET, PIH, APH and PPH. Perinatal mortality, congenital malformations and rates of SGA were also similar between groups. Infants of women with GDM-I compared to GDM-M were delivered earlier (39 vs 40 weeks; p<0.01) but rates of prematurity were similar, and had a greater median birth weight (3595 vs 3440 grams; p<0.01). Rates of macrosomia (22.2% vs 12.7%; p<0.01) and LGA (19.7% vs 12.5%; p<0.01) were greater in GDM-I vs GDM-M but rates of SD and hypoglycemia were similar. GDM-I vs GDM-M mothers had a higher HbA1C (5.6% vs 5.4%; p<0.01) despite treatment. Infants of GDM-I mothers were more likely to require NICU admission (aOR 4.88. 95%CI 3.54- 6.73). On subgroup analysis, a BMI ≥30 kg/m^2 had a greater impact on rates of macrosomia (26.5% vs 16.2%; p<0.01) and LGA (22.5% vs 15.1% p<0.01) in GDM-I compared to GDM-M women. In addition, a BMI ≥ 25 kg/m^2 had a greater impact on rates of elective cesarean section (48.9%, 31.6%, p<0.01) in GDM-I compared to GDM-M women. As the maternal BMI increased, the rates of admission to NICU increased in both groups but was greater in the GDM-I group (p<0.01).
Conclusion: GDM-I and GDM-M mothers have similar rates of maternal medical morbidities despite having a greater baseline risk factor profile. Despite this, the rate of delivery by CS remains greater primarily driven by elective intervention in the GDM-I group. Infant morbidities are similar between groups but macrosomia and LGA continue to be greater. This may be secondary to a higher starting maternal BMI or inadequate glycemic control. Perhaps in women with a higher baseline risk profile, blood glucose targets need to be even tighter. This requires further investigation.

Type 1 diabetes treated with insulin pump or conventional insulin therapy in pregnancy: tertiary hospital outcomes

C. Silvestre[1], A. Gomes[1], M.R. Carvalho[1], A. Wessling[1], L. Pinto[2], M.J. Bugalho[1];
[1]Endocrinology, Hospital Santa Maria- CHLN, [2]Gynecology and Obstetrics, Hospital Santa Maria- CHLN, Lisboa, Portugal.

Background and aims: Good metabolic control at conception and during pregnancy is important for diabetic women, in order to reduce the risk of fetal and maternal adverse outcomes. It is still uncertain whether continuous subcutaneous insulin infusion (CSII) provides better maternal and child outcomes over multiple daily injections (MDI). The aim of this study was to compare metabolic control and maternal-fetal outcomes in women with type 1 diabetes managed on CSII compared with MDI.
Materials and methods: Retrospective study of type 1 diabetes pregnant women data, who attended specialized appointments on a tertiary hospital, from 2012-2016. Macrosomia defined as weight >4000 g, large for gestational age (LGA) as percentile >90 and preterm delivery as < 37 weeks.
Results: From a total of 54 type 1 diabetic pregnant women, 48 patients were included: 22 CSII and 26 MDI, with similar ages (33 vs 30 years), diabetes duration (16 vs 15 years) and complications prevalence (microvascular 45 vs 40%; none macrovascular cases registered). Preconception hemoglobin A_{1C} (HbA_{1C}) was lower in CSII group (7,8 vs 10,1%, p<0,05), as well as global pregnancy HbA_{1C} (6,7 vs 7,5%, p<0,05). This reflects the lower first and second trimesters' HbA_{1C} in CSII compared to MDI (7,2 vs 8,0%, p<0,05 and 6,6 vs 7,3%, p<0,05); however there was no statistically significant difference for third trimester (6,6 vs 7,1%, p=0,106). For maternal outcomes, the difference wasn't statistically significant for weight gain (13 vs 11 kg), preconception or final body mass index, severe hypoglycemia (5 vs 0%), ketoacidosis (0 vs 9%), cesarean delivery (68 vs 74%) and gestational age at delivery (38 vs 37 weeks). Incidences of pregnancy losses (14 vs 15%) and preterm delivery (32 vs 46%) were similar among both groups. For fetal outcomes, a higher birthweight was calculated for CSII (3549 vs 2984 g, p<0,05). Albeit there were more macrosomic (21 vs 6%) and LGA (47 vs 39%) babies in CSII, the difference was not statistically significant. Secondary neonatal outcomes did not statistically differ between CSII and MDI: congenital anomalies (0 vs 3% - cardiac anomaly), neonatal hypoglycemia (12 vs 0%), jaundice (12 vs 7%), perinatal injuries among vaginal deliveries (9 vs 11%) and neonatal intensive care admission (17 vs 33%).
Conclusion: As reported by other authors, there was a lower HbA_{1C} in CSII group without increased risk of severe hypoglycemia or diabetic ketoacidosis. Despite the better metabolic control, the proportion of LGA and macrosomia was higher than expected in this group. The lower mean birthweight observed in the MDI group was probably influenced by a pronounced low birthweight case on a preterm delivery. The lower HbA_{1C} achieved before conception with CSII proves that this method is a useful tool to accomplish metabolic goals.
Disclosure: **C. Silvestre:** None.

Treatment with insulin detemir vs NPH during pregnancy in women with gestational diabetes: comparison of glycaemic control and pregnancy outcome

E. Anastasiou[1], P. Kazakou[1], P. Antsaklis[2], G. Ntali[2], V. Sarantopoulou[1], G. Daskalakis[2];
[1]Deparment of Endocrinology-Diabetes Center, Alexandra Hospital, [2]1st Department of Obstetrics and Gynecology, Alexandra Hospital, Athens, Greece.

Background and aims: In the literature there is only one study comparing insulin detemir (Det) versus neutral protamine Hagedorn (NPH) in women with gestational diabetes mellitus (GDM) regarding safety and efficacy. The objective of this retrospective study was to compare glycemic control, pregnancy outcome as well as fetal/neonatal outcome between treatments with insulin detemir and insulin NPH in women with GDM.
Materials and methods: A total of 192 women with GDM were included and two groups were formed. The first group comprised 98 women who received detemir and the second group comprised 94 women who received NPH. GDM was diagnosed based on IADSPG/WHO criteria. At the beginning all women were recommended to follow a specific diet and to perform self-monitored glucose measurements. Treatment with insulin was initiated based on: fasting blood glucose >95mg/dl or 1-hour postprandial glucose >130mg/dl and/or evidence of macrosomia or polyhydramnios on fetal ultrasound. All patients who needed rapid-acting insulin were excluded. Data regarding medical history, parameters of glycemic control, time and mode of delivery and neonatal outcomes were recorded.
Results: Demographics and baseline characteristics in both groups were similar: ethnicity (Greek: Det 87% vs NPH 82%), age (Det 36±4 vs NPH 37±5yrs), prepregnancy body mass index (Det 29±6 vs NPH 28±7kg/m^2), education, family history of diabetes mellitus type 2 (Det 43% vs NPH 43%), hypertension (0% in both groups), glycemic control estimated by Hemoglobin A1c (HbA1c) at diagnosis (median: Det 5.3 vs NPH 5.4%). There were no differences with respect to the week of insulin initiation (Det 27.7±7 vs NPH 27±7.5 weeks), the total insulin dose (median: Det 540 vs NPH 527 IU), the duration of insulin therapy (median: Det 53 vs NPH 56 days), the daily insulin dose/weight at the start and end of insulin treatment (median: Det 0.1 vs NPH 0.1 IU/kg and median Det 0.14 vs NPH 0.13 IU/kg respectively), as well as the number of insulin injections per day**.** Maternal overall weight gain during pregnancy (Det 10 ±7 vs NPH 12±9 kg), and weight gain per week since the start of insulin through to delivery (median: Det 40 vs NPH 110g/wk) did not differ between the groups. The detemir group had slightly lower, although significant, HbA1c level at the end of gestation (median: Det 5.2 vs NPH 5.4%, p=0.035). There were no hypoglycemias or allergic reactions in both groups. Further, there were no differences regarding perinatal/neonatal outcomes: time (median: Det 38 vs NPH 38 weeks) and mode of delivery (Cesarean section: Det 62 vs NPH 48%), pre-term delivery (Det 14 vs NPH 21%), Apgar score (median: Det 9 vs NPH 9), birth weight (Det 3298±571 vs NPH 3031±589g), birth weight adjusted for gender and gestational age (Det 56^{th}±19 vs NPH 50^{th}±11.5 percentile), percentage of macrosomia (weight >90^{th} percentile) (Det 5.6% vs NPH 0%) and small for gestational age (<10^{th} percentile) (0% in both groups).
Conclusion: Glycemic control and pregnancy outcome were equally effective in women using insulin either detemir or NPH during pregnancy.

Three years experience with FGM/CGM in pregnant women with type 1 diabetes

M. Landin-Olsson[1], H. Strevens[2], U. Moll[1], D.B. Ursing[1];
[1]Department of Endocrinology, Skane University Hospital in Lund, [2]Department of Gynecology and Obstretrics, Skane University Hospital in Lund, Lund, Sweden.

Background and aims: In pregnancies in women with Type 1 diabetes (T1D), the risk is increased for malformations, accelerated growth of the fetus, preeclampsia, premature delivery, shoulder dystophia, sectio and neonatal intensive care. A tight blood glucose control is vital to reduce complications during pregnancy and delivery. The use of flash glucose measurements (FGM) or continuous glucose measurements (CGM) enables a strict glucose control throughout the whole pregnancy. The aim of this study was to explore the outcome of pregnancies after use of FGM/CGM.
Materials and methods: All pregnant women with T1D at our hospital are offered a FGC/CGM system during pregnancy. To date we have had 46 women who have completed the pregnancy wearing a FGM/CGM. FreeStyle Libre® (Abbott) is most used. In case of non-awareness of hypoglycaemia, systems with alarm, as Dexcom® or MiniLink® REAL Time Transmittor (Medtronic) are preferred. Glucose curves were weekly transferred via Diasend system to the diabetologist. Insulin doses were adjusted by the diabetologist every week after phone calls to the patients. Target for glucose control was between 4-8 mmol/L.
Results: During pregnancy the women had a median increase of insulin dose from 43 to 84.5 E/day. Weight went from 71.9 to 86.6 kg. HbA1c decreased from 56.8 to 44.1 mmol/mol. Mean glucose was 7.5±0.9

mmol/L during the whole pregnancy. The main time, 52 %, was spent within glucose target between 4-8 mmol/L. Hypoglycaemia defined as glucose below 4 mmol/L was present during 12% of time and 37% of the time the women had glucose above 8 mmol/L. Gestational length was 38 week, the frequency of preeclampsia was 8.7% and sectio frequency 38%. Birth weight was 3804 g. The frequency of neonatal hypoglycaemia was 13%.

Conclusion: It is possible to achieve almost normoglycemia in pregnant women with T1D with new FGM/CGM technology. The FGM/CGM system is necessary to ensure a safe pregnancy without severe hypoglycaemia. The outcome of these pregnancies was close to women without T1D.

The EValuation Of Ketones INtensive monitoring in women with Gestational diabetes (EVOKING) study: preliminary results

A. Di Benedetto[1], F. Corrado[2], F. Mastrantonio[3], L. Giunta[1], G. Ciccarella[1], R. D'Anna[2], B. Pintaudi[4];
[1]Department of Internal Medicine, University of Messina, [2]Department of Obstetrics & Gynecology, University of Messina, Messina, [3]A. Menarini Diagnostics, Florence, [4]Diabetes Unit, Niguarda Cà Granda Hospital, Milan, Italy.

Background and aims: Women with gestational diabetes mellitus (GDM) are frequently asked to check their ketones levels by measuring ketonuria before breakfast. The presence of ketosis is associated with several adverse outcomes both during pregnancy and in the life of the newborn. Ketosis can be present before main meals (i.e. before lunch and dinner), and a fasting urine ketone measurement is not sufficient to catch all the daily ketosis episodes. Blood ketone monitoring which directly measures β-hydroxybutyrate in blood could be a more accurate test for detecting ketosis compared with a urine test which mainly measures acetoacetate. The aim of this study was to evaluate the effect of blood ketone intensive monitoring for the detection of ketosis in women with GDM with a negative urinary ketone test.

Materials and methods: This was a single center, observational, prospective study enrolling consecutive women with GDM cared for at the Diabetes and Pregnancy Unit of a University Hospital**.** Self-monitoring blood glucose tests (GlucoMen LX, Menarini, Italy), dietary advice and physical activity prescription was given according to standard care to all participating women. Only women with negative fasting urinary ketone tests were included. During the same gestational week (30 weeks) all participants were asked to perform a capillary blood ketone test before breakfast, before lunch and before dinner. Ketosis was defined as the presence for at least 25% of the time of fasting blood ketone levels >0.1 mmol/L and >0.2 mmol/L before lunch and dinner. Information on clinical and antrophometric characteristics, risk factors for GDM and laboratory tests was collected.

Results: Overall, a total of 101 women (mean age 34.7±4.8 years, pre-pregnancy BMI 28.2±5.2 kg/m^2, 59.4% insulin treated) were studied. Blood ketones were present in 37.6% of the cases before breakfast, 13.9% before lunch and 11.9% before dinner. The percentage of women with at least one daily presence of blood ketones was 40.6%.The presence of fasting blood ketones correlated closely with ketone presence before lunch (r=0.63, p<0.0001) and before dinner (r=0.55, p<0.0001) and with one hour after breakfast mean glucose levels (r=0.23, p=0.02). When comparing women with positive blood ketone tests with those with a negative test no differences was detected in clinical and antrophometric mothers' characteristics, risk factors for GDM, nor for insulin treated rate.

Conclusion: Blood ketone testing in women with GDM can detect a greater number of ketosis episodes than urinary ketone testing indicating the benefit of testing specifically for β-hydroxybutyrate. The presence of fasting blood ketone correlated closely with ketone positivity during the day and with glucose levels after breakfast. A detailed investigation of the relationship between blood ketones and pregnancy and neonatal outcomes will be available at the end of the EVOKING study. These preliminary results indicate that blood ketone measurement should be recommended to women with GDM.

Gestational diabetes treated with lifestyle modification, metformin and insulin

W. Wan Mahmood[1,2], T. Cahill[1], E. Rutter[3], C. Coveney[3], U. Daniel[3], L. Harrington[3], J. Walsh[3], M. Higgins[3], M. Hatunic[1,2];
[1]Endocrinology and Diabetes, Mater Misericordiae Hospital, [2]Endocrinology and Diabetes, The National Maternity Hospital, [3]Obstetrics and Gynaecology, The National Maternity Hospital, Dublin, Ireland.

Background and aims: Gestational diabetes (GDM) describes glucose intolerance first recognized during pregnancy. GDM rates are increasing globally and are associated with short- and long-term complications for the mother and her infant. Treatment options for GDM include lifestyle modification (LM) and medical therapies with insulin (INS) or metformin (MF). We reviewed outcome of all our patients with GDM attending our hospital in 2015 and 2016.

Materials and methods: Following risk factor based screening, a two-step approach with Glucose Challenge Test (GCT) and Oral Glucose Tolerance Test (OGTT) were performed to diagnose new patients with GDM in the antenatal clinics. All patients underwent lifestyle modification (LM) with diet and exercise. Medical therapies with metformin (MF) or insulin (INS) were initiated based on patient's capillary blood glucose (CBG) and the latest antepartum scan in order to maintain glycemic targets. Patients were followed until delivery and maternal fetal outcomes characteristics were recorded.

Results: We identified 683 patients with GDM attending our unit, with a mean age of 35.6 ± 4.5 years old. Majority of mothers were overweight and obese at booking (30% BMI 25 to 30kg/m^2, and 35% BMI above 30kg/m^2). There were 479 (70.1%) patients with new diagnosis of GDM while 204 (29.9%) patients with previous diagnosis of GDM. Most were European in origin (n=517, 75.9%) followed by Asians (n=116, 17%), Africans (n=23, 3.4%), Middle-Eastern (n=10, 1.5%), and patients from the American continents (n=12, 1.8%). A total of 423(61.9%) patients continued on LM alone while 116(17%), 111(16.3%) and 19(2.8%) patients required MF, INS and both treatment respectively. Most patients had normal spontaneous vaginal delivery (SVD, n=346, 50.7%) followed by Cesarean section (n=213, 31.2%) and assisted delivery (n=71, 10.4%) while 25(3.7%) patients had miscarriage. A total of 116 babies (17%) were macrosomic (>4kg). There were no differences in macrosomia (p=0.224) and delivery methods (p=0.269) between patients treated with LM, MF or INS. Patients from Asia (32/114 patients, 28.1%) and Africa (6/23 patients, 26.1%) required more INS treatment compared to Europeans (72/507 patients, 14.2%, p=0.006). There was no statistically significant difference in age between the three treatment methods. Mothers treated with INS had higher GCT values (11.24 ± 2.33 mmol/L) compared to MF-treated (9.35 ± 1.64 mmol/L) and LM-treated (9.41 ± 1.9 mmol/L, p <0.005). Plasma glucose at OGTT (fasting, 1 hour post OGTT) were also higher in INS-treated (5.8 ± 0.9, 12.41 ± 1.72 mmol/L) compared to MF-treated (5.19 ± 0.53, 11.18 ± 1.21 mmol/L) and LM-treated (4.7 ± 0.55, 10.7 ± 1.38 mmol/L, p <0.005) group respectively.

Conclusion: Our patients with GDM were older and overweight at baseline. Patients treated with INS had higher GCT values, higher fasting and 1-hour OGTT values compared to MF and LM. Equal numbers of patients were treated with metformin and insulin without differences in the outcome for mothers and babies. Based on these data, considering neonatal and maternal outcomes, metformin appears to be as safe as insulin and lifestyle modification in the treatment of GDM.

Universal versus risk-factor-base screening for gestational diabetes: an analysis from a 5 year Portuguese cohort

C. Matta-Coelho, A. Monteiro, V. Fernandes, M.L. Pereira, S.B. Souto; Braga Hospital, Braga, Portugal.

Background and aims: The criteria to screen for Gestational Diabetes Mellitus (GDM) are not internationally consensual. In opposition to the universal screening performed in Portugal, certain countries favour a risk-factor-based screening. Universal screening allows higher GDM detection rates but more women are submitted to an inconvenient test, additional medicalization of pregnancy and further maternal anxiety. Besides, the additional cases detected have in average a milder form of glucose intolerance and their pregnancy/neonatal outcomes may be similar to the background population. We aim to compare obstetric and neonatal outcomes in pregnant women with and without risk factors treated for GDM.
Materials and methods: Retrospective and multicentre study of 12006 pregnant women diagnosed with GDM between 2011 and 2015, in Portugal, by the International Association of the Diabetes and Pregnancy Study Groups (IADPSG) criteria. Data from the Portuguese National Register. Statistic analysis SPSSv20. Risk factors adapted from National Institute for Health and Care Excellence guidelines: Body Mass Index (BMI) superior to 30 kg/m^2, history of macrossomic newborns, history of GDM and first-degree relatives with type 2 diabetes mellitus (T2DM). We excluded women that had no data regarding risk factors (n=1563).
Results: At least one risk factor (RF) was found in 68,2% (n=7123) pregnant women with GDM. The most common RF was first-degree relatives with T2DM (71,8%, n=4966), followed by BMI superior to 30 kg/m^2 (45,9%, n=3267). In the pregnant women without RF versus with RF, insulin therapy was initiated in 38% (n=1256) vs 49% (n=3441) (p<0,001), the starting week of therapy was deferred one week (30 IQR 23-33 vs 29 IQR 21-32, p<0,001) and total daily doses of insulin were inferior (14 IQR 8-26 vs 18 IQR 10-31, p<0,001). Moreover, treatment with metformin was less frequent (6 vs 10%, p<0,001). Concerning obstetric complications, pre-eclampsia was more frequent in women with RF (3,4 vs 2,4%, p=0,006), but there were no differences in hydramnios or fetal death. Caesarean section was more commonly performed in women with RF (38,4 vs 30,6%, p<0,001). The newborns of pregnant women with RF were more frequently large-for-gestational-age (LGA) (5,1 vs 2,3%, p<0,001). The neonatal morbidity was higher in the newborns of pregnant women with RF (19,3 vs 17,5%, p=0,040), namely hypoglycaemia (4 vs 3,2%, p=0,044), neonatal hyperbilirrubinemia (11,6 vs 9,9%, p=0,014), respiratory distress syndrome (2,8 vs 2%, p=0,018) and congenital anomalies (3,4 vs 2,2%, p=0,002). The Diabetes Mellitus reclassification showed increased frequency of impaired fasting glycaemia, impaired glucose tolerance or diabetes in women with RF (8,6 vs 5,2%, p<0,001).
Conclusion: Almost a third of pregnant women would have remained undiagnosed if risk-based-factor screening were implemented in Portugal (31,8%, n=3320). Our results show that women without RF were less insulinized, had fewer caesareans, fewer LGA newborns and less neonatal complications than the women with RF, even after adjustment for age and maternal weight. However, we emphasize that of these women, 38% (n=1256) had inadequate metabolic control and required therapy with insulin. In the future, we intend to compare pregnant women with GDM and no RF with pregnant women without GDM to further ascertain about the impact of GDM in pregnancy outcomes.

Gestational diabetes: the impact of new diagnostic criteria on prevalence and pregnancy outcomes

S.H. Koning[1], J.J. van Zanden[2], K. Hoogenberg[3], A.J. van Loon[4], F.J. Korteweg[4], H.L. Lutgers[5], P.P. van den Berg[6], B.H.R. Wolffenbuttel[1]; [1]Endocrinology, University of Groningen, University Medical Center Groningen, [2]Laboratory of Clinical Chemistry, Certe, Medical Laboratory North, [3]Endocrinology, Martini Hospital, [4]Obstetrics and Gynaecology, Martini Hospital, Groningen, [5]Endocrinology, Medical Center Leeuwarden, Leeuwarden, [6]Obstetrics and Gynaecology, University of Groningen, University Medical Center Groningen, Groningen, Netherlands.

Background and aims: Gestational diabetes mellitus (GDM) is associated with an increased risk of pregnancy complications. Early diagnosis and treatment of GDM may reduce these complications. In 2013, the WHO adopted the stricter cut-off glucose values of the IADPSG 2010 (WHO2013, fasting plasma glucose (FG) ≥5.1 and/or 2-hour glucose (2HG) ≥8.5 mmol/l). In the Netherlands, the WHO 1999 criteria (WHO1999, FG ≥7.0 and/or 2HG ≥7.8 mmol/l) are still used. In this study, we evaluated the impact on prevalence and pregnancy outcomes when applying the old WHO1999 vs. new WHO2013 criteria.
Materials and methods: 9628 women with singleton pregnancies were screened for GDM with a 75-g OGTT if they had risk factors or signs of GDM between January 2011 and January 2016. Women with GDM diagnosed according to WHO1999 criteria were treated for GDM. In 4431, pregnancy outcomes were retrospectively collected and compared between a non-GDM control group (WHO1999-/WHO2013-: FG <5.1 and 2HG <7.8 mmol/l) and two groups: GDM according to WHO2013 but not WHO1999 (WHO2013+/WHO1999-: FG ≥5.1-6.9 and 2HG <7.8 mmol/l); GDM according to WHO1999 but not WHO2013 (WHO2013-/WHO1999+: FG <5.1 and 2HG ≥7.8-8.4 mmol/l).
Results: Prevalence of GDM in the total cohort was 30% using WHO2013 and 20% using WHO1999. GDM was diagnosed solely on FG in 62% by WHO2013 contrasting to 1% by WHO1999. Compared with the non-GDM group (n=2851), women testing WHO2013+/WHO1999- (n=667, by definition not receiving diet treatment) were older, had a higher pre-gestational BMI (29.1 [IQR 24.8-33.5] vs. 25.2 [IQR 22.0-30.4] kg/m^2, P<0.001), had more often chronic hypertension (3.3% vs. 1.2%, P<0.001) and pregnancy induced hypertension (7.8% vs. 4.9%, P=0.003), showed higher rates of planned caesarean section (10.3% vs. 6.5%, P=0.001) and induction of labour (34.8% vs. 28.0%, P=0.001) and showed more often Apgar score <7 at 5 min (4.4% vs. 2.6%, P=0.015) and admissions to the neonatology dept. (15.0% vs. 11.1%, P=0.004). Frequency of foetal macrosomia and large for gestational age (LGA) neonates (>P90) was not significantly different to the non-GDM group (21.0% vs. 18.0%). Women testing WHO2013-/WHO1999+ (n=234, active treatment) had comparable rates of LGA neonates (15.4% vs. 18.0%) and emergency caesarean section (12.0% vs. 11.5%) compared with the non-GDM group. However, in this group 20.5% of the women needed treatment with insulin.
Conclusion: The lower FG cut-off in WHO2013 will have a major impact on the prevalence of GDM. Yet, it identified a group of women (WHO2013+/WHO1999-) with increased risk of adverse outcome. However, adopting the WHO2013 with a higher 2HG cut-off excluded women who now benefit from treatment. We conclude that change in diagnostic criteria for GDM will have considerable impact on prevalence and pregnancy outcomes.

Is first-trimester HbA_{1c} useful in the diagnosis of gestational diabetes?

L. Gortazar[1], D. Benaiges[1,2], I. Marcelo[2], J. Pedro-Botet[1,2], L. Mañé[1], M. Rodriguez[2], J.J. Chillarón[1,2], G. Llauradó[1], A. Paya[3,2], J.A. Flores-Le Roux[1,2];
[1]Endocrinology and Nutrition, Hospital del Mar, [2]Department of Medicine, Universitat Autonòma de Barcelona, [3]Gynecology and Obstetrics, Hospital del Mar, Barcelona, Spain.

Background and aims: Some clinical guidelines recommend first-trimester universal screening with A1c (1T-A1c) for the diagnosis of unknown type 2 diabetes mellitus. 1T-A1c could have other potential uses such as early identification of women at risk of developing gestational diabetes mellitus (GDM) later in pregnancy. Our aim is to evaluate the utility of 1T-A1c in the diagnosis of GDM and to assess associated costs.
Materials and methods: Observational study of a prospective cohort of consecutive pregnant women attending obstetric follow-up between April 2013 and September 2015. All women had a 1T-A1c determination and GDM screening at 24-28 weeks of pregnancy using a two-step approach with a 50 g screen followed by a 100 g OGTT. Women with pregestational diabetes or undiagnosed type 2 diabetes in pregnancy were excluded. Sensitivity, specificity, positive (PPV) and negative predictive (NPV) values of different first trimester HbA1c cut-off points for the detection of GDM were calculated. A ROC curve was drawn to determine sensitivity and specificity of 1T-A1c in detecting GDM and a rule-in- rule-out diagnostic algorithm was proposed. Costs associated with blood extractions (equipment, salaries), accommodation, reagents and glucose load solution were included.
Results: 1,195 women were included and one hundred and fifty-six (11.85%) were diagnosed of GDM. The area under ROC curve for 1T-A1c to detect GDM was 0.679 (95% CI 0.631 - 0.727). The proposed rule-in-rule-out algorithm is shown in figure. A rule-out threshold for A1c of 4.8% had a sensitivity of 96.7% (95% CI 93.9-99.5), specificity of 10.1% (95% CI 8.3-12.0) and a NPV of 95.3% (95% CI 91.3-99.3). A rule-in value of 5.6% had a PPV of 31.6% (95% CI 24.4-38.9), a specificity of 89.3%(95% CI 87.4-91.2) and a sensibility of 32.9 (95% CI 25.4-40.4). The low PPV of this higher 1T-A1c threshold precludes its use for GDM diagnosis but it identifies a group of women with 31.6% risk of developing GDM, similar to the PPV of a 50 g OGTT. Therefore, an A1c cut-off value of 5.6% could be used to avoid a two-step diagnostic approach and patients could be referred straight to a diagnostic OGTT. Patients with an A1c value between 4.8% and 5.6% would be indeterminate and would require the two-step approach. The number of screening tests performed in the cohort according to 1T-A1c levels in the rule-in-rule-out algorithm is shown in figure. The global saving of the proposed algorithm would be of 8.8% of the total cost with the standard strategy.
Conclusion: 1T-A1c has not enough sensitivity nor specificity to diagnose GDM, although the use of a higher (5.6%) and lower (4.8%) threshold could simplify the GDM diagnostic process reducing the number of OGTTs and associated costs.

Is time to rethink early screening for gestational diabetes?

C. Bianchi[1], G. de Gennaro[2], M. Romano[3], M. Aragona[1], L. Battini[3], S. Del Prato[2], A. Bertolotto[1];
[1]Department of Medical Area, University Hospital of Pisa, [2]Department of Clinical and Experimental Medicine, University of Pisa, [3]Maternal-Infant Department, University Hospital of Pisa, Pisa, Italy.

Background and aims: The IADPSG Fasting Plasma Glucose (FPG) threshold of ≥92 mg/dl for the diagnosis of Gestational Diabetes (GDM) in early pregnancy are not recommended anymore and data regarding risk associated with hyperglycemia in early pregnancy are limited. In 2011 Italian guidelines suggested an early screening of GDM to be performed with a 75g OGTT at 16th-18th gestational weeks in women with obesity, previous GDM, or FPG 100-125 mg/dl at initial prenatal visit. With this study we have evaluated the effectiveness of such an early GDM screening.
Materials and methods: 1338 consecutive pregnant women underwent a 75g OGTT between January 2013 and December 2015 according to national guidelines and diagnosis of GDM was based on IADPSG/WHO 2013 criteria.
Results: 14.4% of screened women had high risk defined as the presence of least one of the following: BMI ≥30 kg/m^2, prior GDM, FPG 100-125 mg/dl at initial visit. Of these women, 84.3% had only one major risk factor (34.8% pGDM, 41.7% obesity and 7.8% high FPG at the first trimester); 7.0% had both pGDM and obesity, 6.1% had both pGDM and high FPG, while 2.6% had both high FPG and obesity. No women had all three major risk factors. Screening between 16th-18th was performed in 50% of cases and 28% of them repeated the OGTT later in pregnancy due to normal glucose tolerance at the first evaluation. Among high risk women, 40% of those with FPG 100 - 125 mg/dl in the first trimester, 53% of the obese ones, and 65% of those with pGDM underwent an early OGTT. The prevalence of GDM in high risk women was 67%. Among those performing early screening, GDM was detected in 40.7% (37/91 women) at the time of first screening and 37% (19/51) at 24th-28th gestational week. Among women performing only late screening, GDM was diagnosed in 74% (66/89) of the cases. GDM was diagnosed at the time of early screening in 56% of the women with pGDM, 67% of those with obesity and 80% of those with high FPG at the first trimester. The prevalence of GDM was higher in women with two risk factors, being 100% in those with obesity and high FPG in the first trimester.
Conclusion: On the basis of these data, we suggest that an early (16th-18th gestational weeks) screening for GDM should be implemented in high risk women, especially in those with FPG in the range 100-125 mg/dl at first prenatal visit and obesity. It remains to be determined whether early diagnosis and treatment may have a positive impact on perinatal outcomes.

Development of gestational diabetes is characterised by impaired fasting insulin sensivity and beta cell dysfunction at early gestation

V. Falcone, G. Kotzaeridi, I. Rosicky, H. Kiss, W. Eppel, C. Göbl;
Medical University of Vienna, Vienna, Austria.

Background and aims: The pathophysiological components of impaired glucose metabolism (mainly impaired insulin action and β-cell dysfunction) could be quantified by advanced clinical examinations including clamp examinations as well as oral and intravenous glucose tolerance tests. However, also simple approximations from fasting measurements are available, which might be useful to provide an early and cheap identification of women with high risk for the later development of GDM.
Materials and methods: 112 pregnant women were included in this study and received a broad metabolic characterisation at early gestation (before 15+6 weeks of gestation) including fasting measurements of glucose,

insulin and C-peptide to provide information on insulin sensitivity by using the homeostatic model assessment of insulin resistance (HOMA-IR) and insulin secretion (HOMA-β). The disposition index (DI) was calculated as the product of HOMA-IR and HOMA-β to provide an estimation of β-cell function (i.e. the ability of the β-cells to adapt for insulin resistance). The amount of insulin action was additionally estimated by the quantitative insulin sensitivity check index from C-peptide (QUICKIc) to provide an estimate of insulin sensitivity from prehepatic measurements.

Results: GDM was diagnosed in 29 women, whereas 82 remained normal glucose tolerant (NGT) until end of gestation. Already at early pregnancy fasting surrogate measures of insulin action were considerably impaired in women who developed GDM as compared to those who remained NGT (HOMA-IR: 2.30 [IQR:1.45-3.93] vs. 1.42 [IQR:0.98-1.96], p<0.001). Moreover, a lower DI indicated β-cell dysfunction in subjects with later development of GDM (76 [IQR:58-97] vs. 115 [IQR:88-158], p<0.001). In particular, QUICKIc (ROC-AUC: 0.79, 95%CI: 0.68-0.90) as well as DI (ROC-AUC: 0.77, 95%CI:0.65-0.87) were closely related to the later development of GDM.

Conclusion: Later development of GDM is characterized by fasting surrogate measures of impaired glucose disposal already at early gestation. These approximations if insulin resistance and β-cell dysfunction might be useful to identify those women with particularly high risk for developing GDM.

Gestational diabetes (GDM) diagnosed at 24-28 weeks' gestation in elderly and obese women already affects foetal growth and abdominal obesity

Y. Kim[1], S. Park[2], W. Kim[1], W. Park[1], J. Kim[1], S. Park[3], K.-S. Kim[3], S.-K. Kim[3], S. Park[3], Y.-W. Cho[3];
[1]Endocrinology and Metabolism, CHA Gangnam Medical Center, CHA University, Seoul, Republic of Korea, [2]Epidemiology and Biostatistics, University of Maryland, School of Public Health, College Park, USA, [3]Endocrinology and Metabolism, CHA Bundang Medical Center, CHA University, Sungnam, Republic of Korea.

Background and aims: Elderly and/or obese women might be associated with increased incidence of GDM and metabolic disturbances occurring early in pregnancy affecting fetal growth even before the diagnosis of GDM. We, thus, investigated whether altered glucose metabolism already exists and affects fetal growth at the time of GDM diagnosis.

Materials and methods: Medical records of 7,597 singleton pregnancies which have done 50-g glucose screening test (GST) were reviewed retrospectively. 1,186(15.6%) did 100-g OGTT with measurement of fasting plasma insulin and HbA1C. NGT (normal glucose tolerance) and GDM were diagnosed by ADA criteria. Insulin resistance (HOMA-IR) and secretion (HOMA-beta %) were calculated by homeostasis model assessment. We investigated gestational age estimated at the same day of 50-g GST by ultrasonographic measurement of abdominal circumference (GA-AC) and femur length (GA-FL). We also calculated ratio of GA-AC/GA-GST (GA at 50-g GST) and ratio of GA-AC/GA-FL as indices for fetal abdominal obesity. Total subjects were divided into 4 groups: group 1 (age <35 & prepregnancy BMI <25), 2 (<35 & ≥25), 3 (≥35 & <25), 4 (≥35 & ≥25), and GDM patients in each group were compared in subgroup analysis. Statistical analysis was performed using SAS 9.4.

Results: 1) Overall incidence of GDM was 5.1% (384/7,597). The incidence was the lowest in group 1 (3.1%, 147/4,721), higher in group 2 (8.8%, 23/261) and group 3 (6.7%, 163/2,432), and the highest in group 4 (22.5%, 51/227). **2)** HbA1C(%) in GDM was significantly higher than in NGT (5.3±0.5, 5.0±0.2, $p<.0001$). In subgroup with GDM, HbA1C in group 4 was significantly higher than in group 1 (5.6±0.55, 5.25±0.42, $p<.05$). **3)** HOMA-IR in GDM was significantly higher than in NGT (2.21±1.25, 1.95±0.90, $p<.001$). In subgroup with GDM, HOMA-IR in group 2 (3.84±1.45) and 4 (2.89±1.16) were significantly higher than in group 1 (2.08±1.31) and 3 (1.91±0.94), $p<.0001$. **4)** HOMA-beta in GDM and NGT were not significantly different from one other, but in subgroup with GDM, it was significantly higher in group 2 (253±207) than in group 1 (174±137) and 3 (140±75), $p<.0005$. **5)** Both GA-AC/GA-GST and GA-AC/GA-FL ratio were significantly higher in GDM (1.04±0.05, 1.02±0.05) than NGT (1.03±0.04, 1.01±0.04), $p<.003$. But only in group 3 and 4, GA-AC/GA-GST of GDM were higher than NGT. In subgroup with GDM, GA-AC/GA-FL in group 4 was significantly higher than group 1 (1.05 ±0.04, 1.03±0.04), $p<.05$. **6)** In correlation analysis, GA-AC/GA-GST and GA-AC/GA-FL ratio showed positive correlation with age (r=0.1140, r=0.0751, $p<.0001$), prepregnancy BMI (r=0.0945, r=0.0681, $p<.0001$) and HbA1C (r=0.1619, r=0.1452, $p<.0001$) and negative correlation with HOMA-beta (r=-0.1148, r=-0.1154, $p<.05$). **7)** In multiple linear regression analysis, age and HbA1C were significantly associated with GA-AC/GA-GST (β=0.0020, $p<.005$ and β=0.0179, $p<.05$) and GA-AC/GA-FL (β=0.0018, $p<.005$ and β=0.0171, $p<.05$).

Conclusion: GDM diagnosed at 24-28 weeks of gestation in elderly and obese women already affected fetal growth and abdominal obesity. Thus, earlier detection of metabolic dysfunction and appropriate intervention might be necessary.

Experience from individualised monitoring of pregnancies with normal 2-hour OGTT

S.M. Krishnan, S.K. Cheah, K. Winter, S. Hamilton, S.S. Seshadri, A. Mathews;
Hinchingbrooke Hospital, Cambridgeshire, UK.

Background and aims: NICE guideline has recommended diagnosis of gestational diabetes (GDM) on the basis of 75gm 2-hour OGTT, with fasting glucose >5.6mmol/L or 2-hour glucose >7.8mmol/L. For those with normal OGTT, it was unclear what are the perinatal and glycaemic outcomes especially those with borderline OGTT or progressive foetal risk factors. We sought to explore the value of individualised approach in subjecting this subset of pregnancies to glucose monitoring in a multidisciplinary setting.

Materials and methods: Excluding those with pre-existing diabetes prenatally, pregnant ladies at risk for GDM attending our centre who had 2-hour OGTT consecutively between 2013-2016 were reviewed. Pregnancies diagnosed with GDM on the basis of OGTT were subjected to self-monitored blood glucose (SMBG) and dietician review. Subsequent needs for treatment escalation with metformin or insulin as dictated by SMBG profile were then recorded in a database. Follow-up were made until fasting glucose was performed 6-week postnatally. We identified a second group of pregnancies who had normal OGTT but similar monitoring and management was prescribed by the attending multidisciplinary team on the basis of progressive foetal risk factors (polyhydramnios and increasing foetal abdominal circumference) or borderline but normal OGTT. The value of monitoring this subgroup based on individualised multidisciplinary approach was evaluated by comparing the perinatal and maternal glycaemic outcomes as depicted in Table 1. Data analysis was performed on IBM SPSS v23. Independent T-test and Fisher-exact test were used to examined relationship for continuous and categorical proportions respectively.

Results: During 2013-2016, 415 pregnancies were diagnosed to have gestational diabetes during OGTT. We have identified another 75 patients with normal OGTT but were followed up in protocol similar to the GDM group in view of borderline OGTT or progressive foetal risk factors. Comparison between these groups were shown in Table 1.

Conclusion: Between pregnancies with gestational diabetes and those with normal OGTT, no significant difference between maternal age, BMI, foetal birthweight and gestational age of delivery was observed. While no difference in postnatal fasting glucose was demonstrated, those who had normal OGTT were less likely to require antenatal metformin or

insulin treatment compared to the GDM group. Despite this, a considerably large proportion (45.7%) of those with normal OGTT in this selective group developed abnormal glycaemic profile during antenatal follow-up and eventually required treatment with metformin or insulin. This suggests that an individualised approach may be required to identify who would otherwise miss the opportunity for treatment if we relied solely on the normal OGTT as a risk stratifying tool. A larger prospective study may be required to justify risk factors to consider for such individualised approach.

	GDM OGTT (N=415)	Normal OGTT (N=75)	
Fasting Glucose (mmol/L)	4.96±0.84	4.40±0.41	P<0.001[a]
OGTT: 2-hour glucose (mmol/L)	8.91±1.54	5.82±2.16	p<0.001[a]
Maternal age (year)	32.10±5.33	30.66±5.99	p=0.040[a]
Maternal BMI (kg/m²)	29.59±7.56	28.43±7.06	p=0.247[a]
Fetal birthweight (gm)	3352.95±487.953	3457.96±446.93	p=0.091[a]
Delivery gestational age (week)	38.98±1.45	38.67±4.85	P=0.286[a]

Gestational diabetes without risk factors: A group with increased risk of small for gestational age babies? Results from a retrospective case-controlled study

R. Jouini[1], L. Aho[2], B. Khallouk[3], M.-C. Brindisi[1], C. Fourmont[1], A. Nguyen[1], B. Vergès[1], S. Baillot-Rudoni[1];
[1]Endocrinology and Diabetologia, CHU, [2]Department of Hygiene, CHU, [3]Obstetrics and Gynaecology Department, CHU, Dijon, France.

Background and aims: Gestational diabetes mellitus (GDM) affects approximately 9% of pregnancies in France in 2013. GDM without risk factors represents 10% of all GDM. The prevalence of small for gestational age (SGA) is estimated at 4 to 12% according to a European meta-analysis, around 5.1% of births in France. The aim of our retrospective case-control study in a cohort of women with GDM was to evaluate the number of SGA and their potential links with the conventional criteria well known in GDM.
Materials and methods: We conducted a retrospective study in 1,464 women with GDM admitted to a university hospital ambulatory diabetology unit between January 2011 and November 2016. After randomly drawing files of GDM with and without risk factors (RF), we analyzed SGA and different parameters in the two different populations. Uni- and multivariate analyses were performed with stata V14 software, using Rank, Chi-2, Kruskal-Wallis and covariance tests; p values < 0.05 were considered significant.
Results: We analyzed 179 births: 63 births in the "cases" group =1 (GDM without RF) and 116 births in the "control" group= 0 (GDM with RF). The SGA rate was significantly higher in group 1 than in group 0: 25.4% vs. 11.6% (p= 0.029). The risk of SGA was higher in those with the lowest HbA1c: OR: 0.26, 95%CI [0.1; 0.7] (p= 0.008) and in smokers: 0R: 4, 69; 95%CI [1.4; 15.7] (p= 0.017). For birth weight in multivariate analysis, we found a positive correlation with maternal BMI in all GDM (r= 0.8) and a significant negative correlation with being in group 1 (p= 0.009).
Conclusion: In our cohort, SGA was significantly higher among women with GDM without RF than among those with RF. SGA correlated significantly with lower HbA1c (p= 0.008) and higher tobacco consumption (p= 0.017). There was a positive correlation between maternal BMI and birth weight (r= 0.8). Having GDM without RF was associated with a higher risk of lower birth weight. We need to confirm these preliminary data in a prospective study in women with GDM, in particular to better understand this high proportion of SGA.
Disclosure: **R. Jouini:** None.

PS 079 Risk and follow-up in patients with gestational diabetes

953

Risk factors of early pregnancy loss in women with type 1 diabetes: 17 year one centre observation

K. Cyganek[1], A. Hebda-Szydło[1,2], B. Katra[1,2], I. Trznadel-Morawska[1,2], P. Witek[1,2], E. Kozek[1,2], L. Dobrucka[2], B. Matejko[2], M.T. Malecki[1,2];
[1]Department of Metabolic Disease, University Hospital, [2]Department of Metabolic Disease, Jagiellonian University, Medical College, Krakow, Poland.

Background and aims: Macrosomia and congenital defects are well-defined complications of pregnancy in women with type 1 diabetes (T1DM). Less data are available for spontaneous abortions and early pregnancy losses. In this 17-year one-centre observation, we examined risk factors of early loss, defined as the spontaneous loss of a pregnancy before 21 weeks' gestation, in T1DM women.
Materials and methods: We analysed medical records of 649 singleton pregnancies in T1DM women treated in a regional tertiary reference diabetes centre. The women received diabetes care during pregnancy between 1998 and 2015. We assessed details of patients' characteristics, use of various therapeutic tools, glycaemic control measured by the HbA1c level and daily mean blood glycaemia (MBG).
Results: Pregnancy ending was identified for 544 women; a total 47 cases (8.6%) lost early pregnancy (mean 11.4 week of pregnancy). Both group of women with pregnancy loss and the rest of the study group did not differ by age (29±5.4 vs 28.2±6.8 years; p=0.4, respectively), T1DM duration (11.9±7.8 vs 12.2±7.7 years; p=0.8), pregnancy planning or not-planning (p=0.8), HbA1c on admission (7.1±1.5 vs 7.0±1.4 %; p=0.7). Women who lost pregnancy had higher weight (pre-pregnancy BMI 24.8±4.6 vs 23.7±3.7 kg/m^2; p=0.049), were earlier admitted at 1st pregnancy visit (6.4±2.4 vs 8.6±4.3 week of gestation; p=0.0001). At the 1st pregnancy visit women with pregnancy loss had a higher systolic (128 ±12.2 vs 121±14.1 mmHg; p=0.001) and diastolic (79.7±8.2 vs 75.8±8.4 mmHg; p=0.0047) blood pressure and MBG (118±42 vs 108±25 mg/dl; p=0.037). In multiple logistic regression analysis, the following variables were identified as risk factors of early pregnancy loss: T1DM duration (OR 0.9 95% CI 8.7-0.9), early admission on the 1st pregnancy visit (OR 0.98 95% CI 7.0-0.9), higher systolic blood pressure (OR 1.0 95% CI 9.9-1.0) and higher MBG (OR 1.01 95% CI 9.9-1.0).
Conclusion: We identified a number of early pregnancy loss risk factors, such as longer T1DM duration, elevated systolic blood pressure and mean blood glucose level as well as early 1st pregnancy admission. Due to an observational nature of this study, we are not able to distinguish between causative factors and incidental associations.
Disclosure: **K. Cyganek:** None.

The effects of insulin resistance and insulin secretion at mid-pregnancy on postpartum glucose intolerance in women with gestational diabetes

K.-S. Kim, S.-K. Kim, S. Park, Y.-W. Cho;
Department of Internal Medicine, CHA Bundang Medical Center, CHA University, Seongnam, Republic of Korea.

Background and aims: Gestational diabetes mellitus (GDM) has implications for postpartum glucose intolerance, as it is characterized by underlying defects in β-cell response due to increased insulin resistance during pregnancy. However, few studies have examined the effects of insulin resistance and insulin secretion on postpartum glucose intolerance in women with GDM. The aim of this study was to evaluate the effects of

insulin resistance and insulin secretion at mid-pregnancy on postpartum glucose intolerance at 6-12 weeks after delivery in women with GDM.
Materials and methods: We enrolled 913 pregnant women diagnosed with GDM from October 2005 to June 2015. Homeostasis model assessment-insulin resistance (HOMA-IR) and homeostasis model assessment β-cell function (HOMA-B) were calculated during 24-32 gestational weeks and 75-g oral glucose tolerance test (OGTT) was performed at 6-12 weeks after delivery. Insulin resistance was defined by more than the median value of HOMA-IR and low insulin secretion was defined by less than the median value of HOMA-B. Patients were classified into four groups: 1) neither low insulin secretion nor insulin resistance, 2) low insulin secretion but no insulin resistance, 3) insulin resistance without low insulin secretion, and 4) both low insulin secretion and insulin resistance. Postpartum glucose intolerance was defined as fasting plasma glucose ≥ 100 mg/dL or 2-h plasma glucose ≥ 140 mg/dL using 75-g OGTT at 6-12 weeks after delivery.
Results: Mean age was 33.3 years and mean pre-pregnancy BMI was 22.3 kg/m^2. The prevalence of postpartum glucose intolerance was 50.8 % (n = 464). Compared to women without insulin resistance, women with insulin resistance had higher postpartum glucose intolerance (60.0% vs. 41.7%, P < 0.001). However, there was no difference between women with and without low insulin secretion. The prevalence of postpartum glucose intolerance was the highest in women with both low insulin secretion and insulin resistance (group 1 = 34.8%, group 2 = 44.4%, group 3 = 56.3%, and group 4 = 68.9%, P for trend < 0.001). Group 3 and group 4 were 2.41 times (95% CI 1.58-3.67) and 4.15 times (95% CI 2.48-6.94) more likely to have postpartum glucose intolerance than group 1.
Conclusion: In women with GDM, insulin resistance at mid-pregnancy is stronger effect on postpartum glucose intolerance than insulin secretion.
Disclosure: **K. Kim:** None.

Health care providers' perspectives on pregnancy related care for type 1 diabetes women in China: an online questionnaire based study

S. Luo[1,2], C. Wang[1,2], X. Zheng[1,2], D. Yang[1,2], J. Yan[1,2], Y. Guo[3], X. Hu[1,2], B. Yao[1,2], J. Weng[1,2];
[1]Department of Endocrinology and Metabolism, The Third Affiliated Hospital of Sun Yat-Sen University, [2]Guangdong Provincial Key Laboratory of Diabetology, [3]Department of Medical Statistics and Epidemiology, School of Public Health, Sun Yat-sen University, Guangzhou, China.

Background and aims: Pregnancy related care (PRC) could improve adverse pregnancy outcomes of type 1 diabetes (T1D) women. Little was known on the current status of PRC for T1D women in China. We aimed to investigate health care providers (HCPs)' perspectives on PRC for T1D women in China.
Materials and methods: It was a cross-sectional study by an online questionnaire designed based on results of previously conducted in-depth interview of HCPs. Doctors and nurses involved in PRC for T1D women were included. The questionnaire was released online and advertised via doctor unions in China. The survey ended when estimated sample size was reached. The data collected were analyzed in SPSS v.19.0.
Results: The survey was conducted from Nov 13 to Dec 30, 2016. 991 responses were received (100% response rate) from 31 provinces of China, including 77.3% doctors and 22.7% nurses. Among them, 69.1% were female; 62.7% from endocrinology department and and 9.5% from the department of gynecology and obstetrics; 63.0% from general hospitals and 37% from primary care facilities. 52.9% had over 10 years of working experience. The results could be summarized as below. 1) On the attitude towards T1D with pregnancy, over 90% HCPs supported T1D women should have to right to get pregnant if well planned and could perceive T1D women's worries on it. 2) On the knowledge of PRC for T1D women, 63.8% reported to have some knowledge of PRC, but 62.5% reported to treat only a small number of T1D women annually. Only 16.6% HCPs thought they provided proper PRC. 3) On the content of PRC, over 90% suggested PRC include diet, exercise, adjustment of insulin regimen, glucose monitoring and T1D examinations (such as diabetic complication monitoring). 4) On the attitude towards social-psychological support, 80.6% considered it important, but only 48.4% thought they had the skill. 5) On the implementation of PRC, 82.0% thought PRC should be done by endocrinologists with the aid of department of gynecology/obstetrics and other related departments. 6) On the sufficiency of communication between T1D women and HCPs regarding PRC, in practice 51.4% considered the HCP-patient communication for PRC was very inadequate. 56.6% reported less than 10 minutes per visit, while 58.2% thought at least 20 minutes was required for sufficient communication. 7) On future perspective and suggestions on PRC for T1D women, investigated HCPs thought it the principal to train related HCPs on knowledge and social-psychological support skills (64.2%) of PRC for T1D women.
Conclusion: Although HCPs in China were aware of the importance of PRC for T1D women and could perceive the patients' worries, the current situation was dissatisfactory, largely due to inadequate experience, knowledge and limited communication time. It is necessary to accelerate and reinforce the training and appeal for more social forces to improve PRC for T1D women.

Macrosomia in pregestational diabetes: associated factors

A. González Lleó[1], B. Vega Guedes[2], M. Armas-Roca[2], A. Wägner Fahlin[1,3];
[1]Endocrinology, Complejo Hospitalario Universitario Insular Materno-Infantil, [2]Gynecology and Obstetrics, Complejo Hospitalario Universitario Insular Materno-Infantil, [3]Instituto Universitario de Investigaciones Biomédicas y Sanitarias (IUIBS), Universidad de Las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain.

Background and aims: Foetal macrosomia is one of the most frequent complications of diabetes in pregnancy, occurring in 20-50% of pregnancies, and is associated with increased risk of obstetric and perinatal complications. The aim of this study was to assess the factors associated with macrosomia in women with pregestational diabetes.
Materials and methods: The clinical records of women with pregestational diabetes, followed during pregnancy at a reference centre and with delivery between January 2011 and December 2016, were reviewed. Only singleton pregnancies and term (>37 weeks' gestation) deliveries were included. Macrosomia was defined as birth-weight of 4000g or more. Group comparison and logistic regression were performed to find factors associated with macrosomia. A two-tailed p<0.05 was considered significant.
Results: A total of 302 women fulfilled the study criteria. Their age was 33 (18-45) years, baseline BMI 28.6 (17.3-60.1) Kg/m2, 45.8% were nulliparous and 46.7% had type 1 and 52% class B (White) diabetes. Their HbA1c was 6.6 (4.6-11), 5.85 (4.3-9.4) and 6.0 (4.5-9.5)% in the 1st, 2nd and 3rd trimesters, respectively. Of the newborns, delivered at 39 (37-42) weeks' gestation, 91 (30.1%) had macrosomia. Third trimester HbA1c [6.3 (4.8-9.5) vs 5.95 (4.5-8.9)% p=0.006] and maternal weight at baseline [78.4 (44-150) vs 73 (41-126) Kg, p=0.044] and in the third trimester [91 (66.5-155) vs 84 (51-134) Kg, p=0.002] were higher and weight gain during pregnancy tended to be higher (13.2 (6.5) vs 11.6 (6.4) Kg, p=0.065] in the group with macrosomia. There were no significant differences between groups in type of diabetes, parity, gestational age, preconceptional care or earlier HbA1c. In multivariate, logistic regression, only maternal, third trimester weight and HbA1c remained significantly associated with macrosomia.

Conclusion: The frequency of macrosomia in singleton, term deliveries of women with pregestational diabetes is 30% and is associated with maternal third trimester HbA1c and weight.

Weight gain during pregnancy in women with diabetes: the pattern differs by diabetes type

R. Corcoy Pla[1], A. García-Patterson[1], A. Morilla[1], P. Gil[1], A. Chico[1], I. Pujol[1], J. Adelantado[2], A. de Leiva[1];
[1]Department of Endocrinology & Nutrition, Hospital de la Santa Creu i Sant Pau, [2]Department of Obstetrics & Gynaecology, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

Background and aims: Extremes of weight gain during pregnancy (WG) are associated with adverse pregnancy outcomes. Institute of Medicine (IOM) recommendations differ by prepregnancy body mass index (BMI). We aimed to analyze WG according to IOM in women with gestational (GDM), type 2 (T2DM), and type 1 diabetes mellitus (T1DM).
Materials and methods: Subjects: Three cohorts of women with diabetes and singleton pregnancies (2770 GDM; 100 T2DM and 469 T1DM). Maternal characteristics analyzed: Prepregnancy age, weight, height, BMI, insulin treatment during pregnancy and WG according to IOM. Statistics: Descriptive statistics; Chi-square to compare WG categories.
Results: Maternal characteristics in women with GDM, T2DM and T1DM were: GDM: age 33 years, height 160 cm, weight 60 kg, BMI 23.4 kg/m2, insulin treatment 47.4%; T2DM: age 34 years, height 159 cm, weight 70 kg, BMI 28.0 kg/m2, insulin treatment 100%; T1DM: age 30 years, height 161 cm, weight 60 kg, BMI 23.0 kg/m2, insulin treatment 100%. WG according to IOM in the three cohorts were: GDM: 52.5% insufficient, 31.4% adequate, 16.1% excessive ($p < 0.001$ *vs* recommendations), T2DM and T1DM: T2DM: 29.8% insufficient, 25.5% adequate, 44.7% excessive ($p < 0.001$ *vs* recommendations and GDM, $p < 0.01$ *vs* T1DM); T1DM: 16.1% insufficient, 35.3% adequate, 48.6% excessive ($p < 0.001$ *vs* recommendations and GDM, $p < 0.01$ *vs* T2DM)
Conclusion: WG distribution in the three cohorts differs markedly vs IOM recommendations and between them. We propose that differences are driven by diet restriction in GDM and by insulin treatment in women with T2DM and T1DM. The knowledge of the current patterns could be of help in clinical practice.

Birth weight of infants of type 1 diabetic and control women in the Tauffer Obstetric Database between 1996 and 2011

A.G. Tabák[1,2], L. Zsirai[3], G.M. Csákány[4], E. Szabó[5], M.M. Svébis[1];
[1]1st Department of Medicine, Semmelweis University, Faculty of Medicine, Budapest, Hungary, [2]Department of Epidemiology & Public Health, University College London, London, UK, [3]Department of Gynecology and Family Planning, Istenhegyi GeneDiagnostic Center, [4]Department of Obstetrics and Gynecology, Jahn Ferenc Hospital, [5]St. Imre Teaching Hospital, Budapest, Hungary.

Background and aims: Parallel to the epidemic spread of obesity a gradual increase in birth weight has been observed in the general population in recent decades. This increase has flattened out according to data from high income countries in the last 4-5 years. There is a lack of information however whether similar changes has occurred in the newborns of type 1 diabetic (T1DM) women. The present study investigated changes in infant birth weight in Hungary stratified by the mothers T1DM status based on the Tauffer Obstetric Database between 1996 and 2011.
Materials and methods: Our analysis was based on data from the compulsory Tauffer Obstetric Database (collected by the National Institute of Obstetrics and Gynecology) between 1996 and 2011. After excluding twin pregnancies and premature or postmature deliveries (<37 or >41 weeks of gestation), we analyzed changes in birth weight of n=1,263,919 control and n=1,152 T1DM newborns separately for males and females using multiple linear regression adjusted for maternal age and gestational week at delivery.
Results: T1DM women were older (29.4±5.3 vs 27.5±5.4 years), had shorter gestation at delivery (38.4±1.0 vs. 39.2±1.1 weeks) and had heavier newborns adjusted for gestational age at delivery (76.0±26.3 vs. 62.2±28.0 percentile, all $p<0.05$). Based on multivariably adjusted models, birth weight of both male and female control infants increased following a negative quadratic curve (female/male) from 3255 [SE 2]/3395 [2] g to 3279 [2]/3420 [2]g (p[quadratic term]<0,0001, increase in 1996 8.0 [0.5]/6.5 [0.5], in 2011 -4.8 [0.5]/-3.0 [0.5]g). Temporal changes of birth weight of female infants of T1DM mothers was similar to controls however babies of T1DM mothers were 299 [99]g heavier than controls throughout follow-up. Male infants of T1DM mothers were heavier than controls (weight difference in 2003 265 [18] g), moreover the weight difference increased throughout follow up (10.8 [3.8]g/year). Furthermore the increase of the birth weight of male infants has not yet finished at the end of follow up.
Conclusion: According to our descriptive epidemiological analysis of the Tauffer Obstetric Database, neonatal birth weights have changed similarly in Hungary and other high income countries. Temporal changes in birth weight of female infants of T1DM mothers was similar to controls, however the increase in birth weight of male infants has not finished during follow-up. The differing trajectories of male and female birth weights requires further investigations both in more recent data of the Tauffer database and prospective collection of potential correlates of birth weight (maternal weight, maternal insulin doses, gestational complications).
Disclosure: **A.G. Tabák:** None.

Perinatal outcomes of pregnencies of type 1 diabetic women in Hungary: an analysis of the Hungarian Tauffer Database 1996-2011

B. Domján[1], M.M. Svebis[1], L. Zsirai[2], G.M. Csakany[3], A.G. Tabak[4];
[1]First Department of Internal Medicine, Semmelweis University, [2]Department of Gynecology and Family Planning, Stenhegyi GeneDiagnostic Center, [3]Department of Obstetrics and Gynecology, Jahn Ferenc Hospital, Budapest, Hungary, [4]Department of Epidemiology & Public Health, University College London, London, UK.

Background and aims: During the last decades the outcomes of pregnancies complicated by type 1 diabetes has improved however most studies still report worse outcomes compared to the general population. As there is no report on the outcomes of pregnancies complicated by type 1 diabetes in Hungary, we aimed to assess outcomes of pregnancies complicated by type 1 diabetes mellitus compared to a control population using data from the Hungarian Tauffer Obstertric Database.
Materials and methods: The Tauffer Database is a compulsory report of each delivery()24-43 weeks of gestation) in Hungary that has records on n=1,401,184 deliveries between 1996 and 2011. Fort the present analysis we excluded multiple pregnancies (n=22,291). Type 1 diabetes was defined by ICD-10 codes (n=1,485). Multiple logistic regression with pregnancy outcomes (stillbirth, perinatal mortality, neonatal mortality, congenital malformations, oligohydramonion, polyhydramnion, small for gestational age (SGA), large for GA (LGA), caesarian section, perinatal intensive centre treatment, 5-minute Apgar <7) as outcomes with type 1 diabetes as a predictor and adjusted for maternal and gestational age at delivery, and further adjusted for obstetrical and medical history were investigated.
Results: Type 1 diabetic mothers were older (29.5[SD 5.3] vs. 27.5[5.5] years), had a lower gestational age at delivery (37.5[2.1] vs. 38.8[2.0] weeks), larger newborn (3387[692] vs. 3275[573] g), and more

frequently had a pregnancy complicated by hypertension (3.4 vs. 0.6%, all p<0.0001). In multiple adjusted models, type 1 diabetic mothers had an extremely increased risk of polyhydramnion (OR 19.0, 95%CI 10.6-33.9), while there was a 2 to 4 fold increased risk of all other outcomes except for SGA (OR 0.45, 95%CI 0.28-0.74) and neonatal mortality (OR 1.08, 95%CI 0.44-2.66).

Conclusion: We found significantly increased risk of several pathological pregnancy outcomes that were robust to multivariate adjustment. However neonatal mortality was similar between pregnancies complicated by type 1 diabetes and controls.

Implementing a reminder system to stimulate postpartum screening for glucose intolerance in women with gestational diabetes: the 'Sweet Pregnancy' project

K. Benhalima[1], S. Verstraete[2], F. Muylle[2], K. Decochez[3], R. Devlieger[4], P. Van Crombrugge[5], A. Verhaegen[6], J. Wens[7], C. Mathieu[1];
[1]Endocrinology, University Hospital of Gasthuisberg, KU Leuven, Leuven, [2]Endocrinology, Diabetes Liga, Gent, [3]Endocrinology, AZ Jan Portaels, Vilvoorde, [4]Obstetrics & Gynecology, University Hospital of Gasthuisberg, KU Leuven, Leuven, [5]Endocrinology, OLV Aalst-Asse-Ninove, Aalst, [6]Endocrinology, AZ Jan Palfijn, Merksem, [7]Primary and Interdisciplinary Care, University of Antwerp, Wilrijk, Belgium.

Background and aims: Women with a history of gestational diabetes (GDM) are at increased risk to develop type 2 diabetes (T2DM). Timely detection of glucose intolerance postpartum is important since progression to T2DM can be prevented with 50% by lifestyle intervention. However, postpartum testing rates in routine clinical practice are often very low. We aimed therefore to evaluate the feasibility and efficacy of a GDM recall register on the long-term screening uptake postpartum and to evaluate the prevalence of (pre)diabetes postpartum.

Materials and methods: Evaluation of the registration and responses of women with a history of GDM in a recall register implemented in 66 obstetrical centers in the Northern part of Belgium from 2009-2016. Registrants receive yearly reminders (postal, email, SMS and/or telephone) to have a fasting plasma glucose (FPG) test in primary care to timely detect (pre)diabetes. The cumulative risk of diabetes was estimated using the Kaplan-Meier method, whereas for prediabetes, the estimation was based on the cumulative incidence function.

Results: Over a 7 year period, 7269 women have registered in the GDM recall register. Of all registrants, 84.4% (5465) responded to the letter sent three months after the delivery and 58.8% (3215) of responders indicated that they had received a screening test to detect glucose intolerance in early postpartum. The yearly response rates varied from 74.4% after the first year to 61.8% after the fifth year and the number of women who reported a screeningtest varied from 67.4% after the first year to 71.9% after the fifth year. Of all women who received a yearly follow-up letter (1157) and were 5 year in follow-up in the register, 75.0% (868) received at least once a screening test, 60.6% (701) received at least twice a screening test, 46.6% (539) received at least three times a screening test, 34.0% (393) received at least four times a screening test and 18.3% (212) of women received yearly a screening test over the 5 year period. Compared to women who responded at least once to a reminder, women who never responded were more often < 30 years (41.4% vs. 33.9%, p <0.001) and were more often obese (29.3% vs. 20.8%, p=<0.001). Over a period of 6 years, 27.4% (CI 23.9%-31.0%) developed impaired fasting glycaemia and 7.3% (CI 6.0%-8.4%) developed diabetes. Independent predictors for diabetes were age and BMI and for prediabetes independent predictors were age, BMI and waist circumference.

Conclusion: We show now the long-term feasibility and efficacy of a GDM recall register to stimulate screening postpartum. However, it remains challenging to stimulate women to get a yearly screening test since only 18.3% of women with 5 years of follow-up in the register, reported a screening test every year. On third of women developed (pre)diabetes within 6 years.

Disclosure: **K. Benhalima:** None.

961

Adherence to a follow-up programme after gestational diabetes in an Italian population

M. Dalfrà, S. Burlina, F. Anti, A. Lapolla;
Department of Medicine (DIMED), University of Padova, Padova, Italy.

Background and aims: Women with Gestational Diabetes Mellitus (GDM) are at high risk of developing type 2 diabetes mellitus, metabolic syndrome and cardiovascular diseases. The aim was to identify the factors that characterize the adherence to postpartum follow-up of patients with previous GDM.

Materials and methods: Data on 1573 women with previous GDM were retrospectively collected. In pregnancy: age, family history of diabetes, ethnicity, prepregnancy BMI, weight gain, gestational week at diagnosis of GDM, timing and mode of delivery, metabolic parameters (fasting plasma glucose, glycated heaemoglobin, total cholesterol, HDL, LDL, triglycerides). After delivery: glucose and insulin values at the OGTT 75g performed after at least 6 weeks from delivery, total cholesterol, HDL, LDL, triglycerides and postpartum weight. Based on OGTT results, women were categorized into two groups: NGT (Normal Glucose Tolerance) and AGT (Altered Glucose Tolerance). Furthermore, factors that could encourage women to undergo postpartum glucose testing were evaluated.

Results: 889 (56,52%) women underwent follow-up after delivery: they had higher frequencies of maternal age > 35 years (44,8 vs 40,8% p 0,000), first degree family history of diabetes mellitus (46 vs 36 % p 0,000), insulin treatment during pregnancy (29,3 vs 18,1% p 0,000) than non-screened women. The adherence to follow-up was higher among Italians than migrants (59,4 vs 51,4 % p < 0,05): by differentiating in more specific ethnic groups, the frequency of follow-up was the highest in Italians and in women from Subsaharian Africa (59%) and the lowest in Asians and Arabs (57% and 55% respectively). At the follow-up, 741 (83,35%) were NGT, 148 (16,65%) were AGT. During pregnancy, women with AGT at postpartum screening had a higher prepregnancy BMI (25,6 ± 5,2 vs 24,5 ± 4,9 kg/m^2 p 0,016), received an earlier dignosis of GDM (22,5 ± 5,5 vs 24 ± 4,3gw p 0,001) and underwent the postpartum follow-up later (10,9 ± 4,5 vs 9,7 ± 3,6 weeks from delivery p 0,004) than women with NGT. Among women with AGT, there were more migrants (45,27 vs 29,96%, p 0,000), more first degree family history of diabetes (54,7 vs 44,3 % p 0,018) and a higher need for insulin therapy(43,2 vs 26,5%, p 0,000)than in women with NGT. Women with postpartum AGT had significantly higher values of first fasting glycaemia (92,1 ± 12,7 vs 86,7 ± 10,8 mg/dl p 0,000), HbA1c at the diagnosis of GDM (5,5 ± 0,5 vs 5,2± 0,4 % p0,000), HbA1c at the third trimester (5,5 ± 0,5 vs 5,3 ± 0,4 % p0,000), 2h-OGTT value(159,9 ± 27,7 vs 147,5 ± 30,4 mg/dl p0,000) and AUC_{glu} (18382,3 ± 2523,5 vs 17377,3 ± 2591,1 mg/ml x min p 0,000) at the diagnostic OGTT than women with NGT. After pregnancy, women with postpartum AGT had significantly higher values of all glycaemic points measured at postpartum OGTT 75g (in particular, 1h-OGTT value: 170,8 ± 45,9 vs 122,9 ± 31,4 mg/dl, p 0,000), of insulin at 1h-(71,1 ± 53,4 vs 57,2 ± 36,4 mU/ml p 0,022) and 2h-(85,8 ± 85,5 vs 41,4 ± 27,8 mU/ml p 0,000) during OGTT, of postpartum triglycerides(104,5 ± 67,7vs 83,1 ± 47,9 mg/dl p 0,001) and lower values of HDL (60,9 ± 18,8vs 66,02 ± 16,34 mg/dl) than women with NGT. Finally, women with NGT were more likely to breast-feed than women with AGT (45,6 vs 34,5 % p 0,009).

Conclusion: Factors that characterize the adherence of postpartum follow-up in patients with previous GDM are age, family history of diabetes, insulin therapy in pregnancy and ethnicity, but the rates of screening are still too low. Need more educational programs to increase the awareness of the risk in GDM women.

The relationship between sudomotor function and insulin resistance in adults with type 1 diabetes

A. Gandecka, A. Uruska, A. Araszkiewicz, S. Piłaciński, B. Wierusz-Wysocka, D. Zozulińska-Ziółkiewicz;
Department of Internal Medicine and Diabetology, Poznan University of Medical Sciences, Poznan, Poland.

Background and aims: The occurrence of insulin resistance in type 1 diabetic patients is one of the risk factors of chronic complications of diabetes. Dysfunction of small fibers is an early clinical manifestation of diabetic microangiopathy. SUDOSCAN+ is a device used to noninvasively assess the function of the sweat glands, which are innervated by C-fibers, on the basis of electrochemical skin conductance (ESC). The aim of the study was to evaluate the association between sudomotor function and insulin resistance in adult patients with type 1 diabetes (DM1).
Materials and methods: The study included 494 adult patients with DM1 (253 men), aged 41 (IQR: 33-52) years, with disease duration of 24 (IQR: 19-32) years and HbA1c level of 7.9 (IQR: 7.1-8.9) %. The sudomotor function was evaluated using SUDOSCAN device on the basis of the electrochemical reaction of chlorine ions secreted in sweat due to low voltage current. Insulin resistance was assessed by calculating the estimated glucose disposal rate (eGDR) according to the formula based on HbA1c, WHR and presence of hypertension. The study group was subdivided into 3 groups based on quartiles of eGDR (<5.5, 5.5-9.5, >9.5 mg/kg/min).
Results: Patients with lower eGDR (higher insulin resistance) had lower Feet ESC [71 (IQR:50-81) vs 79 (IQR:63-85) vs 83 (IQR:74-86) μS; p<0.0001 and Hands ESC (58 (IQR:40-70) vs 61 (IQR:50-72) vs 69 (IQR:60-77) μS; p<0.001)]. We found positive correlation between Feet and Hands ESC and eGDR (Rs=0.28, p<0.001 and Rs=0.21, p<0.001 respectively). In a multiple linear regression model which takes into account age, sex, duration of diabetes, Feet ESC was independently associated with eGDR (β=0.14, p=0.001).
Conclusion: In adult patients with DM1 the higher insulin resistance the greater sudomotor dysfunction is.

Neuroretinal dysfunction is associated with early peripheral motor unit loss in type 1 diabetes

D. Ylli[1], F. Picconi[1], G. Mataluni[2], M. Parravano[3], L. Ziccardi[3], A. Di Renzo[3], S. Coluzzi[1], P. Pasqualetti[4], L. Chioma[1], I. Malandrucco[1], D. Lauro[5], G.A. Marfia[2], S. Frontoni[1];
[1]Department of Systems Medicine, Unit of Endocrinology, Diabetes and Metabolism, S. Giovanni Calibita Fatebenefratelli Hospital, [2]Department of Systems Medicine, Unit of Disimmune Neuropathies, [3]IRCCS-G.B. Bietti Foundation, [4]Department of Systems Medicine, Fatebenefratelli Foundation for Health Research and Education, AFaR Division, [5]Department of Systems Medicine, University of Rome Tor Vergata, Rome, Italy.

Background and aims: It is already accepted that early retinal neurodegeneration has a predictive role in the development of clinically detectable microvascular alterations in diabetic retinopathy (DR). However, no data are available about the relationship between retinal neurodegeneration and diabetic peripheral neuropathy. The aim of the study was, therefore, to investigate the hypothesis that retinal neurodegeneration could be considered as a marker of early diabetic neuropathy.
Materials and methods: 19 subjects affected by Type 1 Diabetes Mellitus (T1DM) with no symptoms/signs of peripheral polyneuropathy, without DR or with very mild non-proliferative DR, and 14 healthy controls (C) matched for age and gender were enrolled. All subjects underwent the following electrophysiological tests: standard nerve conduction studies (NCS), incremental motor unit number estimation (MUNE) from abductor hallucis (AH) and abductor digiti minimi (ADM) with assessment of AH and ADM average single motor unit potential (SMUP) size. The retinal functional analysis was performed by multifocal electroretinogram (mfERG) measuring amplitude density (Amp) and implicit time (IT), for 3 concentric annular rings (Ring 1, R1= 0-2.5°; R2= 2.5-5°; R3= 5-10° degrees of foveal eccentricity), of nasal (N)/ temporal (T)/superior (S)/ inferior (I) macular quadrants.
Results: Amp was significantly decreased in T1DM vs. C (p<0.05), in each ring and quadrant. ADM MUNE and AH MUNE were significantly decreased in T1DM (p 0.039; p <0.0001, respectively), and AH-SMUP significantly increased (p 0.002), vs. C. No abnormalities of NCS were found in any subject. A positive correlation between Amp in N and I quadrant and AH MUNE (Pearson correlations: r^2 0.368, p 0.01; r^2 0.288, p 0.03, respectively) was observed in T1DM subjects.
Conclusion: Retinal neurodegeneration is already present in T1DM patients without peripheral neuropathy. MUNE proved to be a reliable instrument to detect precocious and subclinical peripheral neuropathic damage, representing by the motor unit loss and collateral re-innervation process. The observed relationship between neuroretinal dysfunction and early peripheral motor unit decline supports the hypothesis that neuroretina can be considered as a potential "window" to track the early neuropathic process in diabetes.
Disclosure: **D. Ylli:** None.

Dorsolateral prefrontal cortex activity towards fatigue of type 2 diabetes patients with macro-angiopathy and peripheral neuropathy (pilot study)

K. Kotsa[1], G. Elcadi[2], M. Grammatiki[1], S. Xergia[3], S.B. Catrina[4], P. Tsaklis[4,5];
[1]Diabetes Center, Department of Endocrinology and Metabolism, 1st Department of Internal Medicine, AHEPA University Hospital, Thessaloniki, Greece, [2]Division of Sport Sciences, University of Gavle, Gavle, Sweden, [3]Division of Physiotherapy, European University of Cyprus, Nicosia, Cyprus, [4]Department of Molecular Medicine and Surgery (MMK), Karolinska Institutet, Stockholm, Sweden, [5]Department of Physiotherapy, Alexander TEI, Thessaloniki, Greece.

Background and aims: Patients with chronic type 2 Diabetes Mellitus (T2DM) show a decreased neuromuscular activation and increased fatigue depicted by a raised postural central of pressure (COP) kinetics during standing tasks. The dorsolateral prefrontal cortex (DLPFC) is responsible for many cognitive and motor functions and is believed to be involved in the overriding mechanism of fatigue. It is unclear, however, if there are differences in COP and DLPFC activity between T2DM patients who present macro-angiopathy (MA) without diabetic peripheral neuropathy (DPN) and those with both MA and DPN. The aim of the present study is to determine whether differences in COP kinetics between patients with MA alone and both MA-DPN exist and if these differences correlate with DLPFC activity.
Materials and methods: 15 participants, both males and females, (mean age 66±5,7), divided in 3 groups of 5 [5 healthy controls (HC group), 5 T2DM patients with MA alone (MA group) and 5 T2DM patients with both MA and DPN (MA-DPN group)] were included in the study. They performed 3x2 minutes trials of COP Antero/Posterior (A/P) displacements, with a visual feedback, controlled by a metronome in 20bits/min, moving their weight between 2 points, on the top and the bottom of a screen. Pre-Post Data collection: Near Infrared spectroscopy for DLPFC, Tibialis Anterior isometric strength, COP sway velocity, COP area (mm^2) and COP A/P amplitude (mm) were also measured.
Results: Repeated measures and matched pair T-test analysis was performed. During every 2' trial, the COP Sway area and the avegCOP A/P

displacements amplitude decreased, in both MA group and MA-DPN group, but not in HC group. Moreover, after each 2' trial the average COP sway velocity increased only in MA-DPN group and not in the other 2 groups. The Maximal Voluntary Isometric Contraction of the Tibialis Anterior decreased in MA group and MA-DPN group, but not in HC group, between baseline and immediately after the last bout. Finally, there was an increase trend in total Hemoglobin (tHB, blood volume) at the DLPFC, in MA-DPN group, but not in the other 2 groups, during and at the end of the trials.
Conclusion: T2DM patients with MA alone and both MA and DPN demonstrated decreased mobility during the exercise, but only the MA and DPN patients demonstrated increased DLPFC activity. This can be probably explained by the greater cognitive dependence showed by the MA-DPN group, in comparison with the other two groups, in order to anticipate the peripheral fatigue and follow the task.

Enhanced subclinical inflammation in painful compared to painless diabetic polyneuropathy. A multimarker approach

D. Ziegler, A. Strom, G. Bönhof, S. Püttgen, M. Roden, C. Herder;
German Diabetes Center, Düsseldorf, Germany.

Background and aims: The determinants and mechanisms contributing to the phenotype of diabetic sensorimotor polyneuropathy as a painful (DSPN+p) or painless (DSPN-p) entity remain unclear. Since inflammation has been implicated in the pathogenesis of neuropathic pain, we hypothesized that pro- and/or anti-inflammatory processes could be more relevant in DSPN+p than DSPN-p.
Materials and methods: Using a new multimarker assay (Proseek Multiplex INF I assay, OLINK Proteomics), we measured 92 serum biomarkers including pro- and anti-inflammatory cytokines and chemokines as well as vascular and growth factors in 193 patients with DSPN+p and 171 with DSPN-p from the PROPANE study (DSPN+p/DSPN-p [mean±SD]: age: 65.7±9.9/68.0±10.3 years, male: 68/82%, BMI: 31.3±5.5/29.3±5.1 kg/m²; type 2: 86/83%, diabetes duration: 16.1±12.1/16.1±12.6 years, HbA1c: 7.6±1.4/7.3±1.2%). DSPN was diagnosed using modified Toronto Consensus (2011) criteria, while DSPN+p and DSPN-p were stratified using a cutpoint of 4 points on the Likert scale for chronic pain lasting >1 year in the distal lower limbs.
Results: After adjustment for sex, age, BMI, smoking, diabetes type, diabetes duration, and HbA1c, compared to patients with DSPN-p those with DSPN+p showed increased levels (normalized protein expression values) of the pro-inflammatory markers CUB domain-containing protein 1 (CDCP1: 3.29±0.64 vs 3.16±0.58), signaling lymphocytic activation molecule 1 (SLAMF1: 2.57±0.58 vs 2.71±0.57), and chemokine (C-C motif) ligand 20 (CCL20: 5.40±1.07 vs 5.74±1.31) as well as the anti-inflammatory markers interleukin 10 (IL-10: 2.37±0.43 vs 2.53±0.64) and osteoprotegerin (OPG: 10.23±0.39 vs 10.13±0.38) (all P<0.05). In patients with DSPN+p, several inflammatory markers correlated with diminished quantitative sensory tests (e.g. CDCP1 with cold thermal detection threshold on the hand: ß=-0.241; P=0.002) and nerve conduction velocity (NCV) (e.g. SLAMF1 with peroneal motor NCV: ß=-0.262; P=0.0005), whereas in those with DSPN-p these associations were either absent or markedly weaker.
Conclusion: Patients with painful DSPN show higher systemic levels of pro- and anti-inflammatory mediators than those with painless DSPN, pointing to a role of inflammatory processes in painful diabetic neuropathy.

Effects of epalrestat therapy for diabetic neuropathy evaluated using pain threshold

N. Takahashi;
Takahashi Family Clinic, Nagoya, Japan.

Background and aims: The aldose reductase inhibitor, epalrestat, was approved in Japan after a three-month double-blind trial showed that it improved symptoms and nerve function. Epalrestat effects were more obvious in patients with early neuropathy and modestly elevated levels of glycated hemoglobin. However, the effects of epalrestat in individual patients are still difficult to assess. In annual neuropathy checkups, we found that epalrestat lowered the pain threshold in some patients. Therefore the present study used intraepidermal electrical stimulation (IES) to investigate variation in pain threshold in patients with type 2 diabetes treated with epalrestat.
Materials and methods: This retrospective study investigated pain thresholds in patients selected from among 647 patients (mean age, 61.2 ± 12.2 years; male, n = 428) with type 2 diabetes who were administered epalrestat and who had undergone three consecutive annual neuropathy examinations at Takahashi Family Clinic. We also compared pain thresholds in seven symptomatic patients (mean age, 71.6 ± 5.7 years; male, n = 6) with type 2 diabetes before and three months after starting epalrestat therapy. We determined the pain threshold by stimulating the dorsal skin of the feet using IES electrodes at an initial intensity that was sufficient for patients to feel a pricking sensation, and then reduced the current in 0.05-mA increments until sensation was indiscernible.
Results: The mean pain thresholds in each year were 0.21 ± 0.17, 0.19 ± 0.18 and 0.16 ± 0.13 mA ($F = 3.0$, $p < 0.01$). The mean pain threshold of eleven patients before taking epalrestat therapy were 0.25 ± 0.17 mA and 0.13 ± 0.05 mA ($p < 0.05$), respectively. Three months after taking epalrestat, the mean pain thresholds in these patients were lowered from 0.55 ± 0.34 mA to 0.14±0.03 mA, respectively ($p < 0.05$). Furthermore, symptoms related peripheral neuropathy improved.
Conclusion: The present findings suggest that measuring pain threshold is useful for assessing the effects of epalrestat in patients with neuropathy caused by type 2 diabetes.

Prevalence of diabetic neuropathy in adolescents with type 1 diabetes and the association to insulin pump therapy

M.M.B. Christensen[1], E.E. Hommel[2], M.E. Jørgensen[1], B.J. von Scholten[3], C.S. Hansen[3];
[1]Clinical Epidemiology, Steno Diabetes Center Copenhagen, [2]Steno Clinic, Steno Diabetes Center Copenhagen, [3]Diabetes Complication Research, Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: Two of the most prevalent subgroups of diabetic neuropathy are diabetic peripheral neuropathy (DPN) and cardiovascular autonomic neuropathy (CAN), but data on the prevalence of theses

complications in adolescents with type 1 diabetes are scarce. Since early stages of CAN and DPN may be reversible, screening adolescents with type 1 diabetes may be important. Furthermore, it is unknown whether insulin pump reduces development of diabetic neuropathy. The aim of this study was to investigate the prevalence of DPN and CAN in a Danish population of adolescent patients with type 1 diabetes and to assess the association between treatment with insulin pump and these complications.
Materials and methods: Adolescents with type 1 diabetes underwent examination of CAN and DPN. CAN was assessed by the cardiovascular autonomic reflex tests (CARTs). The diagnosis 'early CAN' was given if one out of the three CARTs was abnormal and 'definite CAN' if two or three out of the three tests were abnormal. DPN was assessed by light pressure perception, pain perception, vibration perception threshold (VPT), Brief Pain Inventory and Michigan Neuropathy Screening Instrument questionnaire, electrochemical skin conductance (ESC), sural nerve conduction velocity (SNCV) and sural nerve action potential (SNAP). Distribution of outcome measures is presented in table 1. The associations between insulin pump therapy and the various measures of CAN and DPN were analysed in logistic and linear regression models.
Results: The 156 adolescents (42% were males) with a mean age of 22 years (SD 1.6), a mean diabetes duration of 11.3 years (SD 5.1) and a median HbA_{1c} of 66.5 mmol/mol (IQR 58;77) (8.3% (IQR 7.4;9.2)) had a prevalence of CAN and early CAN of 9% and 26.1%, respectively. The composite prevalence of DPN was 55.8% encompassing the prevalence of abnormal SNAP of 23.8%, SNCV of 37.1%, ESC on the hands and feet of 4% and 8%, respectively, VPT of 1.3% and BPI questionnaire of 1.9%. No statistically significant association was found between insulin pump therapy and the various measures of DPN and CAN.
Conclusion: DPN and CAN are prevalent in adolescents with type 1 diabetes with no association found with insulin pump treatment. The use of novel measuring modalities in the present study identified a higher number of subjects with DPN compared to established measures. Screening for diabetic neuropathy in adolescents may be beneficial in order to detect and prevent nerve damages at early stages.

Table 1 Distribution of outcome measures and prevalences of abnormal results in a population of adolescents with type 1 diabetes.

Neuropathy outcome measure	n	Mean/median (SD)/[IQR]	Prevalence n (%)
CAN	154	NA	14 (9)
Early CAN	154	NA	40 (26.1)
Symmetric peripheral neuropathy	156	NA	87 (55.8)
Monofilament (≥ 1 missing response)	156	NA	0
Pin prick (≥ 1 missing response)	156	NA	0
VPT (V)	156	4.5 [3.5;5.6]	2 (1.3)
DPN check, symmetric abnormalities	152	NA	80 (53)
SNAP (μV)	152	10.7 [8.3;14.6]	36 (23.8)
SNCV (m/s)	152	50.5 (4.7)	56 (37.1)
ESC - hands (μS)	156	77.5 [69.9;83.5]	6 (3.8)
ESC - feet (μS)	155	82.5 [78.5;86]	12 (7.7)

Data are given in means (SD), medians [IQR] or proportions. *NA:* Not applicable *CAN:* Cardiovascular autonomic neuropathy, *VPT:* vibration perception threshold, *SNAP:* sural nerve action potential, *SNCV:* sural nerve conduction velocity, *ESC:* Electrochemical skin conduction

Simultaneous pancreas kidney transplantation in type 1 diabetes is associated with an early improvement in small fibres

S. Azmi[1], M. Jeziorska[1], M. Ferdousi[1], I. Petropoulos[1,2], G. Ponirakis[2], A. Marshall[3], U. Alam[1], H. Fadavi[1], M. Tavakoli[4], O. Asghar[1], A. Atkinson[1], W. Jones[1], A. Boulton[1], T. Augustine[5], R.A. Malik[1,2];
[1]University of Manchester, Manchester, UK, [2]Weill Cornell Medical College Qatar, Doha, Qatar, [3]Department of Clinical Neurophysiology, Central Manchester NHS Foundation Trust, Manchester, [4]The University of Exeter Medical School, Exeter, [5]Central Manchester NHS Foundation Trust, Manchester, UK.

Background and aims: Simultaneous pancreas kidney transplantation (SPK) can normalise glucose levels and improve the lipid profile and blood pressure in patients with type 1 diabetes (T1DM). The effect on microvacsular complications, in particular neuropathy needs to be defined further. The aim is to determine the effect of SPK on neuropathy in patients with T1DM.
Materials and methods: A detailed assessment of neuropathy was undertaken at baseline, 6 months and annually over 3 years following SPK in 36 patients with T1DM.
Results: HbA1c improved significantly (69·1±16·9 v 39.0±3.0, p<0.0001). Corneal confocal microscopy (CCM) parameters (corneal nerve fibre density (CNFD) (9.4±1.0 v 12.2±1.7, p=0.005), corneal nerve branch density (CNBD) (9.8±0.05 v 13.2±2.7, p=0.05), corneal nerve fibre length (CNFL) (7.2±0.5 v 8.2±0.8, p=0.05)) and mean dendrite length (MDL) (10.9±0.8 v 15.6±1.4, p=0.02) in skin biopsies significantly improved at 12 months. Intra-epidermal nerve fibre density did not improve as well as no early change in neuropathic symptoms, quantitative sensory testing or neurophysiology. However, at 36 months there was a significant improvement in the neuropathy symptom profile (5.3±0.9 v 3.1±1.2, p=0.04) and peroneal nerve conduction velocity (31.1±1.8 v 38.7±2.7, p=0.05) as well as a further improvement in CNFD (9.4±1.0 v 14.4±1.6, p=0.01), CNFL (7.2±0.5 v 10.3±0.6, p=0.001) and MDL (10.9±0.8 v 18.0±1.3, p=0.02).
Conclusion: CCM and skin biopsy demonstrates an improvement in small fibres within 12 months of SPK, followed by an improvement in neuropathic symptoms and neurophysiology at 36 months. These data provide further support for the use of CCM as an early surrogate endpoint in clinical trials of diabetic neuropathy.

Oral alpha lipoic acid adjunctive treatment for symptomatic diabetic peripheral neuropathy: a prospective, double blind, placebo controlled study

M.R.R. EL-Nahas[1], G. El Kannishy[2], H. Abdelhafez[2], I. Taher[2], A. El Sehrawy[2];
[1]Internal Medicine, Port-Said University, Port-Said, [2]Internal Medicine, Mansoura University, Mansoura, Egypt.

Background and aims: Differential efficacy of alpha-lipoic acid treatment on different sensory modalities had been reported. These differences could be attributed to the heterogeneous nature of neuropathy, study designs, routes and duration of administration of alpha lipoic acid (ALA). The aim of this work was to assess the efficacy of oral ALA 600 mg twice daily for 6 months in the treatment of patients with type 2 diabetes and peripheral neuropathy. The primary outcome was to the study the effect of the intervention on pain perception evaluated by neuropathy symptom score (NSS) and visual analogue pain scale (VAS). The secondary outcome was to study the effect of the intervention on vibration perception threshold (VPT) and neuropathy disability score (NDS).
Materials and methods: A total of 200 patients with diabetes and symptomatic peripheral neuropathy were randomly assigned into add on treatment with either ALA (n = 100) or placebo (n = 100) (Batch 1 or Batch 2) for 6 months. Batches were unknown for patients and investigators. Patients followed their usual treatment regimens during the conduct of the study. VPT was quantified with a biothesiometer (Arnold Horwell, UK). NSS, VAS, NDS

and VPT were scored at baseline and at each visit (1, 3 and 6 months).

Results: At randomization, no significant differences between the ALA and placebo groups were noted for age (54.1± 8.2 vs 52.7 ±7.1 years), sex (M/F 38/62 vs 40/60), BMI (33.7± 4.7 vs 32.2±5.7), diabetes duration (11.1± 6.1 vs 11.3±5.8 years), HbA1c (8.3± 1.2 vs 8.1±1.6), VAS (5.7 ±2.5 vs 4.88±2.1) and NSS (7.7±1.2 vs 7.47±1). Significant reduction in the percent change between baseline and Visit 4 (Month 6) was found in NSS (60.9±32.9% for ALA vs 23.2±14.1% for placebo, p <0.001). Whereas, non-significant difference in the percent change of VAS at visit 4 was found (8.4±108.7% for ALA vs 6±103.3% for placebo, p = 0.879). Significant reductions in NDS were noted in the ALA group in comparison to the placebo group after 1month (6.2±2.8 vs 8±2.1, p <0.001), 3 months (3.9±2.4 vs 6.5±1.2 P <0.001), and 6 months (3.5±2.4 vs 6.7±1.7 P <0.001). Thermal perception was the most significantly improved parameter in ALA group in comparison to the placebo group (p < 0.001). Significant differences in VPT favoring ALA over placebo were observed after 1 month (17±7.7 vs 19.83±6.9 volts, p 0.008), 3 months (14.1±6.4 vs 18.92±7.9 volts, p< 0.001) and 6 months (12.6±5.3 vs 16.95±9.7 volts, p < 0.001).

Conclusion: Improvement in patient reported pain as assessed by NSS were observed only after 6 months of oral ALA treatment. However, the reduction of pain was not evident when VAS was used for the assessment. Improvements in NDS and VPT were observed after 1month of ALA treatment and the difference remain significant thereafter. Thermal perception was the most significantly improved parameter. We suggest that various assessment scales should be considered in the interpretation of data.

Bariatric surgery improves neuropathic symptoms, deficits and corneal nerve morphology in obese patients with diabetes

M. Ferdousi[1], S. Azmi[1], G. Ponirakis[2], I. Petropoulos[2], T. Siah Mansur[1], U. Alam[1], A. Marshall[3], J. Schofield[1], S. Adam[1], B. Ammori[4], H. Soran[1], R.A. Malik[1,2];

[1]University of Manchester, Manchester, UK, [2]Weill Cornell Medical College Qatar, Doha, Qatar, [3]Central Manchester NHS Foundation Trust, Manchester, [4]Salford Royal Infirmary, Salford, UK.

Background and aims: Whilst bariatric surgery can lead to remission of type 2 diabetes mellitus, the effect on microvascular complications, in particular neuropathy is unclear. The aim is to determine the effect of bariatric surgery on neuropathy in obese patients.

Materials and methods: 25 morbidly obese patients with diabetes underwent a comprehensive assessment of neuropathy at baseline, 6 and 12 months after bariatric surgery.

Results: There was a reduction in BMI (49.6±1.8 v 37.5±1.7 v 34.4±1.2, P<0.0001), HbA1c (57.3±3.4 v 41.2±2.9 v 38.4±1.9, P<0.0001), systolic (135.7±3.3 v 121.9±3.8 v 118.7±3.5, P=0.002) and diastolic (73.6±3.6 v 66.6±2.9 v 69.0±2.6, P=0.008) blood pressure, 6 and 12 months after bariatric surgery. There was a significant and progressive improvement in neuropathy symptom profile (4.6±0.9 v 2.7±1.1 v 0.7±0.3, P=0.001), neuropathy disability score (2.1±0.4 v 1.4±0.6 P=0.02), corneal nerve fibre density (24.2±1.4 v 25.5±2.3 v 28.1±1.3, P=0.019), corneal nerve branch density (34.1±3.5 v 39.5±4.7 v 42.3±3.7, P=0.048) and corneal nerve fibre length (14.9±0.8 v 16.4±1.0 v 16.9±0.7, P<0.009), with no change in quantitative sensory testing or neurophysiology.

Conclusion: Bariatric surgery improves neuropathic symptoms and deficits and small nerve fibre structure using corneal confocal microscopy as early as 6 months after surgery.

PS 081 Understanding diabetic neuropathy

971

Three question set from Michigan Neuropathy Screening Instrument add independent prognostic information on cardiovascular outcomes: post-hoc analysis of ALTITUDE trial

J.P. Seferovic[1], M.A. Pfeffer[1], B. Claggett[1], A.S. Desai[1], D. de Zeeuw[2], S.M. Haffner[3], J.J. McMurray[4], H.-H. Parving[5], S.D. Solomon[1], N. Chaturvedi[6];

[1]Brigham and Women's Hospital, Boston, USA, [2]University Medical Center Groningen, Groningen, Netherlands, [3]Department of Medicine and Clinical Epidemiology, University of Texas Health Science Center, San Antonio, USA, [4]BHF Cardiovascular Research Centre, University of Glasgow, Glasgow, UK, [5]Rigshospitalet, University of Copenhagen, Copenhagen, Denmark, [6]Institute of Cardiovascular Sciences, University College London, London, UK.

Background and aims: The Michigan Neuropathy Screening Instrument (MNSI) is used to diagnose diabetic peripheral neuropathy. We investigated whether the MNSI (a 15-item self-administered questionnaire) also offers prognostic information concerning risk of death and major CV events in patients with type 2 diabetes mellitus (T2DM) and chronic kidney disease (CKD) and/or cardiovascular (CV) disease from ALTITUDE.

Materials and methods: We divided the cohort of 8561 patients into independent training (n=3300) and validation sets (n=5261). In the training set, stepwise selection techniques identified specific questions that were independently associated with CV composite [CV death, resuscitated cardiac arrest, non-fatal myocardial infarction/stroke, heart failure hospitalization (HF)]. Selected questions were then evaluated in the validation set in adjusted models to assess their potential independent associations with clinical outcomes.

Results: In the training data set, 3 questions (Are your legs numb? Have you ever had an open sore on your foot? Do your legs hurt when you walk?) were significantly associated with the CV outcome composite. In the validation set, 3076 patients (59%) answered "yes" to at least 1 of these 3 questions. After adjustment for other key covariates, these patients demonstrated increased risk for CV composite (HR 1.54, 95% CI 1.28-1.85, p<0.001), all cause death (HR 1.23, 95% CI 0.98-1.54, p=0.072), CV death (HR 1.24, 95% CI 0.93-1.66, p=0.15), HF (HR 1.73, 95%CI 1.28-2.33, p<0.001), myocardial infarction (HR 1.86, 95%CI 1.25-2.76, p=0.002) and stroke (HR 1.74, 95%CI 1.19-2.53, p= 0.004) relative to those who answered "no" to all of the questions (Table). These associations were even stronger if patients answered positively to all of these 3 questions (n=552, 11%). Addition of these questions to existing models significantly improved Harrell's C statistic (0.71 vs 0.72, p=0.011) and continuous net reclassification improvement (+22%, 95%CI 7%-31%, p=0.013).

Conclusion: We identified three straightforward questions which add incremental prognostic information concerning risk of all cause death and major adverse CV events in patients with T2DM and CKD and/or CV disease. If externally validated these questions may be integrated into the clinical history to augment the prediction of CV events in high risk T2DM patients.

Table. Association of the 3- question set and outcomes in validation set (adjusted*)

	Any Yes (vs all No)		All Yes (vs All No)	
Event	**HR, 95 % CI**	**p**	**HR, 95 % CI**	**P**
CV outcome composite 587 events	**1.54 (1.28-1.85)**	**<0.001**	**1.70 (1.30-2.23)**	**<0.001**
All cause death 366 events	**1.23 (0.98-1.54)**	**0.072**	**1.58 (1.14-2.19)**	**0.006**
CV death 220 events	**1.24 (0.93-1.66)**	**0.15**	**1.62 (1.06-2.46)**	**0.025**
Heart failure hospitalization 232 events	**1.73 (1.28-2.33)**	**<0.001**	**1.75 (1.13-2.71)**	**0.013**
Myocardial infarction 143 events	**1.86 (1.25-2.76)**	**0.002**	**2.19 (1.26-3.80)**	**0.005**
Stroke 149 events	**1.74 (1.19-2.53)**	**0.004**	**1.42 (0.78-2.59)**	**0.25**

*Model adjusted for age, sex, race, smoking status, systolic blood pressure, eGFR, urinary albumin to creatinine ratio, HF history, myocardial infarction, stroke, atrial fibrillation, diabetic nephropathy, diabetic retinopathy, amputation, claudication, unstable angina, coronary revascularization, duration of diabetes, HbA1c, and randomized treatment.

Evaluation of clinical diagnostic markers for early detection of diabetic neuropathy

M. Tavakoli[1,2], Early Neuropathy Assessment Study Group (ENA), University of Manchester;
[1]Diabetes and Vascular Resrach Group, University of Exeter Medical School, Exeter, [2]Division of Diabetes, Endocrinology & Gastroenterology, University of Manchester, Manchester, UK.

Background and aims: Diabetic neuropathy is among the most distressing and costly of all the chronic complications of diabetes and is a cause of significant disability and poor quality of life. Early detection, risk stratification and timely intervention to prevent long-term complications by maintaining good metabolic control is a key goal of diabetes management. Therefore identification of subjects with early subclinical neuropathy may provide an opportunity to identify the high-risk individuals who merit more aggressive intervention. The aim of present study was to determine the optimal diagnostic operating characteristics for diabetic neuropathy in cross-sectional analysis for a series of standard clinical neurological examinations.
Materials and methods: 274 diabetic patients and 84 healthy control subjects underwent detailed examinations for assessing symptoms, electrophysiology, quantitative sensory testing, autonomic neuropathy with assessing heart rate, punch skin biopsy and corneal confocal microscopy.Patients classified for presence of neuropathy based on NDS score more than 3.
Results: 274 Diabetic patients including 131 T1DM (60% male; Average age 46.5; Duration of Diabetes: 26.8; BMI 26.2 (4.3); HbA1c: 8.3) and 143 T2DM ((64% male; Average age 63; Duration of Diabetes: 13.1; BMI 31.7 (5.4); HbA1c: 7.7 (SD: 1.4)) and 84 age and sex matched healthy control subjects studied in details for battery of neurological examinations including symptoms profile (NSP), neuropathy deficit (NDS), electrophysiology (Sural and peroneal nerves), quantitative sensory testing (Vibration, hot and cold perception thresholds), autonomic neuropathy with assessing heart rate and deep breathing, punch skin biopsy (IENFD), corneal sensitivity (NCCA) and corneal confocal microscopy for assessing small c-nerve fibres in cornea including CNFD, CNBD, CNFL, CNFT which measured manually. 133 (48%) patients had neuropathy (NDS >3) and that was comparable between type 1 (63 patients, 48%) and type 2 diabetic patients (70 subjects, 49%). All markers except for NCCA showed a statistically significant diagnostic ability with AUC ranging from 0.58 to 0.81. The best marker was VPT. Using a diagnostic criterion VPT > 11 gave sensitivity and specificity values of 75% and 71% respectively, with a PPV of 70% and NPV of 75%. IENFD <6 gave sensitivity and specificity values of 79% and 44% respectively, with a PPV of 54% and NPV of 70%. From corneal nerves parameters, CNFD gave sensitivity and specificity values of 72% and 45% respectively, with a PPV of 55% and NPV of 63%. Corneal nerves fibre length (CNFL) showed sensitivity and specificity values of 71% and 39% respectively, with a PPV of 52% and NPV of 59%.
Conclusion: Evaluation of tested neurological markers in this study showed difference performance in T1DM and T2DM. However we validated the diagnostic thresholds for each of these markers that may be used regardless of diabetes type. To our knowledge this is one of the most complete cohort of subjects that compared the sensitivity of several diagnostic markers for early detection of diabetic neuropathy. Relatively poor performance of all these neurological markers maybe related to lack of standard reference point for diabetic neuropathy. There is a need for longitudinal studies to evaluate the predictive validity of these clinical markers.

Patterns of small and large fiber dysfunction in painful and painless diabetic polyneuropathy

G.J. Bönhof, A. Strom, S. Püttgen, K. Bódis, M. Roden, D. Ziegler; German Diabetes Center, Duesseldorf, Germany.

Background and aims: The distinguishing features contributing to the phenotype of diabetic sensorimotor polyneuropathy (DSPN) as a painful (+p) or painless (-p) entity are poorly understood. We hypothesized that DSPN+p and DSPN-p are characterized by predominant small and large nerve fiber dysfunction, respectively.
Materials and methods: We assessed somatic, cardiac autonomic, and sudomotor function (Sudoscan, Neuropad) in 332 patients with DSPN from the PROPANE study, 179 of whom had DSPN+p and 153 had DSPN-p and 54 diabetes patients without DSPN (DM) from the German Diabetes Study (DSPN-p/DSPN+p/DM [mean±SD]: age: 68.4 ±10.4/66.1±10.0/63.2±5.2 years, BMI: 29.5±5.3/30.9±5.6/30.1±4.9 kg/m²; T2D: 83/86/87%, diabetes duration: 16.4±12.4/16.1±12.1/5.1±3.2 years, HbA1c: 7.3±1.1/7.7±3.3/6.8±0.9%). DSPN was diagnosed using modified Toronto Consensus (2011) criteria, while DSPN+p and DSPN-p were stratified using a cutpoint of 4 points on the Likert scale for chronic pain lasting for >1 year in the distal lower limbs.
Results: After adjustment for sex, age, BMI, smoking, diabetes type, diabetes duration, and HbA1c, compared to patients with DSPN-p those with DSPN+p showed impaired warmth detection thresholds (TDT-w) (foot: 46.0±4.4 vs 45.3±4.4 °C), coefficient of R-R interval variation during deep breathing (5.18±3.95 vs 6.71±4.86%), and electrochemical skin conductance (ESC: hand: 56.1±17.8 vs 60.9±17.3 μS, foot: 57.8 ±20.7 vs 62.8±19.9 μS) (all $P<0.05$). Large fiber function tests (nerve conduction, vibration threshold) did not differ between the DSPN groups. In both DSPN groups, ESC (foot) correlated with peroneal motor and sural sensory nerve conduction, sural sensory nerve action potential, TDT-w (foot), intraepidermal nerve fiber density (IENFD), and Neuropad (all $r=|0.2|-|0.5|$; $P<0.05$). ROC analyses showed that both small and large fiber function tests were useful to detect DSPN+p (AUC vs DM: 0.7-0.9) and DSPN-p, albeit to a slightly lesser degree (AUC vs DM: 0.6-0.8).
Conclusion: Compared to painless DSPN, painful DSPN is characterized by more pronounced small fiber dysfunction involving sudomotor, cardiac autonomic, and cutaneous C fibers, while large fiber dysfunction is common to both entities.

Determinants of incident distal sensorimotor polyneuropathy in a cohort with screen-detected type 2 diabetes followed for 13 years, the ADDITION Denmark Study

S.T. Andersen[1,2], D.R. Witte[1,3], E.-M. Dalsgaard[1], H. Andersen[4,5], P. Nawroth[6], T. Fleming[6], T.M. Jensen[7], N.B. Finnerup[2,8], T.S. Jensen[2,8], M.H. Charles[1];
[1]Department of Public Health, Aarhus University, [2]The International Diabetic Neuropathy Consortium, Aarhus, [3]Danish Diabetes Academy, Odense, [4]Department of Neurology, Aarhus University Hospital, [5]The International Diabetes Neuropathy Consortium, Aarhus, Denmark, [6]Department of Medicine I and Clinical Chemistry, University Hospital Heidelberg, Heidelberg, Germany, [7]Steno Diabetes Center, Gentofte, [8]Department of Clinical Medicine, Danish Pain Research Center, Aarhus, Denmark.

Background and aims: Cross-sectional studies indicate that determinants beyond hyperglycemia, such as obesity, dyslipidemia and cardiovascular disease are important particularly in type 2 diabetes (T2DM) in the development of distal sensorimotor polyneuropathy (DPN).

Methylglyoxal is a marker of oxidative stress and has been proposed as being involved in the damage of nerve fibers. We aimed to study the incidence of DPN prospectively during the first 13 years after a screening-based diagnosis of T2DM and to identify determinants present at the time of T2DM diagnosis associated with DPN development.

Materials and methods: From the Danish arm of the Anglo-Danish-Dutch study of Intensive Treatment in People with Screen-Detected Diabetes in Primary Care (the ADDITION trial), 1256 participants were eligible for this study. Symptoms of DPN were assessed by the Michigan Neuropathy Screening Instrument questionnaire (MNSI) at four time-points and DPN was defined by a MNSI score of 4 or above. We evaluated the cumulative incidence of DPN and used Cox proportional hazard models to calculate hazard ratios (HR) to assess the association of various determinants and the development of incident DPN. Models were stepwise adjusted for trial intervention group, age, sex, lipid-lowering treatment and anti-hypertensive treatment at the 5 year follow-up of ADDITION.

Results: The median age of the study population was 60.8 years (p25;p75: 55.6;65.6), 59% were men and the median baseline HbA1c was 6.3 % (6.0;6.9) or 45.4 mmol/mol (42.1;51.9). The cumulative incidence of DPN during 13 years of follow-up was 10%. The risk of incident neuropathy was higher in older participants with a HR of 1.03 (95%CI: 1.00;1.07) per year, while sex was not associated with incident DPN with a HR of 0.67 (95% CI;0.43;1.05) for men compared to women. In Table 1 the results of Cox proportional regression models are presented.

Conclusion: This study demonstrates a fairly low cumulative incidence of DPN defined by the MNSI in people with screen-detected T2DM. Our study suggests that macrovascular disease, obesity and higher levels of methylglyoxal present at the time of diagnosis of T2DM are determinants for the development of incident DPN. The association between LDL cholesterol and incident DPN needs to be further elucidated.

Table 1. Risk factors for incident DPN (during a 13-year follow-up) present at the time of diagnosis of screen-detected type 2 diabetes expressed as hazard ratios (HR) and 95% confidence intervals (CI) at two levels of adjustment.

	Model A HR (95 % CI)	*Model B* HR (95 % CI)
HbA_{1c} (%)	0.93 (0.75;1.15)	0.93 (0.75;1.15)
Systolic BP (mmHg)	1.00 (0.99;1.02)	1.00 (0.99;1.02)

The association between pulse wave velocity and peripheral neuropathy in patients with type 2 diabetes

A. Tentolouris, I. Eleftheriadou, P. Grigoropoulou, A. Kokkinos, E. Siami, M. Nikoloudi, N. Katsilambros, N. Tentolouris;
1st Department of Propaedeutic and Internal Medicine, Medical School, National and Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece.

Background and aims: Diabetic peripheral neuropathy (DPN) is the most common diabetic complication, affecting up to half of the patients with type 2 diabetes mellitus (T2DM). Increased aortic stiffness, measured with the carotid-femoral pulse wave velocity (PWV), has been associated with incidence of cardiovascular disease independently of traditional risk factors. Previous data showed associations between risk factors for macroangiopathy and DPN in diabetes. However, the association between PWV and DPN is unknown. In this study we examined the association between PWV and presence as well as severity of DPN in subjects with T2DM.

Materials and methods: A total of 381 patients with T2DM were recruited. Participants were classified as having DPN (107) and not having DPN (274). PWV was measured at the carotid-femoral segment with a non-invasive method using applanation tonometry. DPN was assessed by determination of vibration perception threshold (VPT), the Neuropathy Symptom Score and the Neuropathy Disability Score (NDS).

Results: Patients with DPN were significantly more often male and older, had longer duration of diabetes, higher height, larger waist circumference, higher peripheral and central systolic arterial blood pressure (SBP) and higher PWV (all $P < 0.05$). Furthermore, participants with DPN had lower low density lipoprotein cholesterol because they were treated more often with statins; in addition, they were treated more often with antiplatelets, b-blockers and insulin than those without DPN. Univariative logistic regression analysis demonstrated that there was significant association between the presence of DPN and age, gender, diabetes duration, height, waist circumference, peripheral and central SBP, PWV, dyslipidemia, HbA1c, retinopathy and nephropathy. Multivariate logistic regression analysis, after adjustment for age, gender, waist circumference, peripheral and central SBP and nephropathy demonstrated that the odds [OR (95% confidence intervals)] of peripheral neuropathy were associated significantly and independently only with height [1.070 (1.038 - 1.103), $P < 0.001$], diabetes duration [1.051 (1.017 - 1.087), $P = 0.003$], HbA1c [1.579 (1.261 - 1.978), $P < 0.001$], PWV [1.202 (1.081 - 1.337), $P < 0.001$], dyslipidemia [2.425 (1.311 - 4.488), $P = 0.005$] and retinopathy [4.589 (2.361 - 8.918), $P < 0.001$]. In addition, multivariate linear regression, after controlling for age, gender, peripheral and central SBP and nephropathy, analysis demonstrated that an increased NDS was significantly and independently associated with height [standardized regression coefficient (beta) = 0.247, $P < 0.001$], diabetes duration (beta = 0.118, $P = 0.042$), HbA1c (beta = 0.112, $P = 0.038$), PWV (beta = 0.232, $P < 0.001$) and retinopathy (beta = 0.286, $P < 0.001$).

Conclusion: This study has shown that in patients with T2DM beyond the known factors associated with DPN, increased PWV emerged as a new factor associated strongly and independently with the presence and severity of DPN.

Impact of glycaemic variability on Müller cell activation

F. Picconi[1], C. Fulci[2], A. Caccuri[2], M. Parravano[3], D. Ylli[1], L. Chioma[1], I. Malandrucco[1], I. Giordani[1], S. Frontoni[1];
[1]Department of Systems Medicine, Unit of Endocrinology, Diabetes and Metabolism, S. Giovanni Calibita Fatebenefratelli Hospital, [2]Department of Experimental Medicine and Surgery, University of Rome Tor Vergata, [3]IRCCS-G.B. Bietti Foundation, Rome, Italy.

Background and aims: In our recent work, 37 patients affected by type 1 diabetes mellitus (DM1), without diabetic retinopathy (DR) or very mild non-proliferative DR underwent a spectral domain optical coherence tomography (SD-OCT), obtaining individual retinal layer thickness measurements, and a 72-hours continuous glucose monitoring, from which indices of glycemic variability (GV) were measured. From SD-OCT, we found a significant increase of inner nuclear layer (INL), that includes mainly the nuclei of bipolar and Müller cells. A significant positive

correlation between INL e GV was also found. We assumed that the increase of INL may represent a clinical sign of Müller cell activation, due to glycemic excursions. We, therefore, carried out an in vitro study in order to confirm our hypothesis of activation of Müller cells, in response to glycemic variability.

Materials and methods: The effect of glucose was evaluated on the immortalized retinal Müller Cell Line, rMC-1 (Kerafast). rMC-1 cells (1x104cells/cm2) were grown 4 days in DMEM-10% FBS medium and different glucose conditions: continuous normal glucose medium (25 mmol/l) (NG); continuous low-glucose medium (5 mmol/l) (LG); 30-min episodes of "hypoglucose" (to mimic the hypoglycemic condition), twice a day (30' LG); continuous high-glucose medium (45 mmol/l) (HG); alternating normal and high-glucose media every 24 h (NG/HG); alternating low and high-glucose media every 24 h (LG/HG). Mannitol (20 mmol/l) was used in control cultures to exclude a hyperosmolar effect. Control groups were grown in continuous mannitol medium (20 mmol/l) (M), alternating normal glucose and mannitol media (NG/M) or low-glucose and mannitol media every 24 h (LG/M). Changes of the cell culture medium with fresh medium were performed, in each group, every 24h. Müller cells activation was evaluated by measuring glial fibrillar acidic protein (GFAP) expression using Western Blot analysis.

Results: Continuous HG medium administration for 4 days and alternating (NG/HG) media every 24 h did not induce activation of rMC-1. In contrast, a significant increase in GFAP was detected in rMC-1 exposed to alternating LG/HG media every 24 h ($p<0.05$) versus control groups.

Conclusion: These results demonstrate that GV, characterized by hypoglycemic and hyperglycemic excursions, rather than chronic hyperglycemia, is able to activate Müller cells, thus confirming what observed in our previous study in humans.

Skin autofluorescence: correlation with measures of diabetic sensorimotor neuropathy

A.O. Stirban[1], C.I. Bondor[2], B. Florea[3], N.A. Gavan[4], I.A. Veresiu[2]; [1]Sana Klinikum Remscheid, Remscheid, Germany, [2]Iuliu Hatieganu University, [3]Podiatry Clinic, [4]Woerwag Pharma, Cluj-Napoca, Romania.

Background and aims: The production and accumulation of Advanced Glycation Endproducts (AGEs) is exacerbated in subjects with diabetes. AGEs are involved in the pathogenesis of diabetic complications in general, and the pathogenesis of diabetic neuropathy in particular. Skin accumulation of AGEs can be measured quickly (results are displayed within seconds) and non-invasively by assessing skin autofluorescence (SAF). The aim of our study was to investigate the correlation between SAF and measures of diabetic sensorimotor neuropathy (DNP).

Materials and methods: In this multicenter study (8 centers), 497 consecutive subjects with diabetes mellitus (6.6% with type 1, 93.4% with type 2 diabetes, 51% female, 49% male, age: 60.5±9.1 years , HbA1c 7.28±1.02%, mean±SD) were investigated. SAF was assessed using the AGE Reader (Groningen, The Netherlands), measurements were performed at the forearm, and results of 3 measurements were averaged. For the diagnosis of DNP we used the Toronto Clinical Neuropathy Score (TCNS) as a score integrating symptoms and deficits, as well as the Neuropathy Symptoms Score (NSS) and the Neuropathy Disability Score (NDS) that assess separately symptoms and deficits.

Results: (mean±SD):According to the TCNS, SAF (measured in arbitrary units- AU) was significantly higher in subjects with DNP (TCNS>5, n=237 subjects): 2.59 ±0.56 AU compared with patients without DNP (TCNS≤5, n=260): 2.45±0.53 AU, (p=0.04) and significantly increased with the severity of DNP: 2.58±0.53 AU (TCNS:6-8, n=176 subjects), 2.61±0.64 AU (TCNS: 9-11, n=53), 2.76±0.57 AU (TCNS: 12-15, n=8), (p=0.028). SAF was higher in subjects with neuropathic deficits (NDS>2, n=261 subjects): 2.58 ±0.56 AU compared with patients without deficits (NDS≤2, n=236): 2.45±0.53 AU, (p=0.009) and significantly increased with the severity: 2.50±0.48 AU (NDS: 3-5, n=152 subjects), 2.69±0.64 AU (NDS: 6-8, n=107), 2.47±0.85 (NDS: 9-10, n=2), (p=0.002). Higher SAF existed in subjects with neuropathic symptoms (NSS>2, n=410): 2.54±0.56 AU compared to patients without symptoms (NSS≤2, n=87): 2.40±0.47 AU, (p=0.022) and increased numerically with the severity of symptoms: 2.51±0.54 AU (NSS:3-4, n=62 subjects), 2.53±0.57 AU (NSS: 5-6,n=148), 2.56±0.56 AU (NSS: 7-10, n=200), p=0,126. SAF significantly correlated with the duration of DNP (r=0.19, p=0.004) and diabetes duration (type 1 diabetes r=0.38, p=0.03; type 2 diabetes r=0.15, p=0.001) as well as with the HbA1c (r=0.18, p<0.001).

Conclusion: Skin AGEs accumulation assessed by measurement of SAF is increased in subjects with DNP and gradually increases with the severity of DNP. Since SAF measurement represents an easy-to-use, quick and non-invasive method, it might help to identify subjects at high risk for DNP. Especially in subjects without typical neuropathic symptoms, increased SAF could be an indicator for the presence of DNP and thus trigger further confirmatory investigations.

Endothelial progenitor cells are increased in patients with type 2 diabetes and peripheral neuropathy

I. Eleftheriadou[1], N. Dimitrakopoulou[1], N. Kafasi[2], A. Dimitrakopoulou[2], E. Jude[3], N. Tentolouris[1]; [1]First Department of Propaedeutic and Internal Medicine, Medical School, National and Kapodistrian University of Athens, Laiko General Hospital, [2]Department of Immunology & Histocompatibility, Laiko General Hospital, Athens, Greece, [3]Tameside General Hospital, Ashton-Under-Lyne, Lancashire, UK.

Background and aims: Endothelial progenitor cells (EPCs) are a population of adult stem cells with the ability to differentiate into epithelial cells and to promote endothelial regeneration and neo-vascularization in response to tissue ischemia. Several studies have already reported an association between EPCs reduction/dysfunction and diabetic macrovascular complications. Although peripheral neuropathy (PN) has been associated with changes in the microcirculation and reduced endothelial-dependent and endothelial-independent vasodilation, regardless of the presence of macrovascular disease, data about its association with EPCs are scarce. The aim of the present study is to evaluate the relationship between PN and EPCs in patients with type 2 diabetes mellitus (DM).

Materials and methods: A total of 59 patients with DM (29 without PN and 30 with PN) and 20 healthy controls were recruited. Participants were non-smokers and had no clinical macrovascular disease. After venipuncture peripheral blood mononuclear cells (PBMCs) were obtained and stained with monoclonal antibodies against CD45, CD34, CD309 and CD133. A hierarchical gating strategy was employed to count low expressing CD45 cells ($CD45^{dim}$) and $1x10^6$ events per subject was acquired and analyzed using the six-color flowcytometer BD FACSCanto. EPCs were defined as cells expressing the $CD45^{dim}/CD34^+/CD309^+/CD133^+$ phenotype.

Results: The number of EPCs differed significantly between the 3 groups of participants (p=0.015). The sub-analysis showed that patients with PN had significantly higher number of EPCs when compared with patients

without PN (p=0.020) and participants without DM (p=0.012). No significant difference was observed in the EPCs number between patients without PN and participants without DM (p=0.476).

Conclusion: The number of EPCs was significantly higher in patients with PN in comparison with patients without PN and participants without DM. This finding may imply that there is an effort for restoration of the damaged peripheral nerves and more research is warranted to clarify the role of EPCs in diabetic PN.

Protective effect of Nerve Growth Factor (NGF) on retinal ganglion cells degeneration in early stage of diabetic retinopathy

S. Maestroni[1], V. Turco[1], V. Castoldi[2], M. Godi[1], D. Gabellini[1], L. Leocani[2], P. Rama[3], G. Zerbini[1];
[1]Complications of Diabetes Unit-DRI-Diabetes Research Institute, San Raffaele Scientific Institute, [2]Experimental Neurophysiology Unit-INSPE-Institute of Experimental Neurology, San Raffaele Scientific Institute, [3]Eye repair Unit, San Raffaele Scientific Institute, Milano, Italy.

Background and aims: Diabetic Retinopathy (DR) is an ocular microangiopatic disease that affects up to 70% of patients with both type 1 and type 2 diabetes. It takes several years of diabetes before the development of DR, suggesting that subclinical dysfunctions might characterize this "silent" phase. Recent studies show that retinal ganglion cell (RGC) death and retinal thinning precede the onset of DR suggesting an early neurodegeneration of the retina as a prodrome of DR. NGF is an endogenous neurotrophin active on RGC, bipolar neuron and glial cells with a well demonstrated protective effect on RGC in animal models of glaucoma. We tested the effect of NGF treatment on RGC loss and on the prevention of the development the vascular stage of DR. Ins2Akita mouse develops spontaneous diabetes at about 3 weeks of age. At 8 weeks of age we found, by Optical Coherence Tomography (OCT) analysis, a significant thinning of retinal nerve fiber layer (RNFL) and of the total retina compared to controls.

Materials and methods: Based on these observations we performed a study were C57Bl6/J and Ins2Akita were treated twice a day with one drop per eye of NGF (200 μg/ml) or Vehicle (16 C57 Vehicle, 20 Akita Vehicle, 15 C57 NGF, 14 Akita NGF). Treatment started at 3 weeks of age up to 8 weeks of age. Retinal layers thickness was evaluated in vivo by OCT at 3, 5 and 8 weeks. Electroretinogram (ERG) was performed at 8 weeks before sacrifice and RGCs numbers was evaluated by histological analysis.

Results: Weight and glycemia were comparable between the diabetic animals and the controls. At 3 and 5 weeks we did not found significant differences between the different groups, while at 8 weeks NGF was able to counteract the diabetes-induced thinning of RNFL (Akita Vehicle (19.1 ±1.2) Vs Akita NGF (21.6±1.0), Vs C57 Vehicle (22..2±1.1), Vs C57 NGF (22.1±1.0) (mean(μm)±SD): p<0.0001) and of the total retina (Akita Vehicle (182.4±5.2) Vs C57 Vehicle (189.7±4.5), Vs C57 NGF (189.0±4.7): p<0.001; Akita Vehicle Vs Akita NGF (186.2±4,7): N.S.; Akita NGF Vs C57 Vehicle, Vs C57 NGF: N.S.). Rescue induced by NGF was confirmed also by ERG a-wave amplitude (Akita Vehicle (111.0±23.3) Vs Akita NGF (142.4±15.0), Vs C57 NGF (144.0±8.4) (mean(μV)±SD): p<0.001; Akita Vehicle Vs C57 Vehicle (136.5±8.5): p=0.007) and ERG b-wave amplitude (Akita Vehicle (271.9±40.6) Vs Akita NGF (318.2±9.8), Vs C57 NGF (320.1±11.5) (mean(μuV)±SD): p<0.001 and Akita Vehicle Vs C57 Vehicle (310.8±12.9): p=0.019). Both ERG parameters were improved in treated animals. Interestingly, the analysis performed on histological samples showed no difference in RGC and in retinal fiber number.

Conclusion: These data suggest that OCT and ERG can detect the neuroretinal suffering before substantial anatomic alteration (i.e cell death) occurs. Taken together these data are in line with the hypothesis that topic treatment with NGF prevents the early, diabetes driven, retinal neurodegeneration. Further studies are now warranted to clarify whether, on the long run, this same pharmacological approach will allow to avoid RGC death and the progression of DR toward its sight-threatening vascular stage.

Metabolic shift from glycolysis towards lipid oxidation in Schwann cells in response to hyperglycaemia

T.T.A. Smit, T.H. Fleming, P.P. Nawroth;
Department of Medicine I and Clinical Chemistry, University Hospital of Heidelberg, Heidelberg, Germany.

Background and aims: Diabetic neuropathy (DN) is characterized by hypersensitivity in the early stage of the disease, and hyposensitivity at later stages. However, hyperglycemia alone is insufficient to account for the development and the progression of diabetic complications. Metabolomic and proteomic analysis has revealed that a failure of energy homeostasis, particularly within the Schwann cell-rich sciatic nerve may be a driving force in the pathogenesis of DN. The aim of this study was to investigate the effect of hyperglycemia on energy homeostasis in Schwann cells.

Materials and methods: Schwann cells (SW10) were cultured in low glucose (LG, 5mmol/l) DMEM and high glucose (HG, 25mmol/l) DMEM. Mitochondrial properties and oxidative stress were assessed by flow cytometry. Glycolysis, mitochondrial respiration and fatty acid metabolism were measured by Seahorse Bioanalyzer. Transcription and expression of the key regulators involved in energy homeostasis were assessed by quantitative PCR and western blotting. Metabolomic analysis was performed by LC-MS/MS. Experimental DN was studied in streptozotocin-induced diabetes in C57BL/6 mice.

Results: In response to chronic hyperglycemia, Schwann cells showed a down-regulation of both glycolysis and mitochondrial respiration, in particular a decrease in maximal respiration (LG 301.3 -/+ 19.7 vs. HG 216.2 -/+ 9.4; p=0.0014) and glycolytic capacity (LG 86.6 -/+ 5.4 vs. HG 73.3 -/+ 6; p=0.0352). The loss of glucose-dependent metabolism was compensated by a shift towards fatty acid metabolism, as indicated by increased expression of ATP-citrate lyase and acyl-CoA synthase. However, this shift was towards fatty acid oxidation, as indicated by increased phosphorylation of acetyl-CoA carboxylase. This was associated with activation of ERK-dependent endoplasmic reticulum stress response leading to an increased the accumulation and/or secretion of neurotoxic metabolic intermediates, such as methylglyoxal (wt 290.3 -/+ 50.4 vs. diabetes mean 584.6 -/+ 47,6; p=0.0074).

Conclusion: This study shows that hyperglycemia induces a shift in metabolism from glycolysis to fatty acid oxidation in Schwann cells. This shift, driven by ER stress, is ultimately detrimental to the cell.

A short period of slow breathing is able to reveal obstructive sleep apnoea syndrome in type 2 diabetes and obese patients

L. Bianchi[1], P. Valensi[1], F. Duperron[2], L. Bernardi[3];
[1]Department of Diabetology & Endocrinology, Jean Verdier Hospital, Bondy, [2]Functional Respiratory Explorations, Jean Verdier Hospital, Bondy, Paris, France, [3]Folkhälsan Research Center, University of Helsinki, Helsinki, Finland.

Background and aims: Obstructive sleep apnoea syndrome (OSAS) has multifactorial causes and it is characterised by cardio-respiratory reflex imbalance. It heavily worsens cardiovascular prognosis in diabetes and obesity. Accurate diagnosis by polysomnography is expensive and requires night hospitalisation. A brief period of slow breathing (SLB), by transiently improving baro-chemoreflex interaction and oxygen saturation (SAT), could shift an ill-balanced cardiovascular/respiratory reflex interconnection, and acutely trigger OSAS-related respiratory abnormalities.
Materials and methods: In 90 patients (59 diabetics: age 55±13yrs, 30 males, BMI 33.4±7.3 kg/m^2, HbA$_1$c 8.03±1.56%; and 31 obese: 50 ±13yrs, 8 males, BMI 39.2±5.3 kg/m^2) and 20 healthy subjects (55 ±15yrs, 7 males, BMI 22.0±2.3 kg/m^2) we continuously monitored SAT, respiration (inductance plethysmography) and baroreflex sensitivity (BRS) during spontaneous respiration (5min), 5-min SLB at 6 cycles/min and 10-min follow-up under spontaneous breathing (POST-SLB). So far 56 patients underwent standard polysomnography (PSG).
Results: 55/90 patients (36 diabetics and 19 obese) developed apnoeas/hypopneas during POST-SLB (POST-SLB+); comparing SLB test to PSG, 40/41 were true positives, 1/41 was false positive and 10/15 true negatives (5 false negatives, but these patients had only mild OSAS at PSG, apnoeas/hypopneas index<15 per hour), PPV: 98%, NPV: 67%, sensitivity: 89%, specificity: 91%. At baseline POST-SLB+ patients had lower SAT (p=0.003) and BRS (p<0.001) compared to healthy subjects. During SLB all subjects increased SAT (p<0.001) and BRS (p<0.01) compared to baseline. During POST-SLB period, in patients who developed apnoeas/hypopneas SAT fell below (p<0.0001) and BRS returned to baseline, whereas in the other patients SAT and BRS returned to baseline values.
Conclusion: In diabetic and obese patients a short (20min), simple and inexpensive clinical test based upon analysis of cardio-respiratory reflex imbalance can unmask underlying OSAS, due to the post-effects of transient relief of subclinical hypoxia.

Small fiber neuropathy, suggested by clinical examination, is objectively linked to autonomic neuropathy and other complications in type 2 diabetes

W.-N. Nibouche-Hattab, N. Lanasri, F. Zeraoulia, A. Chibane, L. Makhlouf, A. Biad;
Internal Medecine, Algiers' University, Aïn-Taya (Algiers), Algeria.

Background and aims: Early detection of distal diabetic neuropathy (DDN) is essential to slow down its progression. Making an objective diagnosis of Small Fiber Neuropathy (SFN) is nevertheless very challenging in daily practice. All recommendations and validated scores allow the diagnosis, once DDN becomes irreversible. We examined the characteristics of type 2 diabetics with SFN, suggested by a basic clinical examination, and compared them with diabetics who have normal sensory tests and those with evident neuropathy.
Materials and methods: Between 2009 and 2013, we recruited 327 newly diagnosed type 2 diabetics, aged from 40 to 70 years. We collected clinical and biological data and screened for chronic complications for all patients. Foot sensory examination included vibration perception with 128 Hz tuning fork, light touch, heat-pain and cold perception; we tested the ankle reflex and muscle strength (quadriceps and tibialis anterior) symmetrically. We used Michigan Neuropathy Screening Instrument (MNSI) for the diagnosis of DDN, and considered as a SFN the abolition of at least heat and pain perception of the feet and a MNSI within the range of 0-2, with or without distal pain sensation. Statistical analysis was performed with Epi-Info 6.04.
Results: We analyzed 317 patients after excluding 10 patients for having a neuropathy with another etiology than diabetes. We found DDN, SFN and normal neurological examination, respectively in 98 (30.9%), 92 (29.0%) and 127 (40.1%) diabetics. There were no statistical differences between the group of patients with SFN and those with a normal neurological examination, on age, height, smoking status, hypertension prevalence, renal function, glycemic and lipid status, but patients with SFN were less educated (p=0.006), had a higher BMI (p=0.039), higher prevalence of distal pain (p<10-5), diabetic retinopathy (p=0.032), autonomic neuropathy (p=0.021), specially sudoral dysfunction (p=0. 019) and minor distal trophic disorders (p=0.004). Diabetics with DDN were four years older (p=0.001) and had much more ischemic heart disease (p=0.002), dysautonomy (p=0.0002), erectile dysfunction (p=0.001) than the two other groups of patients.
Conclusion: We suggest, in our study, that a simple clinical examination could help to determine a distinguishable group of patients that presents an early stage of diabetic neuropathy. Without specific recommendations, these patients are too often considered as "free of neuropathy" in daily practice, and may not benefit from an appropriate therapeutic intervention to reverse the course of this complication.
Clinical Trial Registration Number: NCT02002091

Association of endothelial dysfunction with autonomic neuropathy in Japanese type 2 diabetes

M. Furuta[1], H. Yamaoka[1], T. Sanke[2], H. Furuta[3], T. Akamizu[3];
[1]Clinical Laboratory Medicine, Wakayama Medical University, Wakayama, [2]Institute for Diabetes, Fuchu Hospital, Osaka, [3]First Department of Meicine, Wakayama Medical University, Wakayama, Japan.

Background and aims: Assessment of endothelium mediated vascular response in the finger tips after occlusion of the brachial artery is reflecting a hyperemic response, which is a measure for arterial endothelial function. Sympathetic nerve function plays a critical role in regulating vascular function. Although the vascular function of diabetes was known to be impaired more seriously than non-diabetic subjects, it is still unclear whether vascular hyperemic response were impaired by autonomic neuropathy in type 2 diabetes (T2DM) or not. To clarify the relationship between endothelial function and diabetic autonomic neuropathy, we measured reactive hyperemia peripheral arterial tonometry (RH-PAT) for evaluation of endothelial function, and heart rate variability (Coefficient of variation of R-R intervals: CV_{R-R}) as an indicator of autonomic function in type 2 diabetes.
Materials and methods: We assessed T2DM with RH-PAT for evaluation of endothelial function, CV_{R-R} for evaluation of autonomic nerve function by 5-min ECG recordings, and vibratory perception threshold for evaluation of diabetic peripheral neuropathy by using the C128 quantitative tuning fork. The results of RH-PAT were expressed as reactive hyperemia index (RHI) for evaluating endothelial function. Plasma VEGF concentration was measured using ELISA as a marker of vascular endothelial marker. Participants with CV_{R-R} less than 2.0 were

determined as impaired autonomic function, or with vibration perception threshold less than 9-seconds were as impaired vibration sensation. Patients with history of heart failure or arrhythmias were excluded.
Results: 281 T2DM were included. Mean age was 68.7±9.1 years (mean ±SD), duration of diabetes 15.5±9.9 years, HbA1c 7.4±1.1%, Plasma VEGF concentration 132.5±40.5 pg/ml, prevalence of albuminuria 40.0%, retinopathy 52%, mean RHI 1.56±0.38, 48% patients have low $CV_{R\text{-}R}$, and 64% patients have impaired vibration sensation. We compared RHI dependent on low $CV_{R\text{-}R}$ or normal $CV_{R\text{-}R,}$ and low vibration sensation or normal vibratory sensation. Our preliminary results show there was no significant difference between groups regarding age, BMI, duration of diabetes or hypertension. The RHI in low $CV_{R\text{-}R}$ group was significantly lower compared with normal $CV_{R\text{-}R}$ group (1.70±0.39 vs. 1.43±0.33, p<0.01). Whereas there was no significant difference in RHI between low vibration sensation group and normal vibration sensation group (1.56±0.31 VS. 1.49±0.45, p=0.09). Plasma level of VEGF were not significant difference in low $CV_{R\text{-}R}$ group compared with normal $CV_{R\text{-}R}$ group (139.7±32.0 vs. 128.5±28.3, p=0.20). RHI was significantly correlated with $CV_{R\text{-}R}$ (p=0.01) after adjustment for age, gender, blood pressure, albuminuria, LDL cholesterol, plasma VEGF concentration, and prevalence of retinopathy.
Conclusion: According to our study, endothelial function was more impaired in T2DM with autonomic neuropathy compared to T2DM without autonomic neuropathy. Our findings support the hypothesis that endothelial dysfunction was independently correlated with autonomic neuropathy in Japanese type 2 diabetes.

The effect of autonomic dysfunction in haemodynamic parameters in patients with type 2 diabetes

M. Nikoloudi, I. Eleftheriadou, A. Tentolouris, G. Drosos, S. Chorepsima, G. Konstantonis, A. Protogerou, N. Tentolouris;
First Department of Propaedeutic and Internal Medicine, Medical School, National and Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece.

Background and aims: Recent studies have reported that central blood pressure hemodynamics, such as pulse pressure (PP) amplification (PPA), augmentation index (AIx) and aortic pulse wave velocity (PWV) may better reflect overall cardiovascular risk compared to traditional risk factors in patients with and without type 2 diabetes mellitus (T2DM). Cardiac autonomic dysfunction (CAD) is a chronic complication of diabetes associated with increased cardiovascular risk. The effect of CAD on central blood pressure hemodynamic is not yet clear. The aim of our study was to investigate the association of CAD with blood pressure hemodynamics in patients with T2DM.
Materials and methods: A total of 142 patients with T2DM were recruited. Hemodynamic parameters, such as PPA, AIx and PWV were determined by applanation tonometry. Cardiac autonomic nervous system activity was assessed with short term analysis of heart rate variability (HRV) and baroreflex sensitivity (BRS).
Results: Univariate linear regression analysis showed that PPA was significantly associated with age, male gender, height, waist circumference, aortic systolic blood pressure (SBP), heart rate, AIx, PWV, central BRS, total power, low frequency power of HRV and use of b-blockers, while there was a trend for association with diabetes duration and high frequency power. No associations were found with smoking, dyslipidemia, HbA1c and renal function. Multivariate analysis, after adjustment for age, diabetes duration, height, waist, PWV, use of b-blockers and central BRS, demonstrated that male gender [standardized regression coefficient (β)=0.154, p=0.008], aortic SBP (β=-0.221, p<0.001), heart rate (β=0.521, p<0.001), AIx (β=-0.441, p<0.001), and total power of HRV (β=-0.156, p=0.005) were associated independently with PPA. No associations in the univariate analysis were observed between AIx and parameters of HRV or central BRS. Similar, no associations were observed between PWV and parameters of HRV or central BRS.
Conclusion: In patients with T2DM, PPA is associated with cardiac autonomic activity irrespective of known factors related to pressure pulsatility, such as age, gender, heart rate, wave reflections and traditional cardiovascular risk factors. However, CAD is not associated with AIx and PWV. CAD may attenuate pressure wave reflections and contribute to higher PPA observed in patients with T2DM.

Benfotiamine in the treatment of diabetic cardiovascular autonomic neuropathy

V.A. Serhiyenko, S. Ajmi, A.A. Serhiyenko;
Endocrinology, National, Lviv, Ukraine.

Background and aims: Cardiac autonomic neuropathy (CAN) represents a serious complication with approximately five-fold risk of mortality. Development of hyperinsulinemia, insulin resistance and chronic hyperglycemia in patients with type 2 diabetes mellitus (DM) have a negative impact on the metabolism of thiamine. Benfotiamine is a relative of the vitamin B_1 that appears to have a therapeutic role in reduction of diabetic complications development and progression. This study was aimed to investigate the effect of benfotiamine on insulin resistance parameters, some markers of chronic inflammation and heart rate variability (HRV) parameters.
Materials and methods: The study involved 32 patients with type 2 DM and moderate CAN of median age 54.13±0.28, median BMI: 27.9±0.26 kg/m^2 and HbA_{1c} level 7.0±0.13%. The diagnosis of CAN was based on the results of five standard cardiovascular tests, 24-hour HRV during the ECG recording (ECG "EC-3H" ("Labtech", Hungary). Patients with CAN were allocated to two groups: control (n=15) received standard therapy and treatment (n=17) received in addition benfotiamine 300 mg/day. We investigated lipid profile, levels of immunoreactive insulin (IRI), leptin, tumor necrosis factor alpha (TNF-α), high-sensitivity C-reactive protein (hsCRP) and interleukine-6 (IL-6). The duration of the study was three month. Statistics: ANOVA.
Results: We found out that the HbA_{1c} of patients with type 2 DM and CAN was not statistically significant influenced by the treatment (p>0.05). Benfotiamine prescription to patients with type 2 DM and CAN did not cause any significant changes in lipid profile and leptin levels (p>0.05), while it probably helped reduce the IRI concentration [26.8±1.37 mcIU/ml (before treatment) and 23.2±0.89 mcIU/ml (after treatment), Δ=-12.7±1.4%, p<0.05]. The use of benfotiamine in the comprehensive treatment of type 2 DM helped reducing hsCRP [2.93±0.16 mg/l (before treatment) and 2.5±0.1 mg/l (after treatment), Δ=-13.3 ±2.1%, p<0.05], TNF-α [5.39±0.24 pg/ml (before treatment) and 4.76 ±0.14 pg/ml (after treatment), Δ=-10.2±1.4%, p<0.05] and IL-6 [5.71±0,3 pg/ml (before treatment) and 4.78±0.2 pg/ml (after treatment), Δ=-15.4 ±2.04%, p<0,05)] concentrations. After 3 month of treatment we found out that there was a increase the percentage of differences between successive NN intervals over 24 hours that are greater than 50 ms (pNN50) [4.94±0.55% (before treatment) and 7.41±1.06% (after treatment), Δ=+45.9±7.91%, p<0.05)], high-frequency (HF) activity parameters during the active [267.7±17.61 ms^2 (before treatment) and 326.4±16.96 ms^2 (after treatment), Δ=+25.8±5.58%, p<0.05] and passive [267.7±17.61 ms^2 (before treatment) and 326.4±16.96 ms^2 (after treatment), Δ=+21,1 ±4,17%, p<0.05] periods of the day.
Conclusion: The administration of benfotiamine for three month promotes reduction of chronic inflammation markers and increase of parasympathetic activity, that allows to recommend prescription of this drug to patients with type 2 DM and CAN.

Longitudinal evaluation of gastric emptying in type 2 diabetes

L.K. Phillips, L.E. Watson, T. Wu, M.J. Bound, H. Checklin, J. Grivell, K.L. Jones, M. Horowitz, C.K. Rayner;
University of Adelaide, Adelaide, Australia.

Background and aims: The rate of gastric emptying is a key determinant of postprandial glycaemia which can be manipulated for therapeutic gain in type 2 diabetes (T2DM). Measurements of gastric emptying using scintigraphy show good reproducibility within healthy individuals in the short term, although little is known about the natural history of gastric emptying in patients with T2DM.
Materials and methods: We examined the records of patients with diabetes who had scintigraphic measurement of gastric emptying for research purposes in our laboratory between 2000 and 2005. Of the 167 subjects with diabetes identified, 42 had type 1 diabetes, 45 were deceased, 16 did not respond to the letter of invitation, 27 did not have a known address, 21 declined to participate, and 4 were excluded due to age, iron deficiency, opiate use, and bariatric surgery. 12 subjects with T2DM [7 female; age 51.6 ± 1.2 years; body mass index 30.4 ± 1.0 kg/m^2; duration of diabetes 8.9 ± 1.6 years at the time of the initial study] were able to return for repeat measurements of gastric emptying over 2 hr using the same dual-radioisotope labelled solid (100g minced beef) and liquid (150mL 10% glucose) meal, a mean of 14.0 ± 0.5 years after their initial study. On each study day, glycated haemoglobin (HbA1c) was measured, blood glucose was monitored before and after meal ingestion, and autonomic nerve function evaluated using standardised cardiovascular reflex tests. Data were evaluated using paired t-tests and repeated measures analysis of variance (ANOVA) and are shown as mean values ± SEM.
Results: Six patients were insulin-treated at follow up, vs. 2 at baseline. Six subjects had cardiovascular autonomic dysfunction at follow up, vs. 7 at baseline. Mean HbA1c was higher at follow up (9.0 ± 0.3 % [73.5 ± 3.5 mmol/mol] vs. 7.4 ± 0.4% [56.8 ± 4.5 mmol/mol], P= 0.03). However, fasting blood glucose (10.4 ± 0.8 mmol/L vs. 9.7 ± 0.8mmol/L, P=0.6) and postprandial blood glucose excursions (incremental area under the curve [0-120 min] 295 ± 55.8 vs. 213.0 ± 37.3 mmol/L.min, P=0.09) did not differ. Gastric emptying of solids was more rapid at follow up (retention at 100 min 42.3 ± 4.3%, vs. 64.1 ± 5.9% at baseline, P<0.01), whereas liquid emptying was unchanged (half-emptying time 31.5 ± 3.3 min vs. 35.6 ± 5.7 min at baseline, P=0.4). Solid emptying was abnormally slow in 6 patients at baseline, but only in one at follow up, while liquid emptying was delayed in 6 patients initially, and 5 at follow up (4 of whom were delayed at baseline). (Figure 1). None had abnormally rapid gastric emptying on either study.
Conclusion: In patients with long-term type 2 diabetes, gastric emptying of solids and liquids does not usually become more delayed over time, and abnormally slow gastric emptying of solids may improve.

Gastric electrical stimulation device decreases inpatient days in the population with diabetes

Z.M. Chong[1], M.R. Talla[1], P. Glen[2], B. Kennon[1];
[1]Department of Diabetes and Endocrinology, Queen Elizabeth University Hospital, [2]Department of General Surgery, Queen Elizabeth University Hospital, Glasgow, UK.

Background and aims: Diabetic gastroparesis is increasingly recognised as a frequent and clinically important complication of diabetes. The efficacy of medical treatment is limited, and gastric electrical stimulation (GES) offers a potential alternative treatment. We performed a retrospective cohort study to determine the effect of gastric pacemaker insertion on all-cause and gastroparesis-related admissions, readmission following post-operative complications, and duration of inpatient stay in patients with diabetic gastroparesis.
Materials and methods: A total of 13 patients with gastroparesis secondary to type 1 diabetes mellitus underwent gastric pacemaker insertion between January 2011 and November 2014 at a single centre in Glasgow. All had the same type of GES device placed by one surgeon. Data was collected retrospectively using the Scottish Care Information Diabetes Collaboration (SCI-DC) database and the Clinical Portal system (electronic patient record) for a period of 24 months pre-operatively, and 24 months post-operatively.
Results: This cohort had a mean age of 37 years. Nine of the 13 patients were female. Mean duration of diabetes was 22.7 years. Mean HbA1c at time of surgery was 88.6 mmol/mol. In terms of microvascular complications, 7 of the 13 (54%) patients had diabetic eye disease, defined as presence of pre-proliferative retinopathy, proliferative retinopathy or maculopathy. Of the 7 patients with eye disease, 6 had undergone laser therapy. Four of the 13 patients (31%) had diabetic nephropathy, with two of these having dialysis-dependent end stage renal disease. Five of the 13 patients suffered from diabetic neuropathy. Two patients in this cohort died out-with the 24-month follow up period - at 28 months and 61 months after pacemaker insertion respectively. In the 24 months prior to gastric pacemaker insertion, this cohort had a mean of 7 admissions from any cause. In the 24 months following pacemaker insertion, this fell to 6.3. The number of gastroparesis-related admissions fell from a mean of 5.5 to 3.8 admissions per patient over the same period. This corresponds to a fall in mean length of stay from 33.5 days to 22.3 days following pacemaker insertion. Inpatient days for gastroparesis-related admissions for the entire cohort fell from a total of 435 days in the 24-month period prior to insertion, to 290 days in the 24-month period following pacemaker insertion. Mean duration of admission for surgery was 3.8 days. Two of the 16 patients required re-admission due to complications following pacemaker insertion. This accounts for 5 of the 82 post-operative admissions for this cohort.
Conclusion: These results demonstrate a reduction in the number of all-cause and gastroparesis-related admissions following gastric pacemaker insertion. Duration of gastroparesis-related inpatient stay fell by 11.2 days, a reduction of 33.4% from baseline, in those who underwent pacemaker implantation. Rate of re-admission with post-operative complications from this procedure was acceptably low. Gastric pacemaker insertion is a safe and effective therapy that has been demonstrated to reduce numbers of diabetic inpatient days in our retrospective cohort study.

Correlation between symptoms of gastroparesis and ^{13}C-octanoic acid breath test in patients with type 2 diabetes

I.O. Kostitska;
Endocrinology, Ivano-Frankivsk National Medical University, Ivano-Frankivsk, Ukraine.

Background and aims: Gastroparesis, one of the commonest gastrointestinal (GI) complications of diabetes mellitus (DM), produces symptoms of gastric retention in the absence of physical obstruction. The aim of this study was to correlate symptoms using the GCSI with delayed gastric emptying in patients with type 2 DM referred for ^{13}C - octanoic acid breath test (^{13}C-OBT).
Materials and methods: We studied 180 subjects with type 2 DM duration of 9.9±6.4 years, mean value of HbA_1C was 8.6±1.7% and control group: 30 healthy volunteers. In results of GCSI all diabetics divided into 2 groups: I group consisted of 94 (52.2%) participants (56 male/38 female, mean age was 54.7±6.7 years) without GI symptoms and II group: 86 (47.8%) patients (48 male/38 female, mean age was 59.8±8.3 years) with diabetic gastroparesis (DG). All subjects had negative markers of other disorders of GI tract. GCSI questionnaire for assessment of GI symptom severity which consists of 9 questions answered by use of a six-point Likert response scale, ranging from 0 (none) to 5 (very severe). The severity of DG was assessed by GCSI questionnaire and Gastric emptying rate (GER) with ^{13}C-OBT.
Results: From the patients of type 2 DM, all subjects of II group were reported one or more GI symptoms from the GCSI scale: 50% reported fullness and/or early satiety from very mild to severe, 30% reported bloating from very mild to severe, 19% reported vomiting or nausea from very mild to moderate, other participants and volunteers without GI symptoms. GCSI total score in the II group was 16.7±0.7, mean GCSI nausea/vomiting score - 0.4±.0.2 and mean GCSI bloating score - 1.1 ±0.4. Low gastric motility has been diagnosed in patients with the help of ^{13}C-OBT: in the II group T ½ - 99.5±13.7 min, but in the I group T ½ - 60.1±5.4 min and control group that result is T ½ - 50.4±6.5 min. There was a strong correlation between ^{13}C-OBT and the GCSI total (r=.85, p=0.001), nausea/vomiting (r = .80, p=0.001) and bloating scores (r = .79, p=0.001).
Conclusion: Gastropaesis is quite a common complication of type 2 DM and use of the questionnaire GCSI allows to screen patients for DG symptoms which is confirmed by the strong correlation between GER and severity symptoms of questionnaire revealed in our study.
Disclosure: **I.O. Kostitska:** None.

PS 083 Do not miss the diagnosis of autonomic neuropathy

989

Diagnostic value of different autonomic symptoms assessed by COMPASS 31 for cardiovascular autonomic neuropathy and diabetic polyneuropathy

C. Greco[1], C. D'Amato[1], F. Di Gennaro[1], A. Sun[1], G. Lombardo[1], M. Campo[1], V. Frattina[1], D. Lauro[1], G. Pierangeli[2], P. Cortelli[2], V. Spallone[1];
[1]Endocrinology, Department of Systems Medicine, University of Rome Tor Vergata, Rome, [2]DIBINEM, Alma Mater Studiorum, University of Bologna, Bologna, Italy.

Background and aims: We recently validated the questionnaire Composite Autonomic Symptom Score (COMPASS) 31 for autonomic symptoms of diabetic neuropathy. In a wider population from the same diabetes centre, we aimed to further investigate the diagnostic performance of different autonomic symptoms (i.e., orthostatic intolerance, vasomotor, secretomotor, gastrointestinal, bladder, and pupillomotor domains of COMPASS 31) for diabetic cardiovascular autonomic neuropathy (CAN) and diabetic polyneuropathy (DPN).
Materials and methods: A total of 93 participants with diabetes (age 54 ±14 years, diabetes duration 13±10 years) completed the COMPASS 31 questionnaire before undergoing cardiovascular reflex tests and assessment of neuropathic symptoms (using the Michigan Neuropathy Screening Instrument Questionnaire), signs (using the Michigan Diabetic Neuropathy Score), vibration, and thermal thresholds.
Results: As expected, the COMPASS 31 total weighted score was higher in the presence of CAN (26.7±19.5 Vs. 12.5±14.3; P=0.0044) and DPN (26.9±17.8 Vs. 12.5±11.3; P=0.0000). Among the 6 domains of COMPASS 31, the highest differences were seen in gastrointestinal (P=0.0004) and orthostatic intolerance weighted scores (P=0.0188) according to the presence of CAN, and in secretomotor (P=0.0000), gastrointestinal (P=0.0000), pupillomotor (P=0.0001), and orthostatic intolerance weighted scores (P=0.0005) according to the presence of DPN. Receiver-operating curve analysis confirmed a fair diagnostic accuracy of total weighted score for CAN [area under the curve (AUC) 0.685 ±0.067, 95% CI 0.583-0.782] and DPN (AUC: 0.755±0.050, 95% CI 0.652-0.836). Among the six COMPASS 31 domains, a fair diagnostic accuracy for CAN was reached only by gastrointestinal domain (AUC: 0.728±0.066, 95% CI 0.630-0.821), whereas it was achieved for DPN by secretomotor (AUC: 0.758±0.050, 95% CI 0.652-0.836), gastrointestinal (AUC: 0.728±0.066, 95% CI 0.630-0.821) and pupillomotor domains (AUC: 0.705±0.056, 95% CI 0.606-0.799). Secretomotor weighted score at the cut-off of 4.28 had a sensitivity of 61.5% (95% CI 46.3-76.8) and a specificity of 81.5% (95% CI 71.1-91.8) for DPN. Vasomotor and bladder domains showed the worst diagnostic performance.
Conclusion: Among autonomic symptoms as assessed using COMPASS 31, the best diagnostic performances were provided by the secremotor domain (exploring sweating changes, dry eyes and dry mouth) for DPN and by the gastrointestinal domain for both CAN and DPN. These findings expand previous observations, give insights into the relationship between autonomic and sensorimotor neuropathy, and further support the inclusion of COMPASS 31 in a comprehensive evaluation of diabetic neuropathy.

Should we avoid the handgrip test in the assessment of cardiovascular autonomic neuropathy in diabetic patients? Exploratory factor analysis

A.E. Körei[1], M. Kempler[1], Z. Putz[1], O. Vági[1], I. Istenes[1], Á.G. Tabák[1,2], V. Spallone[3], P. Kempler[1];

[1]1st Department of Internal Medicine, Semmelweis University, Budapest, Hungary, [2]Department of Epidemiology and Public Health, University College London, London, UK, [3]Department of Systems Medicine, Tor Vergata University of Rome, Rome, Italy.

Background and aims: Historically, a set of five cardiovascular autonomic reflex tests (CARTs) was considered to be the gold standard of cardiovascular autonomic neuropathy (CAN) assessment. Current guidelines however suggest only the use of four with the omission of the diastolic blood pressure response to sustained handgrip. Thus we aimed to assess the association between the handgrip and the other tests.
Materials and methods: We recruited 353 diabetes patients (age: 60.2 ±7.4 years; female: 57.2%; BMI: 29.3±2.1 kg/m^2; diabetes duration: 15.6 ±9.9 years; HbA1c: 8.2±1.9%; type 1 diabetes: 18.1%). We measured the following CARTs: deep breathing test, Valsalva ratio, handgrip test, and orthostatic hypotension test. Definite CAN was defined as ≥2 abnormal CARTs excluding the handgrip test.
Results: The handgrip test had a sensitivity of 24.6% (95%CI 17.7%-33.1%) and a specificity of 79.4% (95%CI 73.3-84.4%) for the diagnosis of definite CAN. According to exploratory factor analysis, the four examined CARTs showed a 2-factor structure with the handgrip test loading to one factor (factor loading: 0.98) and the deep-breathing test, Valsalva ratio and orthostatic hypotension test clustered on another component with factor loadings 0.68, 0.77 and 0.66, respectively. Handgrip test abnormality showed an independent association with higher initial diastolic blood pressure values (OR: 1.05, p=0.0009) and an independent inverse association with the presence of hypertension (OR=0.42, p=0.006).
Conclusion: According to the exploratory factor analysis, there is an independent factor underlying the results of the handgrip test differing from that underlying the results of the other cardiovascular reflex tests. Potential factors influencing handgrip test results could be the presence of hypertension and baseline diastolic blood pressure.

Valsalva test alone is the best and economically valued tool for diagnosing cardiac autonomic neuropathy

R. Del Toro, E. Maddaloni, E. Fioriti, G. Tabacco, G. Defeudis, C. Caggiano, S. Manfrini, P. Pozzilli;
Campus Bio-Medico di Roma, Rome, Italy.

Background and aims: Cardiac autonomic neuropathy (CAN) is a life-threatening diabetes complication. It often goes ignored as the recommended Ewing's battery for CAN diagnosis is time-consuming and difficult to perform.
Materials and methods: To evaluate if the number of required tests could be reduced, we compared each test included in the Ewing's battery and their combinations in 115 diabetic subjects with a median age of 58 [interquartile range: 48-67] years.
Results: According to the Toronto criteria, CAN was diagnosed in 53 subjects. After multivariable adjustments, CAN was associated with higher HbA1c and triglycerides levels, lower HDL cholesterol and higher retinopathy rates (all p-values<0.05). No subject had positive orthostatic hypotension test. The age-adjusted area under the receiver operating characteristic curve of Valsalva maneuver was significantly higher than deep breathing and lying to standing tests alone (Figure) and in combination (p<0.01). Performing a complete Ewing's battery did not increase sensitivity and specificity for CAN diagnosis than performing Valsalva test alone (p= 0.48): Youden's J statistic showed the best age-adjusted sensitivity and specificity for CAN diagnosis were 80.5% and 86.3% respectively with Valsalva vs 85.0% and 85.7% with the full battery.
Conclusion: CAN can be efficiently diagnosed by using Valsalva test alone, thus allowing a fast, economically valued and easy screening for a frequently unrecognised deadly diabetes complication.

Analysis of the relationship between glycaemic variability and autonomic neuropathy in type 1 diabetes

S. Nyiraty[1], F. Pesei[1], A. Orosz[2], S. Coluzzi[3,4], C. Lengyel[1], G. Ábrahám[1], S. Frontoni[3,4], P. Kempler[5], T. Várkonyi[1];
[1]1st Department of Medicine, University of Szeged, [2]Department of Pharmacology and Pharmacotherapy, University of Szeged, Szeged, Hungary, [3]Department of Systems Medicine, University of Rome Tor Vergata, [4]Unit of Endocrinology, Diabetes and Metabolism, S. Giovanni Calibita Fatebenefratelli Hospital, Rome, Italy, [5]1st Department of Medicine, Semmelweis University, Budapest, Hungary.

Background and aims: A relationship is suspected between autonomic neuropathy (AN) and glucose variability (GV) as variability is associated with oxidative stress responsible for neuronal damage while the impaired autonomic function has a detrimental effect on metabolism. The aim of our study was to find relationship between the parameters of AN and GV in type 1 diabetic patients.
Materials and methods: 21 type 1 DM patients were involved (age: 39.5 ±3.4 years, duration of DM: 17.5±2.5 years; HbA1c: 8.1±0.2%, mean ±SE). Autonomic neuropathy (AN) was assessed by the cardiovascular reflex tests (CRT). The interstitial glucose levels were determined following insertion of a subcutaneous electrode during the continuous glucose monitoring (CGM) method on 6 consecutive days. GV was characterized by calculation of 4 parameters.
Results: Standard deviation of interstitial glucose values (SD) correlated positively with the overall AN score and the degree of the orthostatic reduction of systolic blood pressure (AN-score-SD r=0.47, p<0.05; orthostasis- SD: r=0.51, p<0.05). Mean Absolute Glucose: (MAG) correlated with 3 parameters of AN (AN-score-MAG: r=0.62, p<0.01; 30/15 ratio-MAG: r= -0.50, p<0.05; orthostasis- MAG: r=0.59, p<0.01). The HbA1c also correlated with 2 parameters of GV (HbA1c - Continuous Overlapping Net Glycaemic Action (CONGA): r=0.56, p<0.05; HbA1c- MAG: r=0.45, p<0.05). The frequency of hypoglycemia did not exhibit any correlation with characteristics of GV.
Conclusion: Severity of glycemic variability correlates with both parasympathetic and sympathetic dysfunctions in long-standing type 1 diabetes. Higher HbA1c is associated with more severe glucose variability. The relationship of increased glucose variability and autonomic neuropathy might be explained by the higher frequency of hypoglycemia and postprandial hyperglycemia in patients with neuropathy.

The beneficial effect of intracavernosal mirabegron, a selective β$_3$-adrenoceptor agonist, on erectile dysfunction in streptozotocin-induced diabetic rats

D. Yilmaz-Oral[1], E. Kaya[2], D. Askin[1], G. Koroglu[1], S. Gur[1];
[1]Department of Pharmacology, Faculty of Pharmacy, Ankara University, [2]Department of Biochemistry, Faculty of Pharmacy, Ankara University, Ankara, Turkey.

Background and aims: Diabetes mellitus is one of the common risk factors for erectile dysfunction (ED). Phosphodiesterase type 5 inhibitors (PDE5i), which are the first-line treatment for ED, are not effective in the management of diabetes-associated ED. Mirabegron, a recent selective β_3-adrenoceptor (β_3-AR) agonist, has been approved for the treatment of overactive bladder. The aimed of this study is to investigate the possible beneficial effect of mirabegron treatment on ED in streptozotocin-induced diabetic rats.
Materials and methods: A total of 20 adult male Sprague-Dawley rats were equally divided into control and diabetic groups. Diabetes was induced by single intraperitoneal injection of 45 mg/kg of streptozotocin. In vivo erectile responses were evaluated by the stimulation of cavernosal nerves and repeated after intracavernosal injection of mirabegron (dose of 0.4 mg/kg) in anaesthetised rats. The relaxant responses of corpus cavernosum (CC) strips were examined in the presence or absence of mirabegron (10 μM). β_3-ARs expression and localization were determined by Western blot analysis and immunohistochemistry in CC tissue.
Results: In vivo erectile responses in diabetic rats were lower than in control rats, which were partially restored after intracavernosal administration of mirabegron. Basal intracavernosal pressure (8.3±0.9 mmHg) in diabetic rats was markedly increased after mirabegron (39.5±6.9 mmHg, $p<0.001$). Mirabegron induced the marked relaxation after precontraction with phenylephrine in diabetic rat CC (100%). The nitrergic relaxation response to electrical field stimulation (10 Hz) in diabetic CC was lower than in control CC, which was increased in the presence of mirabegron (untreated 10.3%; treated 69.3%, $p<0.001$). Mirabegron markedly enhanced sodium nitroprusside-induced (10nM) relaxation in diabetic CC. The relaxant response to sildenafil (1μM) in the diabetic group was reduced as compared to the control group, which was potentiated after incubation with mirabegron. The expression and immunoreactivity of β_3-ARs localized to the smooth muscle cells of CC were observed in diabetic and control rats.
Conclusion: This study firstly revealed the beneficial effect of intracavernosal administration of mirabegron in partially improving erectile function in diabetic rats. This agent completely enhanced neurogenic relaxation of CC in diabetic rats. These results may be supported further by studies using combinations of mirabegron and PDE5i for the treatment of diabetic ED, especially in patients who do not respond to PDE5i therapy.

PS 084 Diagnosis and treatment of the diabetic foot syndrome

994

Implementation of IWGDF risk classification in predicting the development of diabetic foot in type 2 diabetic patients admitted in the hospital: a three-year follow-up study

X. Hu[1], W. Xu[1], T. Shu[1], J. Wu[1], Y. Yang[2], L. Gao[2], B. Yao[1], J. Weng[1];
[1]Department of Endocrinology, Third Affiliated Hospital of Sun Yat-sen University, [2]Sun Yat-sen University, Guangzhou, China.

Background and aims: Diabetic foot is one of the key areas of morbidity associated with diabetes, which is not only represent a major personal tragedy but also place a substantial financial burden on healthcare systems and society in general. Therefore, preventing the development of diabetic foot in patients with high risk is of important clinical significance. This study aimed to investigate the predictive value of International Working Group on the Diabetic Foot (IWGDF) risk classification on development of diabetic foot in type 2 diabetic patients adimitted in the hospital.
Materials and methods: Consecutive type 2 diabetic patients admitted to the endocrinology department of our hospital who were ≥18 years or older had been enrolled. Those already suffered from diabetic foot, peripheral neuropathy caused by any diseases, hypothyroidism and diseases affecting life span were excluded. Patients fulfilled the above criteria underwent a standardized general medical examination and detailed foot assessment. IWGDF risk classification were evaluated in these patients. Thereafter, patients were regularly followed up for three years. During the follow-up period, information of the patients suffered from diabetic foot were collected and analyzed. Receiver-operating characteristic (ROC) curve was used to evaluate the predictive value of the IWGDF risk classification on diabetic foot development in these patients.
Results: 254 patients (Male 59.4%) with the mean age of 54.7±12.8 years old, and HbA1c of 9.9±2.8% were recruited between September, 2012 and January, 2013. Based on the IWGDF risk classification, 177 patients (69.7%) were graded as risk group 0, 31 patients (12.2%) as risk group 1, 26 patients (10.2%) as risk group 2, and 20 patients (7.9%) as risk group 3. During the three-year follow-up period, 32 patients among the 254 patients (12.6%) experienced diabetic foot, with 12 patients (4.7%) ended up with amputation. It was found that using the combination of risk group 2 and risk group 3 had better value than using risk group 3 alone or the combination of risk group 1, risk group 2 and risk group 3 in IWGDF risk classification when considering the sensitivity and specificity to predict the development of diabetic foot (Table 1). Further analysis also revealed that the ROC curve for patients in risk group 2 and risk group 3 (0.919, 95% CI: 0.893~0.945, $p<0.01$) was superior to that for patients in risk group 0 and risk group 1 evaluated with IWGDF risk classification.
Conclusion: The IWGDF risk classification is an effective tool for predicting the risk of diabetic foot in type 2 diabetic patients admitted to the hospital. Patients who were in risk group 2 and risk group 3 evaluated with IWGDF risk classification may have higher risk to develop diabetic foot in the future.

Table 1. The sensitivity and specificity to predict the development of diabetic foot with different risk groups evaluated with IWGDF risk classification

	IWGDF risk classification		
	Risk group 3	Risk group 2 + Risk group 3	Risk group 1 + Risk group 2 + Risk group 3
Sensitivity	0.593	0.926	1.00
Specificity	0.945	0.799	0.612

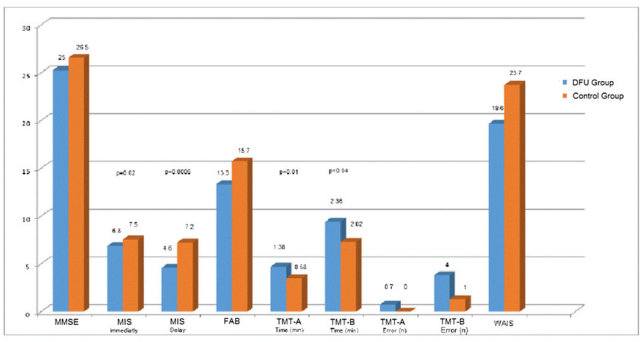
995

Diabetic patients with foot ulcer express lower educational support needs and display more cognitive dysfunction

C. Bouché[1], A. Zucchello[1], P. Troude[2], J. Dumurgier[3], T. Sarron[1], J.-F. Gautier[1];
[1]Diabetology, Lariboisière Hospital, [2]Public Health and Evaluation, Lariboisière Hospital, [3]Memory Research Center, Fernand Widal Hospital, Paris, France.

Background and aims: Therapeutic patient education (TPE) is essential for the prevention of diabetic foot ulcer (DFU). In this study, we explored the neuropsychological abilities of diabetic patients (DP) displaying DFU and their perception of their TPE needs.
Materials and methods: In this proof of concept study, we selected 22 consecutive adult DP with DFU, and a control group (CG) of 22 DP without active or past ulcer history, matched for age (± 5 years). Psycho-sensorial status was assessed by the Hospital Anxiety and Depression Scale and the Saint-Antoine Pain Questionnaire. TPE needs were estimated with a 4-point Likert Scale based on 9 items completed by 4 open questions. The interviews explored different aspects of diabetic self-management, knowledge, understanding and health priorities. Neuropsychological functioning was assessed using standardized tests: Mini Mental State Exam (MMSE), Memory Impairment Screen (MIS), Frontal Assessment Battery (FAB), Trail-making Test A and B (TMT-A and -B) and Wechsler Adult Intelligence Scale (WAIS). Both groups were compared using Wilcoxon's signed rank test for quantitative variables and conditional logistic regression models for qualitative variables.
Results: DP of the DFU group tended to have a longer disease duration (mean: 15 years *vs* 11) and more diabetes-related complications, compared to the CG. No significant difference was found for BMI, HbA1c, anxiety, depression or pain, TPE needs evaluated by Likert Scale, between the two groups. In open questionnaires, DP with DFU tended to declare less medical needs compared to the CG (8/22 *vs* 12/22). Needs were focused on material difficulties, none of them concerned educational skills, in contrast to 5 DP in the CG ($p<0.05$). Moreover, only 15 (68%) DP in the DFU group did consider health as a priority in their lives, whereas 21 (95%) in the CG did ($p= 0.06$). Cognitive abilities in the DFU group seemed to be lower as shown by the lower score obtained in different neuropsychological tests (Graph 1). MIS and TMT scores were significantly lower in the DFU group, reflecting a lower ability to memorize and treat information.
Conclusion: Although DP with DFU displayed more diabetic complications they expressed lower educational needs and less heath priorities. Their cognitive scores are in agreement with lower learning abilities and may suggest need to develop more medical help support to better health care. Whether this association is related to cerebral micro and/or macroangiopathy remains to be investigated.



Graph 1: Mean Scores obtain at the different neurocognitive tests in DP of DFU compare to the CG.

996

Sudomotor examination should be regularly performed in patients from predialysis stage (CKD4) but also after transplantation to detect nerve regeneration

D.S. Tesic[1], N. Papanas[2], E. Stokic[1], M. Mitrovic[1], I. Bajkin[1], T. Icin[1], D. Tesic[3], M. Tomic[1], B. Vukovic[1];
[1]Clinic of Endocrinology, Diabetes and Metabolic Diseases, Institut for Internal Diseases, Novi Sad, Serbia, [2]Diabetic Foot Clinic, Democritus University of Thrace, Alexandroupolis, Greece, [3]Clinic of Cardiology, Institute for Cardiovascular Diseases of Vojvodina, Sremska Kamenica, Serbia.

Background and aims: Diabetes(DM) or hypertension are listed as the primary causes for 70% of new cases of end stage renal disease(ESRD). The aim of this prospective 5-year study was to examine the incidence of foot morbidity among diabetic and non-diabetic patients in different stages of chronic kidney disease(CKD).
Materials and methods: Overall, 199 patients during the preceding 5 years were enrolled. We included 108 diabetic patients (18 with type 1DM, 90 with type 2 DM) with the following conditions: 25 with glomerular filtration rate(GFR) 30-59mL/min /1.73 m^2- stage 3 CKD(G1); 27 on HD(G2b); 56 with GFR $\geq$90 mL/min/ 1.73m^2(G3b). We also included non-diabetic patients with the following conditions: 35 with nephroangiosclerosis on HD(G2a); 30 with other causes HD(G2c); and 26 transplant recipients (5 nephroangiosclerosis, 5 T1DM, 1 T2DM, 15 with other diseases) (G3a). Before 5 years, we had graded severity of foot pathology by Neuropathy Disability Score(NDS) plus Neuropad test (evaluated as time to total colour change), colour doppler, ulcer and/or amputation. Of the entire 199 patient population, 79 had meanwhile died.
Results: Five-year mortality rates were: 68% in G1(CKD3+DM); 57.1% in G2a(HD+NAScl); 70.4% in G2b(HD+DM); 36.7% in G2c(HD+Other); 3.84% in G3a(Transplanted); 19.6% in G3b(No-CKD+DM) ($p<00.1$). Despite the similar mortality, patients in G1 were older (71.12±7.8 years) compared with G2b(HD+DM) (60.3 ±13.1 years) and G3b(59.9±7.75yrs) ($p<0.01$). Comparing G2a(HD+NAScl) vs. G2b(HD+DM) among those who had died, male sex was more prevalent among diabetic patients, (45.7 vs. 70.4%, $p<0.05$); duration of HD was shorter in diabetic patients (5.2±2.5 vs. 4.6±2.5years, $p=0.03$). Prevalence of arterial hypertension in G1 vs. G2b vs.G3b was: 13(52%) vs. 26(96.3%) vs. 9(16.1%) ($p<0.01$) and duration of diabetes was 17.9±6.2 vs.23 ±10 vs. 15.9±7.8 years($p<0.01$). Neuropad time until colour change was: G1 8.9±5.8 min., G2a-c 26.8±8.2min., G3a 9.1±7.6min., G3b 11.3±7.4min. ($p<0.01$). Multivariable logistic regression analysis including Categories 1-3 diabetic foot (IWGDF) and Neuropad test found significant association of Neuropad time with CKD III-V (OR: 1.14, 95% Cl: 1.09-1.19, $p=0.000$) and mortality (OR: 1.05, 95% Cl: 1.02-1.08, $p=0.001$). Peripheral arterial disease among dead patients was: G1 8 (47.1%), G2b 15 (78.9%), G3b 7 (63.6%). No patient without diabetes developed ulceration or amputation in the entire study period. Ulcerations and/or minor amputations were present in G2b 5 (18.5%) and G3b 13 (23.2%). Major amputations were: 1 in G1, 1 in G3b and 6 in G2b(HD+DM) ($p=0.003$).
Conclusion: Category 3 diabetic foot (according to the Interantional Working Group on the Diabetic Foot classification) is exclusively seen in diabetic patients (whether on HD or not). Categories 1 and 2 may be present even in non-diabetic patients. We reccomend prospective monitoring of sudomotor dysfunction from CKD stage 4 onwards, regardless of the presence of diabetes. Indeed, this dysfunction is not only strongly associated with end-stage diabetic foot pathology but also with end-stage renal insufficiency, regardless of the presence of diabetes.
Disclosure: **D.S. Tesic:** None.

997

Toe-brachial index is associated more strongly with healing and recurrence of chronic diabetic foot ulcers than ankle-brachial index in patients with type 2 diabetes

D.-H. Cho, M.-Y. Chung, J.-O. Chung, D.-J. Chung;
Chonnam National University Hospital, Gwangju, Korea, Republic of.

Background and aims: Fifteen percent of people with diabetes develop an ulcer in the course of their lifetime. Eighty-five percent of the major lower-leg amputations in diabetes are preceded by an ulcer. Management of ulcers and preventing their recurrence is important for the quality of life. Both micro- and macro-angiopathy strongly contribute to the development and delayed healing of diabetic wounds. Peripheral arterial disease can be diagnosed noninvasively by segmental blood pressure measurement and calculating an ankle-brachial index (ABI) or toe-brachial index (TBI). The objective of this study was to determine whether ABI or TBI influences healing of chronic diabetic foot ulcers in patients with type 2 diabetes, and to determine whether TBI influences recurrence of ulcer in patients with healed foot ulcers.
Materials and methods: We recruited a total of 102 type 2 diabetic patients (63 men and 39 women) with chronic non-healing diabetic foot ulcers with Wagner grade 1 or 2 ulcers that are ≥2 cm in largest diameter at diagnosis for more than 1-month duration. The age was 69.2±15.8 years, and the diabetes duration was 16.2±11.4 years. Anthropometric, clinical, and laboratory data were measured. All patients were seen bi-weekly for debridement, offloading, and other treatments during the initial 8 weeks. All patients subsequently underwent ABI and TBI testing. ABI and TBI measurements were performed with the subject in a supine position, and were determined as the ratio of ankle or toe systolic blood pressure to the brachial systolic blood pressure, with both determined using an automatic device. To investigate recurrence status in patients with healed foot ulcers, Healed patients were followed with telephone interview after a minimum of 1 year of follow-up [median 2.3 (range 1.1-2.8) years].
Results: At 8 weeks, 64 of the 102 ulcers had completely healed. The patients were assigned into healed group (n = 64) or unhealed group (n = 38) according to clinical outcome of ulcer healing at 8 weeks. There were not significantly different in age, duration of diabetes, HbA1c, or initial wound size in diameter of the ulcer between the healed and unhealed groups. The healing time of foot ulcers in healed group was 6.2±2.4 weeks (range 4.0-8.0). The TBI was significantly ($P<0.05$) lower in the unhealed group (0.59±0.22) as compared with the healed group (0.74±0.21). ABI was not significantly different between unhealed and healed group. Age ($r = 0.481$; $p< 0.01$), duration of diabetes ($r = 0.460$; $p< 0.05$) and ABI ($r = 0.711$; $p< 0.001$) were significantly correlated with TBI. But BMI, cholesterol levels, HbA1c, and systolic and diastolic BP were not correlated with TBI. Univariate analysis revealed that TBI was significantly correlated with healing rate of ulcers ($r = 0.287$, $p < 0.05$) and duration of diabetes ($r = 0.410$, $p < 0.05$). At the end of follow-up (median 2.1 years), 21/64 patients (32.8%) had recurrence of diabetic foot ulcers. The recurrence rate in group with lower TBI (< 0.7) was significantly higher than that in the normal TBI (> 0.7) group (48.1% vs 21.6%; $P < 0.05$), but not correlated with ABI.
Conclusion: This study demonstrated that toe-brachial index is more strongly associated with the healing and recurrence rate of diabetic ulcers than ankle-brachial index. We suggest that the measurement of toe-brachial index may help to identify ulcers at risk of poor healing or recurrences in chronic diabetic foot ulcers in patients with type 2 diabetes.

Bedside blind bone biopsy for suspected diabetic foot osteitis: feasible, simple and useful

F. Féron[1], L. Salle-Teyssières[1], M. Laloi-Michelin[1], T. Vidal-Trécan[1], H. Jacquier[2], E. Lecorche[2], F. Mougari[2], A. Lopes[3], D. Chopin[3], P.-O. Sellier[3], J.-D. Laredo[4], J.-P. Riveline[1], F. Mauvais-Jarvis[5], J.-F. Gautier[1], J.-P. Kevorkian[1];
[1]Diabetology - Endocrinology, Lariboisière Teaching Hospital, [2]Microbiology, Lariboisière Teaching Hospital, [3]Internal Medicine, Lariboisière Teaching Hospital, [4]Radiology, Lariboisière Teaching Hospital, Paris, France, [5]Medicine - Endocrinology, Tulane University of Medicine School, New Orleans, USA.

Background and aims: To shorten therapeutic decision for suspected diabetic foot osteitis, Bedside Blind Bone Biopsy (B4) performed by a diabetologist might challenge biopsy usually performed by either an orthopaedic surgeon or a radiologist.
Materials and methods: Observational, monocentric study of B4 feasibility assessment in a diabetes inpatient setting. Inclusion criteria: foot ulcer (area >2 cm^2, lasting ≥4 weeks), suspected osteitis (clinically and/or X-ray), no antibiotics. B4 performed through clean skin with trocart (Madison^{TM} KDP13/6) following local and light systemic anaesthesia. Primary endpoint: collection of a suitable bone specimen. Adverse events: local (provoked ulcer/inflammation/necrosis, bleeding), general (fever, positive blood cultures) within 72h. Assessment of pain by the face appearance scale during B4 and by evaluating pain reliever consumption within 24h. Systematic blood cultures (1/hour) within 3 hours or in case of fever. Microbiological examinations were completed by histological examinations (HE) in the last ten B4 (table).
Results: 28 consecutive patients with type 2 diabetes. Male: 82%, age: 68 ±12yrs (Mean±SD), diabetes duration: 17±8yrs, HbA1c: 8,5±2%. Ulcer University of Texas scale: Grading 0/1/2/3: 3,5/3,5/3,5/89,5%, Stages A/B/C/D 25/43/11/21%. International scale: Grading 1/2/3/4: 4/0/46/50%. Severe proximal and distal peripheral arteritis: 14% and no arteritis in 35%. Systolic pressure index <0,9: 57%. TcPO2 <30mmHg: 57%. B4 performed within 5 days following indication in every patient. Procedure duration: 60±10mn. B4 sites: metatarsal (65%), proximal phalange (14%), distal phalange (14%), calcaneus (7%). Primary success: 96,5% (2±1 specimens/patient). Positive cultures: 50%. No local complication. Fever occurrence: 21%. Bacteriemia: 11%. Per-B4 pain: 7%. Post-B4 pain: 50% (step 2 relievers prescribed in 7%).

	M+/H+	M-/H-	M+/H-	M-/H+
***n* (%)**	2 (20%)	6 (60%)	2 (20%)	0 (0%)

Table: Results of combined microbiological (M) and histological (H) examinations (10/28). M+: positive culture (contaminated bone not included), H+: presence of neutrophils
Conclusion: For suspected diabetic foot osteitis, B4 is easy and quick to perform. It is informative (notably if completed by HE) and safe with rare major related events. Its daily clinical practice by a diabetologist might shorten therapeutic decision. Its cost-effectiveness remains to be evaluated.

Incidence and predictors of recurrent and new diabetic foot ulcers

S. Engberg, H. Andersen, K. Kirketerp-Moeller, A. Rasmussen;
Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: Patients with diabetic foot ulcers (DFU) have a high risk of amputations and increased mortality compared to patients without DFU. Studies among patients with a healed DFU have shown that two-thirds develop a recurrent (at the same location) or a new (at another location) DFU within 5 years. These relatively small studies with up to 83 patients have found the following risk factors or indicators for recurrent/new DFU: neuropathy, plantar ulcer location, Charcot feet, foot deformities, peripheral vascular disease, osteomyelitis, high HbA1c, macrovascular complications and non-adherence with foot-wear and -care. Some of these studies are restricted to only neuropathic patients

and by not calculating progression rates. Aims: 1) among patients with a healed DFU to estimate the progression rate to recurrent/new diabetic DFU, 2) to compare the progression rates depending on whether the healed ulcer was neuropathic, neuro-ischemic or ischemic, and 3) to study selected risk factors rate ratios (RR) for progression to recurrent/new DFU.

Materials and methods: A retrospective cohort study including all patients with a healed diabetic foot ulcer at our centre from January 2010 to October 2016. Patients were followed to an outcome (a recurrent/new DFU), to end of contacts with our centre, to death or to study end. All information was extracted from our electronic patient record system. Poisson regression analyses were made.

Results: Among 780 patients with a healed DFU, (489 (63%) neuropathic, 202 (26%) neuro-ischemic and 89 (11%) ischemic), 53% (33%/person year) progressed to a recurrent/new DFU during follow-up. The patients were followed for 1249 years in total (median 1.04 (Q1= 0.38 - Q3=2.46) years pr. patient). When adjusted for age and gender, the RR for neuro-ischemic vs. neuropathic was 1.29 (95% confidence interval (CI) 1.03-1.61) and ischemic vs. neuropathic was 1.42 (95% CI 1.04-1.95). A quarter of the patients (26%) died during follow-up. A majority of the DFU seen during follow-up were new (88 %). Men - RR 1.26 (95% CI 1.01-1.56), patients with lost sense of vibration (greater than 50 Volt) - RR 1.31 (95% CI 1.08-1.59), patients with Charcot feet - RR 1.66 (95% CI 1.20-2.28) and patients with foot deformities - RR 1.26 (95% CI1.00-1.59) had higher progression rates to recurrent/new DFU compared to patients without these risk factors. Patients with type 1 diabetes - RR 0.81 (95% CI 1.01-1.56), non-smokers - RR 0.76 (95% CI 0.63-0.93) and patients with a creatinine level less than 90 μmol/l - RR 0.76 (95% CI 0.63-0.93) had lower risk of progression to a recurrent/new DFU compared to patients without these characteristics.

Conclusion: Per year one third of the patients progressed to a recurrent/new DFU which is comparable to other studies. Patients with a neuro-ischemic or ischemic DFU progressed to recurrent/new DFU at a higher rate than patients with neuropathic DFUs. Male gender, type 2 diabetes, smoking, lost sense of vibration, Charcot feet and foot deformities were risk factors for recurrent/new DFU.

Prevalence of distal symmetric polyneuropathy in hospitalised diabetic patients

H.S.S. Gonçalves[1], A. Lopes[2], L. Fonseca[2], A.S. Costa[1], J.B. Calvão[1], J. Gonçalves[3], C.C. Branco[3], R. Martins[3], V. Barbosa[4], M. Mendes[4], A.L. Sousa[5], M. Calejo[5], A.F. Rebelo[1], S.M. Teixeira[2];
[1]Internal Medicine, Hospital de Vila Real, Vila Real, [2]Endocrinology, Centro Hospitalar do Porto, Porto, [3]Internal Medicine, Centro Hospitalar do Porto, Porto, [4]Neurology, Hospital de Vila Real, Vila Real, [5]Neurology, Centro Hospitalar do Porto, Porto, Portugal.

Background and aims: Distal symmetric polyneuropathy (DSPN) is one of the most prevalent chronic complications of diabetes but is largely underdiagnosed. It's frequently painful and if undiagnosed can lead to diabetic foot ulceration. Screening for DSPN enables early intervention, prevention of complications and appropriate treatment of symptoms. The Semmes-Weinstein Monofilament Examination (SWME) is currently the method of choice to screen DSPN, but ideally two neurologic tests should be used. The Michigan Neuropathy Screening Instrument (MNSI), which evaluates vibratory sensation and ankle reflex, has been proposed as a useful screening test of DSPN. DN4 is a scale that evaluates the presence of neuropathic pain. The objective of this study was to determine the prevalence of DSPN in hospitalized diabetic patients by both methods (MNSI and SWME) and the percentage of painful neuropathy.

Materials and methods: Diabetic patients admitted to internal medicine wards of two different Portuguese hospitals within a 5 months period were evaluated using the MNSI and the SWME after exclusion of other causes of polyneuropathy. A score > 2 in the clinical examination of MNSI or a ≤ 7 positive answers in a total of 10 in SWME were considered diagnostic of DSPN. Patients were also evaluated for the presence of neuropathic pain with the DN4 scale. A score ≥ 4 was positive for painful neuropathy.

Results: A total 88 patients were evaluated: 74.7 ± 13.2 years; 54.5% female; 93.2% type 2 diabetic patients with 12.0 ± 8.8 years of disease duration and HbA1c 7.57 ± 1.79 %. Macrovascular complications were present in 40.2% of the patients and microvascular in 26.4% of them. Only 6 (6.8%) patients had a previously diagnosis of DSPN. The MNSI was positive in 66 (75%) of the patients while SWME was positive in 33 (37.5%) of patients. The rate of undiagnosed patients was 93.8% using MNSI and 93.9% using SWME. The agreement rate between MNSI e SWME was 44.3%: 25 patients were positive in both instruments and 14 negative. Using both instruments would classify 74 out of 88 (84.1%) patients with DSPN and painful neuropathy was present in 28 (38.9%) of these.

Conclusion: This study detected a high prevalence of undiagnosed DSPN among diabetic hospitalized patients, suggesting that hospitalization is an excellent opportunity to screen for this complication. Our data indicates that using both MNSI and SWME increases the detection of DSPN.

Multidrug resistant bacteria: an increasing complication of diabetic foot

E. Iacopi[1], A. Coppelli[1], C. Goretti[1], E. Tagliaferri[2], C. Tascini[2], F. Menichetti[2], A. Piaggesi[1];
[1]Diabetic Foot Section Medicine Deparment, University of Pisa, [2]Infectious Disease Unit, University of Pisa, Pisa, Italy.

Background and aims: Multigrug resistant (MDR) infections complicate diabetic foot ulcers (DFU) severely worsening their prognosis. The aim of this study was to assess the prevalence of MDR phenotypes of different bacterial strains in diabetic patients followed by our diabetic foot clinic from January 2001 until December 2014.

Materials and methods: We retrospectively analysed 7.826 culture results from deep wound specimens in diabetic patients (M/F: 6.065/1.761. Age: 63.2±11.7 yrs) followed by our outpatient Clinic for DFU. From all bacterial strains we selected those more prevalent and we analysed antimicrobial sensitivity pattern in relation to the more widespread antibiotic resistance phenotypes. In particular, we evaluated the prevalence of Staphylococcus aureus (SA), Pseudomonas aeruginosa (PA) and Enterobacteriae (EB), sorting out Methicillin-Resistant SA (MRSA), PA resistant to Ciprofloxacin (CiproRPA) and Carbapenem (CRPA), EB resistant to Ciprofloxacin (CiproRE) or Extended Spectrum Beta Lactamase producers (ESBL). To test if the MDR pattern changed overtime, we divided the obtained results in two groups: the first (Group A) included those from 2001 until 2007 while the second (Group B) from 2008 until 2014.

Results: SA was detected in 2.483 specimens in Group A and in 2.131 in Group B (NS), the presence of MRSA was 58.7% in Group A and 51.2% in Group B (NS). PA was observed in 1.428 specimens in Group A and 1.783 in Group B ($p < 0.03$): in particular, CiproRPA was detected in 45.1% of cultures in Group A and 64.1% in Group B ($p < 0.04$) while CRPA in 32.7% in Group A and 34.2% in Group B (ns). The presence of EB was detected in 1.516 specimens in Group A and 2.032 in Group B ($p < 0.001$); CiproRE prevalence was 28.0% in Group A and 47.7% in Group B ($p < 0.02$) while ESBL prevalence was 23.0% in Group A and 39.7% in Group B ($p < 0.05$).

Conclusion: In conclusion, our data confirmed the high prevalence of MDR bacteria infections in DFU and their increasing overtime, stressing the importance of a close monitoring of antimicrobial drugs susceptibility.

Assessment of pain sensitivity and speed of wound healing in rats with streptozotocin-induced diabetes

A.M. Gorbacheva[1], A.B. Berdalin[1], M.P. Morozova[1], E.M. Klochikchina[1], E.V. Artemova[2], Z.N. Abdulvapova[2], S.A. Gavrilova[1], A.J. Tokmakova[2], G.R. Galstyan[2], V.B. Koshelev[1];
[1]Lomonosov Moscow State University, Faculty of Fundamental Medicine, [2]Diabetic foot Department, Endocrinology Research Center, Moscow, Russian Federation.

Background and aims: Diabetes mellitus is often accompanied by peripheral neuropathy and various disorders of reparation processes. However, the relationship between neural disorders and pathological wound healing in DM remains unclear. Our aim was to assess the relationship between the development of peripheral neuropathy and wound healing rate in rats with streptozotocin-induced DM.
Materials and methods: The study was performed in rats, diabetes was induced by a single injection of streptozotocin in 0.1 M citrate buffer in a dose of 65 mcg/kg. In control group an injection of 0.1 M CB was performed. 42 days later, the wound on the rats' back was inflicted. The observation of wounds lasted for 8,16 or 24 days. During whole period of experiment DM rat group received maintenance therapy with insulin detemir 1 IU/kg/day. The assessment of the development of peripheral neuropathy was performed by the pain test with the tail immersed in hot water every 7th day. The evaluation of wound healing was based on wound's area measurement every 3rd day. Skin samples were taken at 0, 8, 16 and 24 days of wound healing. The samples were stained with hematoxylin and, also immunohistochemical staining on ß2 - adrenergic receptors (ß2-AR) and Ki67 were conducted.
Results: To 42 day of DM the time of withdrawal of the tail in rats with diabetes has almost doubled in comparison with the group of CB ($p<0.05$), which allows to establish the presence of sensory neuropathy. At the same time, a significant gap in the rate of wound healing in the group of rats with DM was noticed. According to the results of histological staining it was found that the intact skin was the same in all groups. On 8 day after modeling of the wound in the region of the edges of the wound, the expression of Ki67 was significantly less than in intact areas ($p=0.004$). On the 16th day, the expression of Ki67 in the area of the wound increased and did not differ significantly from the remote areas of the skin. On the 24th day, Ki67 staining was again significantly weaker in the area of the wound edges. The density of ß2-AR in diabetic group at the wound edge was lower than in intact areas.
Conclusion: STZ-induced DM in rats is accompanied by development of peripheral sensory neuropathy and a decrease in the rate of wound healing already to 42 day of the disease. Morphologically, the decrease in the rate of wound healing is manifested by decrease of square cone area and the rate of appearance of keratinocytes in the wound area despite the fact that the intact skin of diabetics did not differ from the intact skin of healthy animals. According to immunohistochemical analysis, time and zone factors were significant for Ki67 expression, and only time factor was significant for ß2-AR expression.

Transcutaneous oxygen pressure as a predictor for short term survival in patients with diabetic foot ulcers

K. Fagher, P. Katzman, M. Löndahl;
Department of Endocrinology, Skane University Hospital, Lund, Sweden.

Background and aims: Ankle-brachial index (ABI) is the most commonly used test for the diagnosis of peripheral vascular disease (PVD), and is considered a marker for increased cardiovascular risk both in the general and diabetic population. Transcutaneous oxygen pressure ($TcPO)_2$ is a test considered to better reflect the microvascular status and has in some studies shown better correlations with diabetic foot ulcer healing. Several studies have suggested a cut-point of $TcPO_2$ >30 mmHg as a threshold for acceptable oxygen supply for wound healing. Whether $TcPO_2$ could be a risk marker for mortality in diabetic foot ulcer (DFU) patients has to our knowledge not been studied. The aim of this study was to evaluate the predictive value of $TcPO_2$ ≤30 mmHg, arterial toe blood pressure (TBP, cut-off level ≤ 50 mmHg) and ABI (cut-off level ≤0.8 and ≥1.4) on 1-year mortality.
Materials and methods: We enrolled 277 consecutive patients aged < 90 years with diabetes and at least one DFU who attended our multi-disciplinary diabetic foot clinic. Patients were screened with transcutaneous oxygen pressure ($TcPO_2$) measurements at the dorsum of the foot, ankle-brachial index (ABI) and arterial toe blood pressure (TBP) with Perimed© diagnostic instrument. All patients were treated according to international guidelines and were evaluated for vascular intervention when needed. After one year mortality data was obtained from the national death registry in Sweden. Survival was analysed with Kaplan-Meier curves and log rank test and to adjust for age and gender a Cox regression analysis was performed.
Results: 277 patients (34% women) with a median age of 75 (67-82) years were evaluated in this study. 15% of the patients died during the first year of follow-up. $TcPO_2$ ≤30 mmHg was associated with a significantly higher 1-year mortality rate compared to TcPO2 >30 mmHg (25% vs 12%, p=0.005, figure 1). Also among patients with TBP ≤ 50 mmHg 1-year mortality was higher compared to patients with TBP>50 mmHg (23% vs. 12%, p=0.014). ABI did not influence 1-year mortality. After adjusting for age and gender in a Cox regression analysis, only age and $TcPO_2$ ≤30 mmHg were independently predicting 1-year mortality with a hazard ratio of 2.4 (1.3-4.4, 95% CI, p=0.006) for $TcPO_2$ ≤30 mmHg. TBP did not independently affect mortality in this analysis.
Conclusion: This study indicates that $TcPO_2$ ≤30 mmHg is an independent prognostic marker for short term survival among patients with diabetic foot ulcers.

The impact of topical phenytoin loaded nanostructured lipid carriers in healing of neuropathic diabetic foot ulceration

M.M.M. Motawea[1], A. Motawea[2], A.-G.H. Abd El-Gawad[2], T. Borg[2], M. Tarshoby[1];
[1]Endocrinology and Diabetes, Specialized Medical Hospital - Faculty of Medicine - Mansoura University, [2]Department of Pharmaceutics, Faculty of Pharmacy, Mansoura University, Mansoura, Egypt.

Background and aims: Many previous researches support various forms of topical phenytoin as an effective promoter for healing of diabetic foot ulceration. Recently, nanostructured lipid carrier was suggested to increase loading of topical drugs. We aim to study the impact of topical phenytoin loaded nanostructured lipid carrier in improving wound healing in patients with neuropathic diabetic foot ulceration.

Materials and methods: Twelve patients with neuropathic diabetic foot ulceration under the metatarsal-heads were enrolled in this study. Patients were comparable regarding ulcer size, grade & control of diabetes with no major deformity. All patients were managed by weekly sharp debridement if indicated & offloading with cast shoes done by the same hands. They were divided into 3 groups: phenytoin loaded nanostructured lipid carrier hydrogel 0.5% (Group 1), phenytoin hydrogel 0.5% (Group 2) & blank hydrogel (Group 3). Wound area was reassessed after 1, 4 & 8 weeks. Also, we investigated the in vitro release of phenytoin & phenytoin loaded nanostructured lipid carrier hydrogels by modified Franz diffusion cell at pH 7.4 up to 48h.

Results: Group 1 showed complete healing of 2 cases & smaller wound area compared to the other groups ($\rho < 0.05$). Baseline wound area of Group 1, 2 and 3 were 3.42±1.77, 3.62±1.98 & 3.87±2.39cm^2, respectively. The average wound area changed to 3.19±1.98, 3.51±1.75 & 3.60±1.63cm^2 after the first week; 0.86 ±0.40, 2.62±1.40 & 4.07±1.65cm^2 after the fourth week; 0.10 ±0.15, 1.69±0.78 & 4.06±1.93cm^2 after the eighth week, respectively. Overall reduction in ulcer size was 97.48±2.61% for Group 1, in comparison to 52.29±9.18% & -9.58±14.85% for Group 2 & Group 3 respectively ($\rho < 0.001$) (as shown in figures 1, 2, & 3). This may be attributed to small particle sizes of the nanostructured lipid carrier hydrogel with subsequent large surface area, its lipoid nature (acts as a reservoir), in addition to solubility & penetration enhancement that increase the skin delivery. Also, the in vitro release study clarified that, drug release from the nanostructured lipid carrier hydrogel displayed a biphasic release pattern with initial burst followed by sustained release. On the contrary, in phenytoin hydrogel drug release was very rapid & completed within 48h.

Conclusion: Phenytoin loaded nanostructured lipid carrier dressing is more effective than phenytoin hydrogel at the same concentration in healing of neuropathic diabetic foot ulceration. This effect may be assigned to its small particle sizes with consequent increase in its solubility, in addition to their biphasic release pattern that is recommended for topical products. These promising results encourage large scale trials for use of phenytoin loaded nanostructured lipid carrier in treatment of diabetic foot ulcers & other chronic wounds.

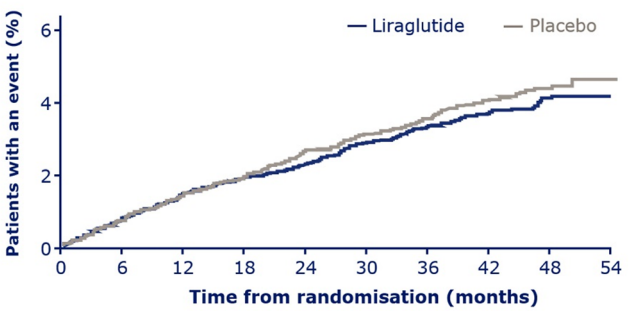
Exploring the impact of liraglutide on diabetic foot ulcers on subjects with type 2 diabetes and increased risk of cardiovascular events: results from the LEADER trial

K. Dhatariya[1], S.C. Bain[2], R.E. Pratley[3], J.B. Buse[4], R. Simpson[5], L. Tarnow[6], M. Stellfeld[7], M.S. Kaltoft[7], K. Tornøe[7], on behalf of the LEADER Trial Steering Committee and Investigators;
[1]Elsie Bertram Diabetes Centre, Norfolk & Norwich University Hospital NHS Trust, Norwich, [2]Abertawe Bro Morgannwg University NHS Trust, Swansea, UK, [3]Florida Hospital, Orlando, [4]University of North Carolina School of Medicine, Chapel Hill, USA, [5]Monash University and Eastern Health, Victoria, Australia, [6]Nordsællands Hospital, Hillerød, [7]Novo Nordisk A/S, Søborg, Denmark.

Background and aims: The risk of developing foot ulcer in people with type 2 diabetes (T2D) is increased due to various factors, including peripheral neuropathy and peripheral arterial disease. The LEADER trial (Liraglutide Effect and Action in Diabetes: Evaluation of cardiovascular outcome Results) reported cardiovascular (CV) risk reduction vs placebo in addition to standard of care (SoC). To date, limited information on the treatment effect of glucagon-like peptide-1 receptor agonists (GLP-1RAs) on diabetic foot ulcer (DFU) or their outcomes has been published. We investigated these measures with liraglutide vs placebo from the LEADER trial.
Materials and methods: LEADER was a randomised, double-blind, international, multicentre, placebo-controlled CV outcomes trial assessing the CV and long-term safety of liraglutide up to 1.8 mg/day vs placebo, both in addition to SoC for up to 5 years, in patients with high CV risk and T2D. Information on DFU was systematically collected in LEADER. Based on this, DFU complications were assessed post-hoc by the sponsor through review of the individual cases.
Results: DFU was reported as medical history at baseline in 4.5% and 4.2% of patients receiving liraglutide and placebo, respectively; 1.5% and 1.3% of patients, respectively, had DFU at screening. Proportions of patients reporting at least one episode of DFU during LEADER were similar between patients receiving liraglutide vs placebo (3.9% vs 4.2%, HR=0.91, 95% CI [0.75-1.12] p=0.38). A lower rate of DFU events was observed in the liraglutide group vs placebo from around month 18; this continued for the remainder of the trial, although not reaching statistical significance (Figure). Among patients with DFU during LEADER, proportions reporting complications of DFU included infection (60.8% [107/176] vs 68.6% [131/191], p=0.12), involvement of underlying structures (36.4% [64/176] vs 41.9% [80/191], p=0.28), any amputation (25.0% [44/176] vs 35.1% [67/191], p=0.04) and peripheral revascularisation (11.4% [20/176] vs 12.0% [23/191], p=0.84) with liraglutide and placebo, respectively. Of those in need of amputation, a lower proportion of amputation of the foot, lower leg or leg was reported for liraglutide vs placebo (29.5% [13/44] vs 44.8% [30/67], p=0.01).
Conclusion: LEADER is the first trial of GLP-1RAs in T2D to report DFU data. These findings may suggest a reduced risk of DFU and associated complications with liraglutide vs placebo in patients with T2D and increased risk of CV events.

Figure: Time to first DFU among all patients in LEADER



Kaplan-Meier plot. Full analysis set. Based on MedDRA search (version 18.0) of SAEs + non-serious MESIs. DFU, diabetic foot ulcer; MedDRA, Medical Dictionary for Regulatory Activities; MESI, medical event of special interest; SAE, serious adverse event

Treatment of a new diabetic foot ulcer in a diabetic foot service: a one year follow up prospective study of 347 patients

G. Ha Van, C. Amouyal, C. Aubert, A. Carlier, O. Bourron, T. Couture, A. Hartemann, A. Hartemann;
Diabetologie, Unite de Podologie Batiment IE3M, Paris, France.

Background and aims: The objective of the study was to evaluate the 1 year outcome of the management of 347 new diabetic foot ulcers by the multidisciplinary team of our diabetic foot service (DFS)
Materials and methods: A single centre prospective cohort study of 347 patients with a new diabetic foot ulcer (DFU) between 1/07/2009 and 31/12/2010. We used university Texas (UT) and PEDIS classification for all the DFU Patients who needed parenteral antibiotic therapy, revascularization or surgical debridement were hospitalized in our DFS The follow up was 1 year après the date of inclusion Multiple logistic regression modeling was used to identify independent predictors of outcome (non healing, major amputations and deaths)
Results: At inclusion: Average age : 64.88 ± 13.7 years, 68% male, Type 2 Diabetes mellitus (D) in 87%, Age of DM: 18.7± 12.3 years Average age of the DFU : 187 ± 546 days According to PEDIS classification, 69% DFU were classified P2 or P3, infected in 55%, 82% had a surface > 1cm², and Depth 2 et 3 in 51% According to UT classification, 28% C, 33% class D, 14% class B, 52% (75%: B+C+D) Depth 2 and 3: 51% At M12 (12 months): 312 patients were reviewed (9% lost of follow up) Healing rate was 68%, average duration of healing 189 ± 160 days The univariable associations of the potential predictors of non-healing were hemodialysis (p =0.006), Peripheral arterial disease (PAD) (p=0.000001), Surface of DFU (p= 0.003) et DM age (p=0.05) The multivariable association with independent predictors of non-healing were PAD :OR 0.251 [95% CI 0.112-0.563], p =0.001, Extent of the DFU: OR 0.385 [95% CI 0.186-0.799] p= 0.01, hemodialysis OR 0.323 [95% CI 0.143-0.726]p= 0.006, Duration of DM: OR 1.025 [95% CI 1.002-1.049] p =0.032 Amputations : 7.1% major amputations (5.7% below-knee, 1.4% above-knee) ,11.5 % minor amputations (toes ; 11.5%, trans metatarsal 6.1%) In univariate analysis major amputations were associated with PAD (p= 0.03), Osteomyelitis (p= 0.01) and hospitalization in post acute department(p= 0.000) In multivariate analysis predictor was hospitalization in post acute department : OR 23.5 [95% CI 7.10-78.15] P=0.000 Mortality Death rate was 8.3% at M12, and alive healed patients without amputation: 60% In univariate analysis predictors of mortality were PAD (p= 0.0000), Age (p= 0.0009), Duration of DFU at inclusion (p=0.001), Body mass index (p= 0.008) and non healing at M12 (p= 0.00002). In multivariate analysis mortality was associated with PAD: OR 13.2 [95% CI 1.81-96.2]; p= 0.01 and non healing at M12 : OR 0.191 [95% CI 0.07-0.523] ; P=0.001
Conclusion: Despite an average age of 65 years, a duration of DFU of more of 6 months, and 75% of DFU with infection, ischemia (or both) the healing rate was 68 %, the death rate of 8.3% and the major amputation rate of 7.1%. In France according to a recommendation of the HAS (Health Authority) patients with DFU of at risks foot have to be addressed within 48 hours to a diabetic foot service This study showed that the results are not so bad and could probably have been even better with an earlier management. Ischemia is the main risk factor for healing, death and amputation

Long-term changes in BMD and bone turnover markers in diabetes patients with or without previous Charcot foot

O.L. Svendsen[1], R.B. Jansen[1], T.M. Christensen[1], J.B. Bülow[2], L. Rørdam[2], P. Holstein[3];
[1]Dept of Endocrinology, Copenhagen Diabetes Foot Center, [2]Dept of Clinical Physiology and Nuclear Medicine, Bispebjerg University Hospital, [3]Center for Wound Healing, Bispebjerg University Hospital, Copenhagen, Denmark.

Background and aims: It remains controversial whether the bones in the diabetic Charcot foot is osteoporotic, and whether the skeleton in general in these patients is osteoporotic. In a previous study, diabetes patients with acute Charcot had increased markers of bone turnover, whereas patients with chronic Charcot had decreased BMD of the calcaneus in the Charcot foot, -otherwise there were no differences in BMD or markers of bone turnover between diabetes patients with acute or chronic Charcot or without Charcot. The aim of the present study was to investigate changes after 8.5 years in BMD and markers of bone turnover in diabetes patients with or without previous Charcot.
Materials and methods: An 8.5-year follow-up study of 49 individuals with diabetes mellitus, 24 of whom also had acute or chronic Charcot foot at the baseline visit in 2006. BMD (total body, hip, spine and calcaneus) by DXA (Lunar Prodigy) and standard biochemical markers of bone turnover (P1NP, CTX-1 and osteocalcin) were measured.
Results: 22 diabetes patients were included in the follow-up, whereas 12 had passed away, 4 were out of reach, 7 declined and 4 had had amputations. Of the 22 diabetes patients included, 11 had previously had a Charcot foot, while the other 11 did not. On average, the age of the included diabetes patients at the follow up was 69 yrs, diabetes duration 27 yrs, HbA1c 59 mmol/mol, 18 were males and 4 females, 7 with type 1 diabetes and 15 with type 2 diabetes, with no difference between those with or without previous Charcot ($p>0.05$). There was no difference in the change in BMD from baseline to follow-up between the diabetes patients with and without previous Charcot, in neither total-body, hips, lumbar spine, calcaneus ($p>0.3$) nor in calcaneal BMD between the previous Charcot foot or healthy foot in those patients with a previous Charcot foot ($p>0.3$). The mean annual change in BMD, over the 8.5 years, in the different skeletal sites ranged from -0.3% to +1.2%. At the follow up, 16 of the diabetes patients had normal T-score, 3 had osteopenia, and 4 had osteoporosis (according to WHO criteria, T-score < -2.5) with no difference in the distribution between those with or without previous Charcot ($p>0.05$). Furthermore, there were no differences between the diabetes patients with or without previous Charcot in changes from baseline to follow-up, nor at follow-up, in the markers of bone turnover ($p>0.05$).
Conclusion: After more than 8 years of follow up, diabetes patients with, or without, previous Charcot had similar BMD and biochemical markers of bone turnover. Thus, in diabetes patient, a Charcot foot does not seem to have long term negative impact on bone mineral or risk of osteoporosis.
Clinical Trial Registration Number: NCT02335931

1008

Five year mortality following diabetic amputation has not changed over 14 years

B.P. Soo[1], U. Ranasinghe[1], R. Jayatilake[1], A. Egun[2], S.M. Rajbhandari[1];
[1]Diabetes Dept, Chorley & South Ribble Hospital, Chorley, [2]Vascular surgery, Lancashire Teaching Hospital, Preston, UK.

Background and aims: Diabetes is the most common cause of non-traumatic limb amputations. The consequences of undergoing an amputation remain significant. There is an increased risk of mortality compared to non - diabetic patients. Other factors such as the emotional impact and the associated rehabilitation programme also need to be taken into account. There is higher 5- year mortality following diabetes related amputations which is about 70% as per NICE literature review. We wanted to study if this has changed over the last 14 years in our cohort.
Materials and methods: This was a retrospective study on 356 patients who underwent amputation between 1997 and 2010. List was obtained from discharge summary and theatre record. Subjects who underwent amputation between 1997 - 2003 were 'Early' cohort and those between 2004 - 2010 were 'Late' cohort. Amputations were grouped at their first surgery into major (above ankle) or minor (below ankle). Electronic database was examined in 2016 to know the date of their death. The cause of death could not be ascertained.
Results: There was no difference in the mean number of total amputations performed annually between early and late cohort (25 +/- 8.8 vs 25.9 +/- 4.9; $p > 0.05$), however there was a significant reduction in major amputations performed annually (18.4 +/- 3.9 vs 12.9 +/- 3.2; $p = 0.01$) and a trend for a rise in minor amputations (6.6 +/- 6.3 vs 13.0 +/- 5.1; $p = 0.07$) between these cohorts. 5-year mortality was 59% which was significantly higher in major amputation group than minor (63.9% vs 51.1%; $p = 0.02$). There was no difference between 'Early' and 'Late' cohorts in 5-year total mortality (60.1% vs 57.4%; $p > 0.05$), major amputation mortality (63.2% vs 64.0; $p > 0.05$) or minor amputation mortality (43.9% vs 52.8%; $p > 0.05$).
Conclusion: There has been no change in total mortality with time in subjects with diabetes who needs lower limb amputations. There is significant reduction in major amputation with increase in minor amputation between these cohorts. The change in amputation level started with the introduction of multi-disciplinary diabetic foot clinic in 2001.

Care path of patients with diabetic foot wound in France: a multicentre observational study

C. Amouyal[1], J. Martini[2], I. Dumont[3], L. Ouvry[4], J.-E. Salem[5], A. Hartemann[6], DSFD group Pied Diabetique;
[1]Pitié Salpétrière Hospital, APHP, INSERM UMRS_1166, ICAN, Paris, [2]Rangueil Hospital, Toulouse, France, [3]Multidisciplinary, Diabetic Foot Center, Ransart, Belgium, [4]Pitié Salpétrière Hospital, APHP, ICAN, [5]Pitié-Salpêtrière Hospital, APHP, Clinical Investigation Center, CIC-1421, [6]Pitié Salpétrière Hospital, APHP, INSERM UMRS_938, ICAN, Paris, France.

Background and aims: Prevalence of hospitalizations for a diabetic foot ulcer or amputation remains very high in France (912 per 100 000 diabetic patients in 2013). However, national and international recommendations on diabetic foot ulcers are clear: patients should be addressed to a multidisciplinary foot centre within 24 to 48 hours after wound

occurrence. The aim of this study was to describe the care pathway of patients with a diabetic foot ulcer before arriving in foot centers, and to look for factors, influencing pathways dysfunction.
Materials and methods: This is a multi center, observational study including 21 french foot centres. Each center included the ten successive patients attending for a new foot ulcer between May and July 2015. The only exclusion criteria was " French not spoken". Patient pathway was accessed by a pre-defined questionary. The primary outcome was " time between ulcer occurrence and consultation in the foot centre". Analysis was performed by Student or Man-Whitney test, and ANCOVA.
Results: 209 patients were included: 133 men, 76 women, 29 to 97 years old (mean: 68 years) ; 89% had type 2 diabetes ; 39% have had a previous wound ; 17% had an amputation and 31% had peripheral arterial disease. 26% have had a prescription of an offloading device before referring to the foot center but only 35 patients (17%) complied. Concerning wounds 84 (40%) were infected and 95 (45%) reached joint, tendon or bone. Time between ulcer occurrence and the first GP contact was 12 (+/- 2) days, median 5 days. Patients were addressed to the foot center after an average of 83 days (+ / -15), median 26 days. Factors that significantly influenced the delay before referring were " having had a prescription of offloading ($p = 0.043$)", "having had dressing by a nurse ($p = 0.01$)", or "being resident of Ile de France region ($p = 0.002$)". The significant statistical relationship for these criteria persisted in multivariate analysis.
Conclusion: The mean delay before referring patients with a diabetic foot wound to a foot center in France is major. Some regions are more concerned than others. The prescription of an offloading device by GP is rare. Partial care of the wound (dressing or offloading device) participate to this delay. Information on foot centers location and diffusion of international guidelines on diabetic foot care is urgently needed.

Effectiveness of implementing a joint diabetes-renal-microbiology initiative in individuals with active diabetic foot disease receiving dialysis

P.R.J. Vas, J. Casey, J. Tremlett, S. Taori, M. Edmonds, C. Manu, A. Rankin;
King's College Hospital, London, UK.

Background and aims: Diabetic foot disease (DFD) and lower extremity amputation are considered to be 10 times higher in diabetic individuals receiving dialysis. Furthermore, they have disproportionately high rates of foot-related hospital admissions. Those on dialysis often lose contact with care outside the dialysis units and access to foot care is limited in dialysis units. Therefore, interventions and strategies aimed at reduction of DFD burden in dialysis patients are important. We report on our joint diabetes-renal-microbiology multidisciplinary team (JDRMDT), set up to address the challenge and facilitate cross-specialty care.
Materials and methods: Retrospective analysis of all the patients discussed at the JDRMDT meetings over a 24 month period. Patients were reviewed by the acute foot team while undergoing dialysis with liaison and referral to the hospital multidisciplinary foot unit when required. Where necessary a vascular or orthopaedic review was arranged whilst the patient was still in the dialysis unit. A summative team discussion was held at the end of each week comprising of a podiatrist, diabetologist, nephrologist and microbiologist to update and address any concerns. Our analysis was limited only to those with *active* DFD mandating closer surveillance.
Results: We discussed 37 patients with an average age 65±12 years (mean±SD), males 51%, with active DFD. Duration since dialysis start was 3.5±3.1 years. Glycated haemoglobin was 56±18 mmol/mol with BMI of 28.4±6.9 kg/m^2. In 24/37 (67%) of patients, there was evidence of significant peripheral vascular disease; they underwent 2.3±2.1 revascularisation procedures. There were 14 (38%) minor amputations (13/14 had CLI) and 4 (11%) major amputations (all had CLI). Microbiology was predominantly polymicrobial (44%) with gram-negative organisms predominating although pure MSSA (17%), MRSA (21%) VRE (10%) were also noted. Overall, 8/37 (22%) died during this period with a higher (50%) mortality observed among those with major amputations. While emergency hospital admissions were 6.0±5.1 episodes/patient; only 1 ±1.25 episodes/patient were foot-related.
Conclusion: The JDRMDT was an effective way of bridging the care gap in diabetic foot patients receiving dialysis. It allowed for complex diabetic foot care delivery within the dialysis unit reducing the dependency on the main foot clinic while demonstrating encouragingly low foot-related hospital admissions. In addition, our observed major amputation rate was lower than reported in the literature. Such an initiative may represent significant quality of care and cost benefits.
Disclosure: **P.R.J. Vas:** None.

Should calcaneal ulcers be managed in a class of their own?

D. Hirani[1,2], L. Bloomfield[2], J. Valabhji[2], V. Salem[1,2], V. Bravis[1,2];
[1]Division of Diabetes, Endocrinology and Metabolism, Imperial College London, [2]Department of Diabetes & Endocrinology, St Mary's Hospital, Imperial College Healthcare NHS Trust, London, UK.

Background and aims: Diabetic foot ulcers affecting the calcaneum are experientially the most challenging to manage, and automatically score a point on the SINBAD severity staging system. This study aims to interrogate the specific clinical features of this subpopulation of diabetic foot patients.
Materials and methods: 34 calcaneal ulcers in 28 patients presenting to our diabetic foot service between March 2010 and November 2016 were retrospectively studied. Clinical, laboratory and radiological data were collected on all patients. All episodes were assigned a SINBAD score. Outcomes of interest included mortality rates, average healing time, and major limb amputation. Data collection for an age-matched control group with non-calcaneal foot disease is in progress.
Results: The average age of our calcaneal cohort was 65 years and the mean diabetes mellitus duration was 25 years (which does not differ significantly from our overall diabetic foot disease population). However, the mortality rate in the calcaneal ulcer cohort was strikingly high at 43% (12/28) compared with 11% in previously published data for all patients with diabetic foot ulcers in our unit over the same 6-year time period. In 6 of the patients who died, the calcaneal ulcer was still an active problem at the time of death, with a mean preceding duration of 30 months. Only 1 calcaneal ulcer (3%) healed by 24 weeks. 10 ulcer episodes took longer than 24 weeks to heal, with an average healing time of 15 months. By comparison, National Foot Audit data reports that 49% of all diabetic foot ulcers can be expected to heal by 12 weeks. 7 calcaneal ulcer episodes were still ongoing at the time of data analysis, although all had been present for more than 12 weeks, with an average preceding duration of 12.7 months. A below knee amputation (BKA) was required in 21% (7/34) of calcaneal ulcer episodes. 2 episodes requiring BKA were due to chronic ulceration lasting a mean duration of 51 months. 94% (32/34) of episodes had a SINBAD score greater than or equal to 3. Chi squared testing reveals that, compared with our non-calcaneal ulcer population, heel ulcers are more significantly associated with peripheral vascular disease ($P<0.01$).
Conclusion: Our data confirms that diabetic calcaneal ulcers have a significantly poorer prognosis. They are associated with poor healing rates,

higher rates of amputation, and a 5-year mortality rate of close to 50%. We plan to interrogate predictors of healing in calcaneal diabetic foot disease, which may be a marker of other significant underlying co-morbidities beyond neuropathic and vascular disease. The diabetes foot community should consider revising current treatment guidelines for calcaneal disease, considering earlier, more aggressive interventions to prevent chronic and potentially life threatening longer-term sequelae.
Disclosure: **D. Hirani:** None.

Is it reasonable to indicate autologous cell therapy of critical limb ischaemia in diabetic patients with chronic kidney disease?

M. Dubsky[1], A. Nemcova[1], A. Jirkovska[1], R. Bem[1], V. Fejfarova[1], A. Pysna[1], V. Woskova[1], K. Navratil[2];
[1]Diabetes Centre, Institute for Clinical and Experimental Medicine, [2]Clinic of Transplant Surgery, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Background and aims: Autologous cell therapy (ACT) by bone marrow derived mononuclear cells is an alternative therapeutic option for diabetic patients with critical limb ischemia (CLI) not eligible for standard revascularization. The impact of severe stages of chronic kidney disease (CKD) on the outcome of ACT is rarely published, because these patients are usually excluded from clinical trials. In our previous studies we proved favorable clinical effect of ACT on amputation rate in patients with end-stage renal disease in comparison with conservative treatment. The aim of our current study was to compare the clinical effect of ACT in diabetic patients with regard to CKD stages.
Materials and methods: Eighty-seven patients with diabetic foot and no-option CLI who underwent ACT in our foot clinic between 2008-2016 were included into the study. Patients were divided in 3 groups in accordance with CKD stages. Fifty-four patients with CKD stages 1-2 (glomerular filtration rate [GFR] 60-90 ml/min/1.73 m^2 or higher) were included in group 1, 12 patients with CKD 3-4 (GFR 15-59 ml/min/1.73 m^2) were included in group 2 and 20 patients with CKD 5 treated by hemodialysis formed group 3. Survival and major amputation rate were assessed in the mean follow-up of 49 ± 29 months; the clinical effect of ACT measured by changes in transcutaneous oxygen pressure ($TcPO_2$) and wound healing was evaluated at 12 months after the procedure.
Results: $TcPO_2$ significantly increased in all study groups after 12 months compared to baseline ($p < 0.0001$, $p = 0.0043$ and $p = 0.0003$ in the first, second and third group), with no significant difference among them. Patients in group 1 had significantly higher survival rate during follow-up period compared with group 3 (87.1 vs 50 %, $p = 0.0006$), no other significant differences in survival were observed. Major amputation rate was without a significant difference among all study groups (27.8 vs 25 vs 35 %, NS). Ulcer healing after 12 months was also without any significant difference among the first, second and third study group (38.9 vs 41.7 vs 30 %, NS).
Conclusion: Our study showed that autologous cell therapy by bone marrow-derived mononuclear cells significantly improved CLI in patients with diabetic foot and enhanced ulcer healing regardless of CKD stages. There was a trend to a little higher frequency of major amputation in hemodialysis patients in comparison with other CKD groups, but comparable major amputation rates in patients in CKD 1-2 and 3-4 stages. Hemodialysis patients had significantly lower survival rate compared with patients with CKD stages 1-2. These results suggest that ACT is a reasonable therapy of CLI even in patients with severe CKD, but major amputation and survival rate are influenced by comprehensively different factors.

Serum levels of angiogenic cytokines in the assessment of vasculogenesis after autologous cell therapy in diabetic patients with critical limb ischaemia

A. Němcova, A. Jirkovska, M. Dubsky, R. Bem, V. Fejfarova, A. Pysna, J. Skibova;
Diabetes Centre, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Background and aims: Autologous cell therapy (ACT) is a promising method of revascularization for diabetic patients with no-option critical limb ischemia (CLI). Vasculogenesis, which is difficult to prove, is the likely mechanism of action of ACT, while percutaneous transluminal angioplasty (PTA) improves ischemia by different mechanism. The aim of our study was to evaluate the serum levels of angiogenic cytokines in diabetic patients with CLI treated by ACT in comparison to patients treated by PTA, and to assess the association of these cytokines with the clinical effect of ACT measured by transcutaneous oxygen pressure ($TcPO_2$) and with the number of injected angiogenic precursor cells (CD34+).
Materials and methods: Thirty-five patients with CLI treated by ACT in our foot clinic during 2008-2014 were consecutively included into the study. Fourteen patients who underwent PTA during the same period were included in a control group. The serum levels of pro-angiogenic cytokines such as vascular endothelial growth factor (VEGF), basic fibroblast growth factor (b-FGF), platelets-derived factors (PDGF-AA and PDGF-BB), and anti-angiogenic cytokine endostatin were measured by Luminex before revascularization and at 1, 3 and 6 months after the procedure and were correlated with the changes of $TcPO_2$ at the same intervals. The number of injected CD34+ cells was measured by fluorescence-activated cell sorting. Wilcoxon pair test and Spearman correlation coefficient were used for statistical analysis.
Results: We did not observe any significant increase of serum levels of pro-angiogenic cytokines in both groups. By contrast, the anti-angiogenic cytokine endostatin increased significantly at 1 and 3 months after ACT (both $p < 0.001$), however, no significant changes of endostatin after PTA was observed. $TcPO_2$ increased significantly at 1 and 3 months after ACT (from 17.9 ± 10 to 35 ± 15.8 mmHg, respectively 39.4 ± 11.6 mmHg, both $p < 0.001$). A significant correlation of $TcPO_2$ with endostatin at 1 month after the ACT ($r = 0.53$; $p < 0.001$) was observed. There was no significant correlation between endostatin and the number of injected CD34+ cells in ACT group.
Conclusion: Our study showed no relation between serum levels of pro-angiogenic cytokines and clinical effect of ACT measured by $TcPO_2$. On the other hand, the anti-angiogenic cytokine endostatin could be a potential marker of local vasculogenesis after cell therapy in diabetic patients with critical limb ischemia because of its significant increase after this therapy in contrast to PTA.

Are conventional risk factors enough to predict peripheral vascular disease?

B. Sosale[1,2], S. Reddy[2], P. Kumar[2], K.G. Seshadri[2], A.R. Sosale[2];
[1]Diacon Hospital, [2]Primer Academy of Medical Sciences, Bangalore, India.

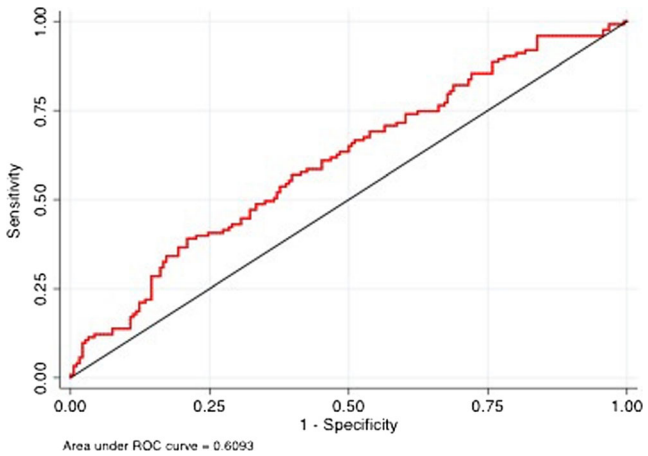
Background and aims: Patients with peripheral arterial disease (PAD) are at a high risk of lower limb amputations and cardiovascular mortality.

Screening for PAD is recommended in individuals with type 2 diabetes if one or more risk factors are present: age≥50 years, duration of diabetes≥10 years, overweight, obesity, hypertension, dyslipidemia and smoking. PAD is asymptomatic in the majority. Asymptomatic individuals have worse clinical outcomes. Screening, diagnosis and adequate treatment of risk factors is necessary even in asymptomatic individuals. In this study we aim to develop a prediction model that can accurately identify asymptomatic individuals at high risk of PAD.

Materials and methods: This was a cross-sectional study of 309 patients with diabetes and one risk factor for PAD: age≥50 years, diabetes duration≥10 years, hypertension, dyslipidemia, BMI≥23 kg/m^2 or smoking, attending the diabetes outpatient from April 2016 to October 2016. Symptomatic patients and those with preexisting PAD were excluded. PAD was diagnosed in individuals with an ankle brachial index (ABI) ≤0.9 and >1.3. Mean (95% CI), frequency (%), p values at 5 % level of significance were calculated using STATA 14. A logistic regression model to predict PAD was developed.

Results: Mean age (years), duration of diabetes (years), HbA1c % and BMI (kg/m^2) was 59.6 (58.7-60.5), 13.0 (12.2-13.8), 8.4(8.2-8.6) and 26.5(26.1-29.9). Sixty-five percent were men. Hypertension, dyslipidemia, smoking was present in 79.6%, 93.8% and 21.6%. Ischemic heart disease (IHD) was present in 11% and 2% had a previous stroke. PAD was diagnosed in 123 (39.8 %) patients. The log odds of developing PAD = -0.5+0.01*age-0.07*sex-0.01*diabetes duration in years + 0.06*hypertension + 0.5*dyslipidemia - 0.05*smoking - 0.1*HbA1c + 0.002*BMI + 0.5*IHD + 1*stroke. The Hosmer-Lemeshow goodness of fit showed good calibration(p=0.5). The AUC was 0.61.

Conclusion: The predictive model, despite good calibration had poor discrimination. Thus traditional risk factors are insufficient to discriminate between asymptomatic patients with and without PAD. It is hence necessary to look beyond conventional risk factor modelling, identify newer biomarkers and develop models to improve the predictive capacity of existing models. Till such time, it is essential to continue screening all type 2 diabetes individuals for PAD as per current recommendations.



Disclosure: **B. Sosale:** None.

Glucose variability and cardiovascular mortality in type 2 diabetes with lower limb lesions: Italian Leukaemia Association Treviso Project

M. Sambataro[1], A. Tura[2], L. Sambado[1], E. Trevisiol[3], E. Seganfreddo[4], M. Marcon[1], A. Furlan[5], P. Stefani[5], A. Paccagnella[1], M. Cacciatore[6], A. Dei Tos[6];

[1]Metabolic Unit, Santa Maria di Ca' Foncello Hospital, Treviso, [2]Institute of Neuroscience, CNR, Padova, [3]Pharmaceutical and Pharmacological Sciences, Santa Maria di Ca' Foncello Hospital, Padova, [4]Transfusion Medicine, Santa Maria di Ca' Foncello Hospital, Treviso, [5]Hematologic Unit, Santa Maria di Ca' Foncello Hospital, Treviso, [6]Pathology Unit, Santa Maria di Ca' Foncello Hospital, Treviso, Italy.

Background and aims: Diabetic foot treatment is a good target to reduce non traumatic limb amputations and cardiovascular mortality. Epidemiological studies confirm that vascular mortality prevalence in diabetic foot is similar to lung cancer mortality and its reduction is a public health burden. One possible link between diabetic peripheral and coronary heart disease is common distal limb and coronaric neuroischemia where vasculogenesis by bone marrow derived circulating endothelial progenitor cells and angiogenesis by local distal cells could reflect glucose variability load.

Materials and methods: 74 type two diabetic (T2D) patients with neuropathic foot lesions without (N1=30) or with (N2=44) critical limb ischemia (pO2 <30 mm Hg). N2 were older (60±2 vs 69±1 yrs), without differences in diabetes age, BMI, lipidis and HbA1c (8.2±0.3 vs 7.9±0.2). N2 patients were more complicated relatively to retinopathy, CHD, arterial hypertension and nephropathy. At time 0 we evaluated bone marrow precursor (BMPC)/peripheral blood precursor cells (PePC) CD34+ and bone marrow endothelial progenitor (BMEP)/peripheral blood endothelial progenitor cells (PeEP) CD34+KDR+ by flow citometry FACSCanto. We also considered available retrospective biochemical data (2-12 years) for mathematical indexes of variability relative to HbA1c and glycemia (Stability (SI) and Lability (LI) indexes, Standard Deviation (SD), Coefficient of Variation (CV), CONGA), and prospective 5 years interval time for death observation.

Results: We observed 5 cardiac deaths in N2 group and no deaths in N1 group. BMPC/PePC CD34+ ratio was significant higher in N1 vs N2 (71±18 vs 39±7 p=0.046) with a non significant BMPC CD 34+ increment in N1 vs N2 (4±1% vs 2,6±0,3 p=0.089) PeEP were significant higher in N1 vs N2 (7,8 ±1,1% vs 4,5±0,8 p=0.017). There were good correlations beetween SI for HbA1c and % BMPC (p=0.007 R^2=.364), SI for HbA1c and BMPC/PePC ratio (p=0.003, R^2=.29); correlation beetween SI for HbA1c and BMEP /PeEP ratio was borderline (p=0.0578, R^2=.132). In N2 group we also compared (for omology) alive (AN2) vs dead (DN2) patients and we found for HbA1c: SD: 6.27 [8.71] vs 10.97 [21.41] (median [IQR]), p=0.0364; CV: 10.20 [10.53] vs 16.96 [29.41], p=0.0217; CONGA: 5.59 [7.87] vs 20.75 [33.47], p=0.0043; LI: 8.10 [23.07] vs 93.08 [259.29], p=0.0008.

Conclusion: For the first time, we demonstrated that extracellular/hemathologic glycosylation could directly or indirectly impacts in tissue bone marrow progenitor stem cells capacity and distal tissues repair function. Mathematical indexes demonstrated to have a possible good clinical prognostic value for cardiac death in complicated neuroischemic T2D patients with diabetic foot. We hypothyze that at the beginning of prediabetic history normal bone marrow is an extremely sensible euglicemic setting where homeostasis of endothelial progenitor and tissue cells is prematurely lost with irreversible regeneration capacity.

Negative pressure wound therapy inhibits inflammation in diabetic patients with foot ulceration

R. He, F. Liu, W. Jia;

Department of Endocrinology and Metabolism, Shanghai Jiaotong University Affiliated Sixth People's Hospital, shanghai, China.

Background and aims: Negative pressure wound therapy (NPWT) was one of the most important treatments of diabetic foot, but the underlying mechanisms still remain elusive. This study aimed to evaluate the inflammatory signals involved in the effects of NPWT on diabetic foot ulcers.

Materials and methods: We enrolled 22 patients with diabetic foot ulceration, eleven treated with NPWT and others treated with traditional debridement. All the patients were treated and observed for 1 week. Granulation tissue harvested and analyzed in both groups, and was histologically and immunohistochemical analyzed. Enzyme-Linked Immunosorbent Assay (ELISA), Western blot analysis and real-time PCR were performed to evaluate expression of IL-6, TNF-α, iNOS, Nuclear Factor-κB P65, I_kB-α and activating transcription factor-3 (ATF-3).
Results: After 7 days treatment, NPWT could obviously promote diabetic wound healing because of the mild inflammation and densely cell deposited matrix. Meanwhile, NPWT significantly decreased the expression of TNF-α, IL-6 and iNOS (all $P<0.05$). The result of Western blotting and real-time PCR indicated that NPWT obviously decreased the level of I_kB-α and NF-κB P65 and increased the level of ATF-3 (all $P<0.05$).
Conclusion: NPWT exerts an anti-inflammatory effect possibly through the suppression of pro-inflammatory enzymes and cytokines resulting from IkB-α inhibition and ATF-3 activation, which maybe prevented the activation of NF-κB pathway in human diabetic foot wounds.

Negative pressure wound therapy effect in diabetic foot ulcer may be mediated through differential gene expression

S. Borys, A. Ludwig-Galezowska, P. Kapusta, M.T. Seweryn, J. Machlowska, T. Koblik, J. Hohendorff, B. Kiec-Wilk, P. Wolkow, M.T. Malecki;
Jagiellonian University Medical College, Krakow, Poland.

Background and aims: Diabetic foot syndrome (DFS) frequently leads to patient disability due to foot and leg amputations. Negative pressure wound therapy (NPWT) has been successfully used for ulcerations in DFS. However, its mechanisms of action on the molecular level are not fully understood. The aim of this research was to assess the effect of NPWT on the gene expression.
Materials and methods: We have included 21 type 2 diabetes (T2DM) patients with foot ulcer treated with NPWT and 8 T2DM patients treated by conventional debridement. Tissue samples were obtained from the bottom of the ulceration at two time points: before the therapy was started and after 8 days of treatment. Total RNA was extracted and gene expression profiling was performed by means of Illumina human gene expression arrays. Differential expression of mRNAs was performed using the standard R Bioconductor pipeline based on 'limma' package.
Results: The studied groups were similar in terms of age at the examination 69.0 ± 8.3 vs. 67.5 ± 4.3 years (p=0.62), sex: 80,9% vs. 75,0% male (p=0.72), T2DM duration: 14.7 ± 7.1 vs. 14.9 ± 6.0 years (p=0.95), and other basic clinical characteristics. We identified 6 genes with differential expression ($p<0.05$) between the two time points studied (after the Benjamini-Hochberg correction for multiple testing). Expression of only one of them - RRP7A which is involved in rRNA processing - increased over 2-fold after the treatment (logFC = 0.322, p=0.032), while the remaining 5 genes were downregulated. Two of differentially regulated genes - CYP27A1(logFC=-0.57, p=0.02) and CLYBL (logFC=-0.08, p=0.034)- associate with mitochondrial function. Two other genes - SRGAP3 (logFC = -0.14, p=0.013) and TRAPPC6A (logFC = -0.12, p=0.032) are associated with endoplasmic reticulum and Golgi apparatus, respectively. Finally, the KIAA1683 gene (logFC = -0.105, p=0.035) encodes a protein interacting with Calmodulin (CaM) messenger protein, which specific function has yet to be determined.
Conclusion: In summary, we found initial evidence that NPWT effect in diabetic foot ulcer may be mediated through differential gene expression. This finding requires further confirmation.

Endoplasmic reticulum stress and autophagy dysfunction: implications in skin repair in a mouse model of diabetes

E. Carvalho[1,2], A. Burgeiro[3], E. Leal[1], T. Emanuelli[1];
[1]Center for Neurosciences and Cell Biology, University of Coimbra, Coimbra, Portugal, [2]Department of Geriatrics, University of Arkansas for Medical Sciences, Little Rock, USA, [3]Center for Neurosciences and Cell Biology, Coimbra, Portugal.

Background and aims: Emerging evidence links dysfunction in key cellular organelles with insulin resistance, impaired insulin secretion and diabetic complications. This study was aimed at investigating whether dysfunction in endoplasmic reticulum (ER) and changes in the autophagy response, are associated with impaired wound healing and repair in diabetic mice.
Materials and methods: C57BL/6 male mice (n=8/group) were divided into diabetic (streptozotocin-induced; glycemia above 250 mg/dL) and control (non-diabetic) groups. The skin from the dorsal region was excised (6-mm diameter) to create wounds (day 0) and skin samples used to assess molecular markers at baseline. Ten days after wounding skin biopsies were harvested to assess gene and protein expression of metabolic intermediates involved in the unfolded protein response (UPR) ER stress and autophagy.
Results: The expression of UPR pathway proteins GRP78 and GRP94 was increased in the skin of control mice after wounding (8.5 and 2.2-fold vs. before wounding, $p\leq0.05$) without changes in gene expression. Diabetic mice also presented increased expression of these proteins after wounding (10.5 and 5-fold vs. before wounding, $p\leq0.05$), although the post wounding levels for GRP78 were about 2 fold lower compared to control mice ($p\leq0.05$). Skin wounds from diabetic animals did not show increased ER stress-mediated apoptosis since CHOP levels were similar to those in the control mice 10 days after wounding. Moreover, proteins involved in chaperone-mediated autophagy (Lamp2) and macroautophay (Beclin1, p62) were also significantly increased after wounding ($p\leq0.05$) without changes in gene expression.
Conclusion: Macroautophagy is increased in skin wound healing of control mice while in diabetic mice have impaired expression of proteins involved in this pathway. UPR, macroautophagy and chaperone-mediated autophagy were activated during skin wound healing regardless of the presence or absence of diabetes. Thus, autophagy and the UPR activation crucial for wound healing and tissue repair. Under diabetes conditions the macroautophay response was impaired, in part contributing to the dysfunctional healing/repair capacity observed in diabetes. This suggest that macroautophagy could be a potential therapeutic target for diabetic foot ulcers.

Effector T-cell accumulation and reduction in TCR diversity as a promising early DFU biomarker

J. Moura[1], J. Rodrigues[2], M. Gonçalves[2], C. Amaral[2], M. Lima[2], E. Carvalho[1];
[1]CNBC, Coimbra, [2]HSA-CHP, Porto, Portugal.

Background and aims: Chronic diabetic foot ulcerations (DFUs) are the most debilitating complications of diabetes and are caused by uncontrolled infections of foot wounds, often a consequence neuropathy, impaired angiogenesis and chronic low-grade inflammation. Long-term hyperglycemia promotes NF-kB activation, impairing leukocyte activation and migration and leading to a chronic inflammation, but glucose-lowering treatment does not reduce the risk of DFU, because the effects of long-term hyperglycemia on the immune system continue even after

glycemic stabilization. We have demonstrated that diabetes has a profound impact on the circulating T-cell pool, promoting the accumulation of effector T-cells to a point where T-cell receptor (TCR) diversity may become an issue to the immune response and that these effector T-cells aggravate the inflammatory phenotype thorough the secretion of inflammatory cytokines, such as TNF-α and IFN-γ.

Materials and methods: To ascertain if effector T-cell accumulation and reduction in TCR diversity can be used as an early DFU biomarker, we underwent longitudinal studies on patients with first-time, acute, foot ulcerations (n=17), and evaluated the percentage of peripheral blood effector ($CD3^+CD27^-CD28^-$) and naïve ($CD3^+CD27^+CD28^+CD45RO^-$) T-cells, by flow-cytometry and measured the TCR repertoire diversity by PCR-based studies using the well-established Biomed protocol. We also analyzed the same parameters on familiars of patients with DFU (n=5), to evaluate the influence of genetic predisposition on the reduction in TCR repertoire diversity. We divided the patients with diabetic foot ulcerations into two groups, the ones that healed in less than 3 months (n=9) and the ones that did not heal in the 3 months' period (n=8).

Results: When plotting the ratio between effector and naïve T-cells in the two DFU groups, our results show that patients that have acute ulcers that fail to heal in less than 3 months have a much higher ratio (3,5±1,7) than the ones that heal in less than 3 months (p&lt0,05). The higher effector/naïve T-cell ratio is accompanied by a severe reduction in TCR repertoire diversity (p&lt0,05). We also show that sons of patients with DFU have higher effector T-cell counts, when compared to control individuals, even when they are not diabetic, but these results are still not statistically significant due to the reduced sample size.

Conclusion: Taken together, our results demonstrate the usefulness for the quantification of blood effector T-cells and the analysis of the TCR repertoire diversity as early DFU biomarkers and open new perspectives on DFU treatment trough the negative regulation of effector T-cell function.

Long-term changes in the RANK/RANKL/OPG system in diabetes patients with and without a Charcot foot

R.B. Jansen[1], T. Møller Christensen[1], J. Bülow[2], L. Rørdam[2], P. Holstein[3], N. Rye Jørgensen[4], O. Lander Svendsen[1,3];
[1]Dept. of Endocrinology, Bispebjerg Hospital, [2]Dept. of Clinical Physiology and Imaging, Bispebjerg Hospital, [3]Copenhagen Diabetes Foot Center, Bispebjerg Hospital, Copenhagen, [4]Dept. of Clinical Biochemistry, Glostrup Hospital, Glostrup, Denmark.

Background and aims: Charcot osteoarthropathy (Charcot foot) is a rare but severe complication to diabetes mellitus and peripheral neuropathy. While the precise pathogenetic mechanism is unknown, recent studies have reported changes in biomarkers of bone inflammation and resorption in individuals with Charcot foot, specifically within the RANK/RANK-L/OPG system. It has been suggested that there is an increase in the RANKL/OPG ratio in the acute Charcot foot. The aim of this study was to investigate this system further in individuals with diabetes with and without Charcot foot.

Materials and methods: An 8.5-year follow-up case-control study of 44 individuals with diabetes mellitus, 24 of whom also had acute or chronic Charcot foot at the baseline visit in 2005-2007, who were followed up in 2015. Serum from baseline were stored at -80° C, and all samples analyzed by ELISA at follow-up for fsRANK-L and OPG, as well as sRAGE.

Results: Of the 44 participants at baseline, 22 were able to participate in the follow-up, while 9 had passed away, 3 were out of reach and 10 were unable or unwilling to re-participate. No participants had active foot ulcers, recent foot surgery or Charcot activity at follow-up. At follow-up, the average age of the participants was 69 yrs with a diabetes duration of 27 yrs. There were 18 were males and 4 females, 7 with type 1 diabetes and 17 with type 2 diabetes, and the average HbA1c was 59 mmol/mol. From baseline to follow-up, there was a significant difference in the change in levels of fsRANK-L between the diabetes patients with Charcot compared the diabetes patients without Charcot (-0.11 and -0.02 respectively)(p=0.018). There was no difference in the OPG levels, or change to these between the groups. At baseline, there was a significantly higher fsRANK-L/OPG ratio in the diabetes patients with Charcot than in the patients without Charcot (5.3 versus 1.6)(p=0.016), as well as a significant decrease in the fsRANK-L/OPG ratio from baseline to follow-up in the diabetes patients with Charcot (1.8 to 0.5 respectively)(p=0.006). Regarding sRAGE, there were no difference between the diabetes patients with and without Charcot at baseline and there was no difference in the change between baseline and follow-up between them either (p=0.470).

Conclusion: This study showed that there may be an elevated fsRANK-L/OPG ratio in diabetes patients with an acute Charcot foot, and that this increased level seems to decrease again with time to a level similar to diabetes patients without previous or current Charcot foot.

PS 087 The lifelong story of retinopathy

1021

Relationship between choroidal thickness, microalbuminuria, neuropathy and metabolic abnormalities in subjects with different degrees of glucose tolerance

F. Gerchman[1], G.F. Piccoli[2], M.A. Beer[3];
[1]Endocrine Division, Hospital de Clínicas de Porto Alegre, [2]Universidade Federal do Rio Grande do Sul, [3]Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil.

Background and aims: Hyperglycemia is classically related with the development of microvascular complications associated with diabetes mellitus. However, several studies have demonstrated the development of these complications in subjects with prediabetes and the metabolic syndrome. This study aims to identify earlier findings of microvascular complications in subjects with different degrees of glucose tolerance.

Materials and methods: In this cross sectional study 64 subjects underwent a standard protocol comprising anthropometric evaluation, biochemical assessment of fasting glucose, 2h-glicemia, glycosylated hemoglobin, vitamin B12, HDL-cholesterol, triglycerides, urinary sample albumin and the estimation of glomerular filtration by CKD-EPI. Ophthalmologic evaluation was performed by funduscopy and optical coherence tomography (OCT) on both eyes. Autonomic, peripheral, and small fiber neuropathy were respectively assessed by heart rate variability (HRV), Michigan questionnaire and quantitative sensitive test (QST). We used tuning fork to evaluate vibratory thresholds and Semmes-Weinstein 10g monofilament to assess foot sensitivity. A 24-hour ambulatory blood pressure monitorization (ABPM) was performed to evaluate pressure homeostasis.

Results: Patients were classified according to their glucose tolerance as normal glucose tolerance (NGT=14), prediabetes (PDM=20) and type 2 diabetes (T2DM=30). Groups differed by age, systolic blood pressure (day and night) and triglycerides (table 1). Choroidal thickness decreased with decreasing glucose tolerance in the right [NGT 332 (250.5-421.5) vs. PDM 260.0 (214.2-341.2) vs. T2DM 214.0 (170.0-273.0) μm; p<0.001] and left [NGT 320.0 (288.0-428.0) vs. PDM 271.0 (185.2-343.0) vs. T2DM 221.0 (181.0-274.0) μm; p< 0.01] eyes. One patient in the NGT and 3 patients in T2DM group had diabetic retinopathy (p=0.35). Albuminuria increased with decreased glucose tolerance [NGT 5.0 (3.0-19.2) vs. PDM 7.4 (3.0-27.7) vs. T2DM 18.5 (7.3-51.3) mg/dl; p=0.033]. Likewise, a higher pulse pressure, a cardiovascular risk marker, was found in patients with progressive decrease of glucose tolerance (NGT 42.43±5.52 vs. PDM 56.50±13.82 vs. T2DM 53.54±12.08 mmHg. p=0.003). No differences were found in peripheral neuropathy and most of the cardiac autonomic tests.

Conclusion: This study demonstrates a tendency to early microvascular changes related with worsening glucose tolerance.. It also suggests that earlier abnormalities of the choroidal vasculature may be identified in subjects with PDM being possibly an earlier marker of the development of diabetic retinopathy in a population with impaired glucose metabolism.

Prediction models for the risk of retinopathy in people with type 2 diabetes. A systematic review

A.A.W. van der Heijden, F. Badloe, G. Nijpels, J.W. Beulens;
Amsterdam Public Health Institute, VU University Medical Center, Amsterdam, Netherlands.

Background and aims: A complication of type 2 diabetes (T2D) is retinopathy and early detection and treatment of vision-threatening retinopathy is of importance to prevent blindness. Prediction models for retinopathy enable identifying persons at high retinopathy risk, facilitating tailored monitoring. We aimed to identify all prediction models for retinopathy risk applicable to people with T2D and to assess their quality and accuracy.

Materials and methods: A systematic search was performed in PubMed and Embase in March 2016. Studies were included when: (i) the prediction model was applicable to people with T2D; (ii) the outcome was any stage of retinopathy or blindness and (iii) minimal follow-up of the development study was one year. Data extraction and risk of bias assessment was performed using the CHARMS-checklist. Performance of the models (internal validation) was assessed by discrimination, the ability of the model to identify those at risk (e.g. c-statistic), and calibration, the ability of the model to accurately quantify the absolute risk (e.g. Hosmer-Lemeshow-test). Screening, full-text assessment and data-extraction was performed independently by two reviewer and by a third reviewer in case of disagreement.

Results: From 6481 studies, nine were included in the systematic review. The models predicted the development of retinopathy, macular edema or blindness over a period of two to ten years based on two to nine predictors per model, of which). Age, duration of diabetes, HbA1c, systolic blood pressure and presence of a less severe form of retinopathy, were the most commonly used predictors. Eight studies performed an internal validation. Discrimination was reported in five studies with c-statistics ranging from 0.61 (95% CI:0.52 to 0.71) to 0.79 (95% CI: 0.76 to 0.81). Only two studies reported calibration using the Hosmer-Lemeshow test (p-values:0.2 and 0.13). Four studies reported external validation in an independent population as part of the model development and the discriminative ability ranged from 0.55 (95% CI: 0.47 to 0.62) to 0.84 (95% CI: 0.78 to 0.88).

Conclusion: Nine prediction models for the risk of retinopathy in people with T2D are available with moderate to good performance. However, most models were not validated in an external population. Performance of four models in an independent population ranged from poor to good. Before application in clinical practice, external validity of all these models and their impact on the efficiency of care should be assessed.

Diabetic retinopathy in cystic fibrosis related diabetes

M.S. Ahmed, A. Tahrani;
Diabetes and Endocrinology, Heart of England NHS Foundation Trust, Birmingham, UK.

Background and aims: Diabetes mellitus is a major comorbidity associated with cystic fibrosis. The prevalence of cystic fibrosis related diabetes (CFRD) has risen over time contributing up to 40% of adults and 25% of adolescents with cystic fibrosis (CF).The life expectancy of these patients has increased significantly in the recent years and it is more likely that some will develop

microvascular complications.Aim of this study is to determine the prevalence and predictors of diabetic retinopathy (DR) in patients with cystic fibrosis related diabetes (CFRD)

Materials and methods: A retrospective study of patients attending the CFRD clinic in a tertiary care centre was conducted. Data regarding patients with CFRD and CF exacerbations were obtained from CF database at our centre. Retinal images and grades were obtained from the national retinal screening programme. Patients were included if they had at least 2 retinal screening visits at least 1 year apart

Results: 54 patients with average age of 32.5 years (range 19-63) were included. The mean diabetes duration was 8.6 years (range 2-26); 92% of patients were Caucasian; 26(48%) were men. Baseline mean HbA1C was 7.2% (range 5.1-13.8). At baseline DR prevalence was (77.8%R0, 20.4%R1, 1.9%R2, 0%R3, 0%M1). From baseline DR progressed in 7 patients (17%) after a mean follow up of 3.7 Years. 6(14.6%) patients progressed from R0 to R1 and 3(7.3%) from M0 to M1. There was no progression from R0 to R2 or R3 but 1(2%) patient progressed from R1 to R3. After adjusting for age, gender, duration of diabetes, baseline HbA_1C and retinal grading and study end FEV_1, only total cholesterol at baseline predicted progression of retinopathy (OR 3.6; 95% CI 1.02-13.02). BMI, smoking status, number of exacerbations of CF, type of organism grown in sputum culture/sensitivity and serum creatinine did not have any correlation with DR progression

Conclusion: DR was common in CFRD but sight threatening retinopathy was uncommon. A small proportion of patients developed DR after 3.7 years of follow up. Total cholesterol, not Hba1C or duration of diabetes predicted DR progression. There is a need for further research to understand the pathogenesis of DR in CFRD

Abnormal renal profile predicts proliferative diabetic retinopathy and diabetic macular oedema in patients with type 2 diabetes: an 8-year prospective cohort study

Y.-T. Hsieh[1], M.-C. Hsieh[2], M.-J. Tsai[3], S.-T. Tu[2];
[1]Ophthalmology, National Taiwan University Hospital, Taipei, [2]Internal Medicine, Changhua Christian Hospital, Changhua, [3]Ophthalmology, Taipei Tzu Chi Hospital, Buddhist Tzu Chi Medical Foundation, New Taipei, Taiwan.

Background and aims: To investigate the effect of diabetic kidney disease on the development of diabetic retinopathy (DR) and diabetic macular edema (DME) in type 2 diabetes (T2D).

Materials and methods: An 8-year prospective cohort study with 2,135 patients of T2D were conducted in Taiwan. The baseline and mean follow-up renal profile including serum creatinine level, estimated glomerular filtration rate (eGFR) and urinary albumin creatinine ratio (ACR) were measured. Cox regression analysis was used to evaluate the hazard ratios (HRs) of the renal profile for the new onset of DR, proliferative diabetic retinopathy (PDR) and DME.

Results: A higher serum creatinine level (HR = 2.358 for an increase of 1 mg/dL, $p < 0.0001$), an eGFR <60 mL/min/1.73m^2 (HR = 3.037 to 6.436, $p < 0.0001$), and a urinary ACR >30 mg/g (HR = 3.202 to 6.652, $p < 0.0001$) at baseline were all significant predictors for the development of PDR. After adjusting the baseline values, the mean follow-up values including a higher serum creatinine level (HR = 2.369 for an increase of 1 mg/dL, $p < 0.001$), an eGFR <30 mL/min/1.73m^2 (HR = 6.807, $p < 0.0001$), and a urinary ACR >30 mg/g (HR = 2.344 to 4.193, $p = 0.011$ and 0.003) were significant predictors for the development of PDR. A baseline urinary ACR >30 mg/g (HR = 1.563 to 2.717, $p = 0.018$ and < 0.0001) was significantly predictive for the development of DME.

Conclusion: Both baseline and mean follow-up abnormal renal profiles including a high serum creatinine level, a low eGFR and a high urinary ACR were all significant predictors for new-onset PDR in patients with T2D. A high baseline urinary ACR was a significant predictor for the development of DME.

1025

10 year follow-up of background diabetic retinopathy within a national screening programme in Wales

R.L. Thomas, R.V. North, D.R. Owens;
Diabetes Research Unit Cymru, Swansea University, Swansea, UK.

Background and aims: The aim of this study was to examine the progression of diabetic retinopathy (DR) in persons with non-sight-threatening DR (NSTDR e.g. background DR [BDR]) over a 10 year period.

Materials and methods: Data from persons with diabetes attending Diabetic Eye Screening Wales (DESW) between 2003 and 2013 were evaluated. Survival analysis (Kaplan Meier and Cox regression) were used to explore the progression from NSTDR to sight-threatening DR requiring referral to hospital eye services.

Results: A total of 1,538 people with Type 1 diabetes and 17,407 with Type 2 diabetes with NSTDR were included in the analysis. Of those with type 1 diabetes 712 had minimum BDR and 826 had Moderate BDR and of those with Type 2 diabetes 10,553 had minimal BDR and 6,854 had moderate BDR. In Type 1 diabetes there was a 2 fold increased risk of progression to Sight-threatening DR in those with moderate compared to minimal BDR when adjusted for age, gender and duration of diabetes (Table 1). Similarly there and a 2.9 fold increased risk of progression to referable DR in type 2 diabetes

Conclusion: Extending the screening interval from 1 to 2 years in persons with type 2 diabetes with minimal BDR appears justified (progression rate of 0.1% in the first 12 months). However, for persons with type 2 diabetes with moderate BDR and Type 1 diabetes with any severity of BDR annual screening should be retained.

Table 1: Cox regression analysis for the progression to sight-threatening DR

	multivariate		multivariate
Age	0.99 (0.97, 0.996)	Age	0.98 (0.98, 0.99)

1026

The role of clinical covariates in informing personalised retinopathy screening intervals

A. Ochs[1], S. McGurnaghan[1], G.P. Leese[2], P.M. McKeigue[3], H.M. Colhoun[1,4], SDRN Epidemiology Group, Scottish Diabetic Retinopathy Collaborative;

[1]The Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, [2]Department of Medicine, Ninewells Hospital and Medical School, Dundee, [3]Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, [4]Department of Public Health, NHS Fife, Kirkcaldy, UK.

Background and aims: Diabetic Retinopathy (DR) is a diabetes complication of the eye and the leading cause of blindness in the working age population. Blindness from DR is preventable through early diagnosis and treatment. Scotland, among other countries, introduced a DR screening programme, where all patients with diabetes aged ≥12 are screened annually. As risk of developing referable DR is low on average, but varies between patients, it seems useful to personalise screening intervals to patients' individual risk. Previous literature has focussed on using prior screening outcome to stratify subsequent risks. This study investigates the benefits of additionally including patient demographics and clinical covariates to stratify risk of progressing to referable DR and shows how using this prediction in setting screening intervals affects discrimination between patients and number of screenings.
Materials and methods: This retrospective cohort study used screening data, for patients aged ≥12 with type 1 (T1D) and type 2 (T2D) diabetes, from the Scottish Diabetic Retinopathy Screening Programme and linked clinical data from Scottish Care Information Diabetes for the years 2007-2015. Binary logistic regression with cloglog link function for interval-censored data was used to model absolute risks of transition from the second screening episode to referable DR. Models with various covariates, including previous DR grade, patient demographics and potentially relevant clinical covariates (BMI, HbA_{1c}, blood pressure, blood lipids, eGFR, visual acuity, smoking status, statin and hypertensive drug use, cardiovascular disease status), were fitted using different model selection mechanisms. Models were developed on a training dataset and evaluated on a test dataset. Models were assessed for their goodness of fit (AIC) and classification (AUROC) along with their impact on yield and number of screenings.
Results: Analyses were based on 215501 patients (T1D n=17788) and 999961 screenings. Screening yield of referable DR was 3.96%/1.34% per annum for T1D/T2D. Patients' previous DR grade was a strong predictor of transition to referable DR (AUROC: 0.6862/0.7126 (T1D/T2D)). Additionally, including a full set of clinical covariates increased the AUROC to 0.7165/0.7761 (T1D/T2D) and statistically significantly ($p<0.001$) improved model fit. Restricting the model to the four most important predictors offered a comparable AUROC and model fit. Models including clinical covariates had better predictive performance than those that only used examination results. Individualised screening intervals could be based on the time at which the predicted risk of a referable DR reaches a specified level e.g. 1%; using 1% as the threshold these models could reduce the number of screenings by 11% for T2D, and leave the number of screenings for T1D unchanged.
Conclusion: This study shows that including clinical covariates improves prediction of transition to referable DR and that it is a useful step towards personalising screening intervals, and reducing screenings for T2D.

Prevalence of retinopathy among United States adults with both diabetes and chronic kidney disease

M.E. Pavkov, C.-F. Chou, J.B. Saaddine;
Centers for Disease Control and Prevention, Atlanta, USA.

Background and aims: Diabetes is the leading cause of kidney failure in the United States (U.S.). The presence of diabetic retinopathy (DR) is a reliable screening tool for identifying those at highest risk for chronic kidney disease (CKD) progression. No national population-based estimates of the prevalence and severity of DR exist among people with diabetes and kidney disease. The aim of the present study was to estimate the prevalence of DR among U.S. adults with both diabetes and CKD.
Materials and methods: Prevalence of DR was estimated in adults 40 years and older with both diabetes and CKD participating in the National Health and Nutrition Examination Surveys (NHANES) 2005-2008. DR was defined by the presence of +1 retinal microaneurysm or retinal blot hemorrhages with or without more severe lesions on fundus photographs taken with a digital non-mydriatic camera. Vision-threatening DR was defined by the presence of severe non-proliferative DR, proliferative DR, or clinically significant macular edema. CKD was defined by albumin/creatinine ratio above 30 mg/g or estimated glomerular filtration rate below 60 ml/min/1.73m². Diabetes was defined as HbA1c greater than 6.5% or self-report of diagnosis by a doctor or other health professional. Logistic regression was used to examine demographic and clinical determinants of DR.
Results: The study sample included 387 adults with diabetes and CKD, representing 4.9 million U.S. adults. The prevalence of DR was 36.2% (95% CI 30.1-42.7), and of vision threatening DR 8.2% (95% CI 5.4-12.2). Compared with persons without DR, those with DR were on average older, with higher HbA1c, higher blood pressure, longer diabetes duration, and had insulin treatment. In a multivariable adjusted model, the odds of DR were 50% higher per 1% increase in HbA1c (95% CI 1.2-1.9), 40% higher for every additional 5 year diabetes duration (95% CI 1.1-1.7), 3% higher per 10 mmHg increase in systolic blood pressure (95% CI 1.02-1.1), and 13-fold higher with insulin treatment (OR=13.3, 95% CI 2.2-81.7) ($p<0.001$ for each risk factor, with additional age, sex, and race/ethnicity adjustment). Overall, the prevalence of DR was higher than in the earlier NHANES after adjusting for age, sex, race/ethnicity, mean blood pressure, and HbA1c, whereas the prevalence of vision threatening DR remained largely unchanged over time.
Conclusion: Over one third of this nationally representative sample of adults with both diabetes and CKD had DR, representing 1.8 million U.S. adults at high risk for CKD progression. Many of the studied risk factors associated with DR are modifiable.

Cluster analyses of patients with dysregulated type 2 diabetes based on routine clinical markers reveal cluster-specific prevalence of diabetes complications

A. Ali[1], N. Safai[1], P. Rossing[1,2], M. Ridderstråle[3];
[1]Steno Diabetes Center Copenhagen, Gentofte, [2]University of Copenhagen, Copenhagen, [3]Novo Nordisk A/S, Søborg, Denmark.

Background and aims: Type 2 diabetes is a heterogeneous disease with genetic and lifestyle factors contributing to its development and progression. In addition, there is a large variation between patients in the development of diabetes related complications making it unlikely that it represents one disease entity. Here we tested the hypothesis that diabetes patients may be clustered based on routine clinical variables in patients with dysregulated type 2 diabetes referred to a specialist center for treatment.
Materials and methods: Diabetes related clinical measures including age of disease onset, diabetes duration, GAD antibody positivity, and BMI, HbA1c, HOMA-B, and HOMA-IR at presentation, were

used for clustering the patients using the K-means clustering algorithm. Odd ratios for diabetes complications including cardiovascular disease, nephropathy, neuropathy and retinopathy, were calculated using logistic regression in R.

Results: Based on our data from patients referred for dysregulated type 2 diabetes (n = 2290) we found that a maximum 5 cluster solution was possible when tested for within-cluster similarity from 1000 bootstrapped similarity estimates. The five clusters were primarily characterized or driven by early insulin resistance (C1; 21%), autoimmunity (C2; 3%; miss-classified type 1 diabetes), age (C3; 32%), insulin deficiency (C4; 22%), and obesity and insulin resistance (C5; 22%), respectively (Table 1). Retinopathy was significantly more common (odds ratio (CI) 2.45 (1.67-3.47), p = 1.14E-05) in the cluster characterized by insulin deficiency (C4), and nephropathy was significantly more common (odds ratio (CI) 1.80 (1.31-2.49), p = 2.99e-04) in the cluster characterized by obesity and insulin resistance (C5), in logistic regression models adjusted for age of disease onset, sex and diabetes duration. In addition, we found a lower incidence of cardiovascular disease in the small cluster likely to represent miss-classified type 1 diabetes (odd ratio = 0.45, p = 0.04). We found no significant cluster specific association for diabetic neuropathy.

Conclusion: Patients referred for dysregulated type 2 diabetes may be clustered into clinically relevant subgroups based on routine clinical markers. The prevalence of diabetes complications seems to be cluster-specific. Our data underlines the need for a tailored strategy for the treatment of type 2 diabetes and prevention of its complications.

Assigned Cluster / Cluster Characteristics	Cluster 1 early Insulin resistance	Cluster 2 Autoimmunity	Cluster 3 Age	Cluster 4 Insulin deficiency	Cluster 5 Obesity and Insulin resistance	All patients
Patients (n)	490	65	727	510	498	2290

An effective risk-stratification algorithm to prioritise diabetes retinal screening in previously unscreened, low income, minority communities

E. Ipp[1], L. Serpas[1], P. Genter[1], J. Macias[1], D. Campa[2], Y. Lu[3];
[1]Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, [2]Los Angeles County Department of Health Services, Los Angeles, [3]California State University Long Beach, Long Beach, USA.

Background and aims: Routine screening for diabetic retinopathy (DR) is a cornerstone of secondary prevention in people with diabetes because treatment of sight-threatening DR (STDR) - if recognized early enough - is effective in preventing visual loss. Yet diabetes remains the single most common cause of blindness in the working-age population in the United States. Low DR screening rates account for this in part, and are especially prevalent in low-income and minority populations. The aim of this study was to develop and validate a risk-stratification algorithm (RSA) to identify patients at high risk for STDR to prioritize DR Screening based on risk. Our overall goal is to improve DR Screening in low income, safety net populations in resource poor environments.

Materials and methods: The algorithm was developed with patient registry data in Clinic 1, and used to predict STDR risk using data from Clinic 2. Both clinics serve primarily Latino and African American patients in low-income areas of a large metropolitan area. In Clinic 1, we used readily available clinical data (age, sex, albumin-creatinine ratio, A1C, insulin use status) to develop an RSA. The RSA was set up without the benefit of results from earlier DR screening as a parameter for the algorithm. This was necessary because in our low-resource health care system many patients did not have prior retinal screening. To our knowledge this is the first RSA developed specifically for a low-resource, safety net population.

Results: Risk factors for DR were similar in the 2 clinics: presence of microalbuminuria (24-28%) and A1C were similarly distributed (p=NS). However in Clinic 1, patients were younger (mean 53 vs. 57 yrs) and fewer used insulin (15 vs 22%) than in Clinic 2 ($p<0.05$). The RSA to predict STDR was developed in Clinic 1 using data from 752 patients with diabetes who had undergone routine DR Screening (%STDR = 13.9). Area under the Receiver Operating Characteristics curve was 79.8% with sensitivity 69.2% and specificity 79.0%. We then applied the RSA to two retrospective validation cohorts in Clinic 2 to determine its effectiveness to identify patients at high risk for STDR. Cohort A included 585 diabetic patients who underwent routine teleretinal DR Screening. STDR was found in 55 patients (9.4%), most of whom were ranked as high risk by the RSA. By applying the RSA, 76.4% of the patients with STDR would have been identified before the program completed screening half of all patients. In Cohort B, there were 105 patients with STDR (8.9% of 1,178). Of these, 88.6% (n=93) would have been similarly identified by the RSA.

Conclusion: These data suggest that using a combination of simple and routinely obtained demographic and laboratory data, it is possible to predict the likelihood of identifying STDR. We conclude that a simple risk-stratification algorithm can be used to prioritize patients for early DR screening in low-income, minority patients. Because the algorithm was successful without the benefit of results from a previous DR screening, this approach may be useful in other low resource communities with a high prevalence of diabetes.

Relation between the glycaemic exposure indicated by total excessA_{1c} index and retinopathy in type 1 diabetes: a DCCT/EDIC subgroup analysis

A. Hirose[1], S. Kitano[1], Y. Uchigata[2];
[1]Diabetic Ophthalmology, Tokyo Women's Medical University, [2]Tokyo Women's Medical University, Tokyo, Japan.

Background and aims: It has not been sufficiently examined that the combination of how high and how long of the glycemic exposure may give effects on retinopathy in patients of type 1 diabetes, though degree of hyperglycemia indicated by HbA1c and duration of diabetes were shown to be the most important factors on retinopathy in DCCT. We have reported that an index, total ΣexcessA1c, integrating both data of HbA1c and duration of diabetes may substantially predict retinopathy, if we use HbA1c data of the total diabetes duration to exclude the disturbing effect of metabolic memory in our type 1 diabetes patients. We examined relation between excess glycemic exposure and early retinopathy in type 1 diabetes using the total excessA1C value in the public data of DCCT/Epidemiology of Diabetes Interventions and Complications (EDIC).

Materials and methods: To examine only selected cases of DCCT/EDIC, those who had HbA1c data during nearly their entire period of hyperglycemia, we included patients of primary prevention with the shortest diabetes duration (≤14 months) at DCCT baseline. We also included only patients who had data of retinopathy in all of the three periods (year 5, year 9 and year13 after diabetes onset). Retinopathy was evaluated by steps in the final Early Treatment Diabetic Retinopathy Study (ETDRS) severity scale for persons. Total excessA1C(7.5%) was calculated by adding all the values of each yearly HbA1c value minus a threshold of 7.5% (National Glycohemoglobin Standardization Program value; 58mmol/mol) from the first year of onset of diabetes to a given year. We calculated it supposing that each case had one-year duration at DCCT baseline. We examined relations between total excessA1C(7.5%) value and retinopathy steps of ETDRS (step 1-4). The Wilcoxon rank sum test was performed using JMP version 13.0.0 (SAS, Cary, NC). Two-sided P value<0.05 was considered significant.
Results: The mean duration of diabetes of the 70 patients who fulfilled the criteria was 12.2 months (range 8-14) at the DCCT baseline, indicating that patients were followed from almost just after onset. In each of 4 steps of retinopathy, there were no significant differences in total excessA1C(7.5%) value between any pairs of groups of year 5, 9 and 13 (P>0.3278 in all of 12 pairs). Then we combined values of year 5, 9 and 13 in each 4 steps (n=70 in each step). P values between step 1-2, step 2-3 and step 3-4 were 0.1463, 0.0254 and 0.0418, respectively. Median values of total excessA1C(7.5%) showed a substantial linear distribution (0.18 in step 1, 3.65 in step 2, 6.80 in step 3 and 12.84 in step 4; Figure). For example, the value of 13 in total excessA1C(7.5%) almost corresponds to the HbA1c value of 10% for 5 years, 9% for 9 years and 8.5% for 13 years, respectively.
Conclusion: Total excessA1C may have a capacity in describing the relation between glycemic exposure and early retinopathy in type 1 diabetes regardless of years of observation.

Can (poly)phenols metabolites ameliorate the outcome of diabetic retinopathy

D.F. Santos[1,2], C.N. Santos[3,4], G.A. Silva[1];
[1]CEDOC, Chronic Diseases Research Centre, NOVA Medical School|Faculdade de Ciências Médicas, Universidade NOVA de Lisboa, [2]ProRegeM PhD Programme - NOVA Medical School|Faculdade de Ciências Médicas, Universidade NOVA de Lisboa, Lisboa, [3]Instituto de Tecnologia Química e Biológica António Xavier, Universidade Nova de Lisboa, Oeiras, [4]iBET, Instituto de Biologia Experimental e Tecnológica, Oeiras, Portugal.

Background and aims: Diabetes Mellitus is a chronic disease with increasing worldwide prevalence, with several associated complications, including Diabetic Retinopathy (DR). DR is the most frequent microvascular complication affecting diabetic adults. Despite significant efforts, the pathways underlying DR are not completely clarified, compromising the development of efficient treatments. Here we explore one potential therapeutic approach that relies on products resultant from human metabolization of phenolic compounds. These compounds have been studied by Santos and co-workers for their cytoprotective, hypertension-lowering, and anti-inflammatory properties. Retinal inflammation and an imbalance between pro- and anti-angiogenic proteins is observed in DR. Therefore in this work we aim to explore the potential of these metabolites for the treatment of DR, firstly in an *in vitro* setup mimicking hyperglycemia and secondly in an animal model of DR.
Materials and methods: Human RPE cell line, D407, was cultured with increasing concentrations of glucose, under normal and hypoxia conditions, and challenged with Catecol-O-sulfate. Expression of PEDF, VEGF and Glut1 were assessed by Western blot.
Results: Our *in vitro* studies shown that exposure of D407 cells for 24h to Catecol-O-sulfate (5 μM) under hyperglycemic and hypoxia conditions leads to an increase in the expression of anti-angiogenic protein PEDF and reduction of expression of pro-angiogenic VEGF. We have also analyzed the expression of the glucose transporter in the retina (Glut1), whose expression is reduced after exposure to Catecol-O-sulfate, in both hyperglycemic and hypoxic conditions.
Conclusion: Catecol-O-sulfate, a metabolite resultant from dietary (poly)phenols shown to have a beneficial role in decreasing the expression of VEGF and expression of Glut1, and increasing the expression of PEDF under hyperglycemia conditions in D407 RPE cells. Further studies will include testing other metabolites in the same conditions and use an animal model of DR to evaluate their therapeutic potential for DR.

Association of apnoea hypopnea index during rapid eye movement sleep with diabetic retinopathy in patients with type 2 diabetes

A. Nishimura[1], T. Kasai[2], S. Kikuno[1], K. Nagasawa[1], M. Okubo[1], K. Narui[3], Y. Mori[1];
[1]Department of Endocrinology and Metabolism, Toranomon hospital, [2]Cardio-Respiratory Sleep Medicine, Department of Cardiology, Juntendo University School of Medicine, [3]Sleep Center, Toranomon Hospital, Tokyo, Japan.

Background and aims: Forty to 80 % of patients with type 2 diabetes (T2DM) have sleep disordered breathing (SDB). SDB may exacerbate DR via poor glycemic control, hypertension, oxidative stress and chronic

inflammation which are known risk factors for diabetic retinopathy (DR). Although a few previous studies with portable sleep test showed independent association between SDB and DR, the overall results were conflicting. On the other hand, it is well known that rapid eye movement (REM) sleep is associated with greater sympathetic activity than in non-REM (NREM) sleep and that SDB events cluster in REM sleep. Furthermore, a few recent studies showed that apnea hypopnea index in REM sleep (REM-AHI) which can be measured only by polysomnography is associated with HbA_{1c} and presence or onset of hypertension whereas NREM-AHI wasn't. We therefore hypothesized that REM-AHI is associated with DR. However, no study evaluated this association and hence we performed the present study.

Materials and methods: We recruited 264 T2DM patients who were followed in our diabetes clinic and who underwent a fully attended polysomnography. Patients with heart failure, active lung disease, currently treated for SDB and REM sleep <30 minutes during polysomnography were excluded. Patients with simple or more severe DR were defined as having DR. In the first analysis, multivariate stepwise logistic regression analysis for DR included categorical REM-AHI (quartile) as the independent variable. The model was adjusted for known risk factors for DR such as diabetes duration, HbA1c, BMI, hypertension and dyslipidemia. The following variables with a p <0.25 in the univariate analysis were also included; age, sex, insulin use, ACE inhibitor/angiotensin receptor blockers use and sleep pills use. In the secondary analysis which included ln_REM-AHI, ln_NREM-AHI value was included for the model.

Results: Characteristics of the patients (n=131) are summarized in the table. In the multivariate logistic regression analysis, quartile of REM-AHI (p=0.011 for trend) and T2DM duration (OR: 6.131; 95 % CI: 2.616-14.369, p <0.001) were independently associated with DR. The OR and 95 % CI for each quartiles of REM-AHI compared with Q1 (reference) are as follows; Q2: 3.944 (0.780-19.938), Q3: 11.928 (2.405-59.149), Q4: 13.372 (2.178-82.099). Similarly in the secondary analysis, ln_REM-AHI (OR 3.196, 95 % CI 1.392-7.337, p=0.006) and T2DM duration (OR 5.976, 95 % CI 2.604-13.719, p <0.001) were independently associated with DR whereas NREM-AHI wasn't.

Conclusion: This is the first study to demonstrate independent association between REM-AHI and DR in patients with T2DM. SDB, especially during REM sleep could be the potential risk factor for diabetic retinopathy.

Table Characteristics of the patients.

	Overall	REM-AHI Q1	Q2	Q3	Q4	*P* value
Age, years	57.5 ± 11.8	57.2 ± 11.7	59.1 ± 11.3	57.8 ± 11.9	55.2 ± 12.9	0.478
Male sex, %	90.1	91.2	88.2	94.4	85.2	0.699
T2DM duration, years	7 (2-14)	8 (4-14)	8 (3-14)	8 (4-14)	5 (1-12)	0.613
DR, %	23.7	8.8	20.6	36.1	42.1	0.047
Hypertension, %	67.2	58.8	64.7	69.4	77.8	0.452
Dyslipidemia, %	61.8	44.1	76.5	52.8	77.8	0.008
BMI, kg/m²	26 (24-29)	24 (23-27)	27 (25-30)	27 (24-29)	27 (25-32)	0.002
HbA1c (NGSP), %	7.6 (7.0-8.8)	7.5 (6.8-8.9)	7.5 (6.8-8.5)	7.9 (7.2-9.0)	7.5 (6.7-9.0)	0.500
Insulin use, %	9.9	2.9	8.8	19.4	7.4	0.233
AHI, events/h	29.8 (20.1-43.1)	17.1 (8.0-29.7)	28.6 (20.1-38.1)	36.0 (24.9-51.1)	40.1 (26.4-65.1)	0.000
REM-AHI, events/h	36.6 (21.1-53.5)	13.9 (7.2-17.7)	28.9 (24.7-33.3)	45.8 (41.8-52.7)	63.2 (57.7-69.7)	0.000

Data are mean ± SD, median (interquartile range) or %. REM, rapid eye movement; AHI, apnea hypopnea index; T2DM, type 2 diabetes; DR, diabetic retinopathy. Analysis performed using the chi-square test for categorical variables, the analysis of variance (ANOVA) for normally distributed variables and the Kruskal-Wallis test for skewed variables.

Deregulation of the retinal renin-angiotensin system precedes the onset of diabetic retinopathy

S. Simão[1], D.B. Bitoque[2,3], D.F. Santos[2,3], I.M. Araújo[1], G.A. Silva[2];
[1]CBMR-University of Algarve, Faro, [2]CEDOC, NOVA Medical School, Lisboa, [3]ProRegeM PhD Program, NOVA Medical School, Lisboa, Portugal.

Background and aims: The renin-angiotensin system (RAS) is a set of complex pathways with a well-defined function in the regulation of blood pressure and body fluid homeostasis. Deregulation of the RAS has been found in different pathologies and this was mainly attributed to the over-activation of renin and the renin receptor. Recently it was found that the RAS encompass a protective axis which includes the MAS receptor. The RAS is present in the eye and its dysfunction is associated with the development of ocular pathologies. Evidences point to the contribution of the RAS in diabetic retinopathy, but at what stage of the disease the deregulation of this system occurs is still unknown. The aim of the present study is to assess the RAS in the retina of a mouse model of diabetes at an early stage of the disease.

Materials and methods: The Ins2Akita is a well described experimental model to study diabetes-associated complications, it has a C57BL/6 background and spontaneously develops type 1 diabetes. Hyperglycemia begins at 2-months of age and this model develops symptoms of diabetic retinopathy around 6-months of age. Retinas of diabetic and non-diabetic (C57BL/6) mice with 4-months of age were collected and assessed for the expression of renin, renin receptor and MAS receptor using Western blot.

Results: It was found that the expression of renin was significantly increased in the retina of the diabetic mice when compared with the non-diabetic. The expression of the renin receptor was unchanged in the retinas of both diabetic and non-diabetic mice at 4-months of age. The expression of the MAS receptor was significantly decreased in the retinas of diabetic mice compared with age-matched controls.

Conclusion: Our data demonstrate that the RAS is deregulated in the retina of a diabetic model, at a stage where retinopathy is not yet installed. We hypothesized that the deregulation of the RAS might contribute to trigger diabetic retinopathy. We are currently exploring further ages to completely characterize the RAS profile in diabetic retinopathy, which will allow to better understand the involvement of this system on the disease course.

Apolipoprotein A1 and B predicts development of diabetic retinopathy in patients with type 2 diabetes

J.-S. Yun[1], S.-A. Cha[1], S.-H. Ko[1], Y.-B. Ahn[1], S.-A. Chang[2], H. Son[2], S.-H. Ko[1];
[1]Internal Medicine, The Catholic University of Korea, Suwon, [2]Internal Medicine, The Catholic University of Korea, Seoul, Republic of Korea.

Background and aims: We aimed to determine whether, in patients with type 2 diabetes, apolipoprotein A1 and B level have stronger associations with diabetic retinopathy (DR) than do traditional lipids.

Materials and methods: From January 2006 to December 2009, a total of 599 patients with type 2 diabetes without diabetic retinopathy were consecutively enrolled. The serum apolipoprotein A1 (apoA1) and B (apoB) concentrations were measured by rate immunonephelometry assay, and a standardized clinical examination and retinal photographs were checked annually by an ophthalmologist. We used a Cox proportional hazard regression analysis to test the associations between diabetic retinopathy and apoA1 and apoB.

Results: The median follow-up time was 8.8 years. The mean age was 54.6 ± 9.9 years, and the duration of diabetes was 6.2 ± 5.7 years. During the follow-up period, 149 patients (24.9%) developed DR. The patients in the DR group had a higher level of apoB (85.6 ± 21.0 vs 92.5 ± 22.6 mg/dL, P = 0.001) and apoA1/apoB (1.6 ± 0.6 vs. 1.5 ± 0.5, P =0.001), although at the baseline time they had had apoA1 (128.0 ± 21.5 vs. 126.3 ± 20.8 mg/dL, P = 0.405) and LDL cholesterol (106.9 ± 32.6 vs. 103.6 ± 33.3 mg/dL, P = 0.319) levels. Baseline apoB (r = 0.250, P <0.001) and apoA1/B (r = -0.157, P <0.001) levels significantly correlated with LDL cholesterol level. A Cox hazard regression analysis revealed

that the development of DR was significantly associated with the high level of serum apoB (per 10 mg/dL increase; hazard ratio 1.13, 95% CI 1.04-1.21, $P = 0.002$) and apoA1/B level (hazard ratio 0.61; 95% CI 0.42-0.88, $P = 0.008$) after adjusting for sex, age, diabetic duration, mean $HbA1_C$, treatment of insulin, ACE inhibitor/ARB and lipid lowering agents. In contrast, LDL cholesterol level showed insignificant association with DR (per 10 mg/dL increase; hazard ratio 0.97, 95% CI 0.92-1.02, $P = 0.185$).

Conclusion: In conclusion, we found that, in patients with type 2 diabetes, the ApoB and apoA1/B are stronger predictors for the development of DR than the LDL cholesterol level.

Methylglyoxal activates microglia and induces heat shock proteins in the rat retina

A. Schlotterer, N. Dietrich, M. Kolibabka, C. Sticht, H.-P. Hammes;
Medical Faculty Mannheim, Mannheim, Germany.

Background and aims: Reactive metabolites such as methylglyoxal are involved in the damage of the neurovascular unit (NVU) of the diabetic retina. Our aim was to analyze methylglyoxal-induced damage of the NVU *in vivo*.

Materials and methods: Methylglyoxal (50 mM) was applied to Wistar rats by drinking water for 4 weeks. Microglial activation was quantified by immunohistochemistry. Retinal gene expression was analyzed by DNA microarray (GeneChip Rat Gene 2.0 ST) and gene set enrichment analysis.

Results: Oral application of methylglyoxal resulted in activation of retinal microglia from 6.5 $CD74^+/mm^2$ in untreated controls to 18.5 $CD74^+/mm^2$ in treated animals ($p<0.01$). Ranking of retinal expression changes revealed the crystallin gene family as the most prominent candidate. In addition, gene set enrichment analysis indicated regulation of several pathways, including carbohydrate metabolism, translation, MAPK signaling pathway, and insulin resistance.

Conclusion: In the NVU of the retina, reactive metabolites are associated with microglial activation, induction of heat shock proteins and pathway changes.

Behavioural risk of diabetic retinopathy among Bangladeshi subjects with type 2 diabetes: a 15-year follow-up study

K.R. Ahmed[1], P.C. Banik[2], L. Ali[3], A. Hussain[4];
[1]Health Promotion and Health Education, Bangladesh University of Health Sciences (BUHS), [2]Noncommunicable Diseases, Bangladesh University of Health Sciences (BUHS), [3]Biochemistry and Cell Biology, Bangladesh University of Health Sciences (BUHS), [4]Health Promotion and Health Education, University of Oslo, Dhaka, Bangladesh.

Background and aims: Lifestyle plays an important role in the development of diabetic retinopathy (DR). Previous studies have examined individual dietary and lifestyle factors in relation to type 2 diabetes mellitus (T2DM), but the combined effects of these factors for DR among T2DM are largely unknown. The objectives of this study were to investigate the prevalence of diet, lifestyle, and the risk of diabetic retinopathy and determinants of DR among T2DM.

Materials and methods: We followed 977 T2DM subjects from 1993 to 2008; these subjects were free of diagnosed cardiovascular disease, DR and cancer at base line. Information about their diet and lifestyle was updated periodically. A low-risk group was defined according to a combination of five variables: a body mass index of less than 25; a diet high in cereal fiber and polyunsaturated fat and low in trans fat and glycemic load (which reflects the effect of diet on the blood glucose level); engagement in moderate-to-vigorous physical activity for at least half an hour per day; no current smoking; and regularly eye examine, at least six months within a year.

Results: During 15-years of follow-up, we documented 495 new cases of DR. Co-existing of hypertension was the single most important predictor of DR. Lack of exercise, a poor diet, current smoking, and abstinence from eye check-up were all associated with a significantly increased risk of DR, even after adjustment for the hypertension. A total of 95 percent of the diabetes related DR in this cohort (95% CI, 87 to 99 percent) could be attributed to habits and forms of behavior that did not conform to the low-risk pattern.

Conclusion: In conclusion, our findings suggest that type 2 diabetes related DR could be prevented by weight loss, regular exercise, modification of diet, abstinence from smoking, and the periodical eye examination. Weight control would appear to offer the greatest benefit.

Development and progression of diabetic retinopathy and associated risk factors in type 1 diabetic patients: a 15-year follow-up study

M. Tomić, R. Vrabec, Ž. Rogulja Pepeonik, S. Ljubić, T. Bulum, L. Duvnjak;
Vuk Vrhovac University Clinic Merkur University Hospital, Zagreb, Croatia.

Background and aims: Diabetic retinopathy (DR) is an important cause of visual impairment in developed countries, especially in working age adults. The aim of this study was to evaluate the 15-year incidence of development and progression of retinopathy in a sample of type 1 diabetic patients and determine the associated risk factors in these patients.

Materials and methods: 123 type 1 diabetic patients (62 male / 61 female) were enrolled in this study and followed for 15 years. Basic and anthropometric parameters assessed were age, gender, diabetes duration and body mass index (BMI). Glycated hemoglobin (HbA_1c), total cholesterol, HDL and LDL cholesterol, triglycerides (TG), C-reactive protein (CRP), homocysteine (HCY), fibrinogen (FIB), plasma viscosity and serum creatinine were determined using routine laboratory methods. Urinary albumin excretion rate (UAE) was measured from a 24-hr urine sample. Blood pressure was measured with a mercury sphygmomanometer after a 10-min resting period. Ophthalmologic examination included binocular indirect slit lamp fundoscopy, color fundus photography after mydriasis according to the EURODIAB retinal photography methodology and optical coherence tomography of the macula. Possible risk factors for the development and progression of DR were examined in backward stepwise Cox's multiple regression analysis.

Results: At the beginning of the study patients were 24.60 ± 4.45 years old with mean diabetes duration of 9.64 ± 4.42 years. Mean/median values of BMI (23 ± 2.43 kg/m^2), total cholesterol (4.92 ± 1.11 mmol/L), HDL cholesterol (1.57 ± 0.36 mmol/L), LDL cholesterol (2.73 ± 0.77 mmol/L), TG (0.82 ± 0.43 mmol/L), CRP (0.8 (0.1 - 5.1) mg/L), HCY (10.5 (7.5 -14.2) μmol/L), FIB (2.9 (1.9 - 4.1) mg/L), plasma viscosity (1.55 ± 0.10 mPa.s), serum creatinine (81.59 ± 15.05 μmol/L), systolic (113 (95 - 130) mmHg) and diastolic blood pressure (75 (60 - 85) mmHg) were within normal range for diabetic patients, whereas HbA_1c (7.72 ± 1.48 %) and UAE (10.05 (3.18 - 8036.07) mg/24h) were elevated. At baseline, 87 (71%) patients had no retinopathy and

36 (29%) had nonproliferative diabetic retinopathy (NPDR). After 15 years, 54 patients (43.9%; 29.3/1000 person-years) developed NPDR or progressed to proliferative diabetic retinopathy (PDR). None of the patients had diabetic macular edema (DME) at baseline, nor has it developed after 15 years. From the 87 patients with no retinopathy at baseline 24 (27.6%; 18.4/1000 person-years) developed NPDR, while from the 36 patients with NPDR at baseline 30 (83.3%; 55.5/1000 person-years) progressed to PDR. Higher HbA_1c (HR=2.276, P=0.006), lower HDL cholesterol (HR=0.161, P=0.025) and higher UAE (HR=0.388, p=0.045) were significant risk factors for development and progression of retinopathy, whereas the presence of DR at baseline (HR=2.319, p=0.023) was significant factor for its progression to PDR. Diabetes duration, BMI, inflammatory and hemostatic disturbance markers showed no significant values in the statistical analysis.

Conclusion: The results of this study suggest that 15-year incidence of development and especially progression of retinopathy in type 1 diabetic patients is still very high. This points to the need for close monitoring of type 1 diabetic patients aimed at early detection, prevention or limitation the progression of retinopathy, especially those with higher HbA_1c, lower HDL cholesterol, higher UAE and the initial presence of DR.

Impact of puberty and long term glycaemic control from diabetes onset on incidence of simplex and proliferative retinopathy in type 1 diabetes: the VISS-study

H.J. Arnqvist[1], M. Abrahamsson[2], M. Dhir[2], M. Fredrikson[3], J. Ludvigsson[4], M. Nordwall[5];
[1]Diabetes and Endocrinology, Clinical and Experimental medicine, Linköping University, [2]Department of Ophthalmology, Vrinnevi Hospital, Region Östergötland, Norrköping, [3]Occupational and Environmental Medicine, Clinical and Experimental Medicine, Linköping University, [4]Division of Paediatrics, Department of Clinical and Experimental Medicine, Linköping University, [5]Division of Paediatrics, Department of Clinical and Experimental Medicine, Linköping University, Norrköping, Sweden.

Background and aims: Glycaemic control and diabetes duration are strong risk factors for diabetic retinopathy but there is evidence that the effect of duration is not uniform, being modified by puberty. Our aim was to evaluate sex, onset before, during and after puberty and HbA1c followed from diagnosis as risk factors for developing diabetic simplex and proliferative retinopathy.

Materials and methods: In a population based prospective observational study, 451 patients diagnosed with type 1 diabetes before the age of 35 years during 1983-1987 in the region of South East Sweden were followed. Long term weighted mean HbA1c (wHbA1c) from diagnosis and during the whole follow up of 20 - 25 years was calculated and categorized into 5 levels, ≤50, 51-60, 61-70, 71-80 and >80 mmol/mol. Retinopathy was evaluated by fundus photography.

Results: The time to first appearance of any retinopathy, studied in a subgroup of patients (n=281), who had not moved out from our region, decreased with increasing HbA1c, the difference being most obvious after about 15 years duration (See Figure!). With time most patients developed background retinopathy and the difference in background retinopathy between the HbA1c categories decreased or disappeared. At the end of the follow up 10 of 32 with wHbA1c ≤50 mmol/mol were without any retinopathy while only 1 of 44 in the group >80 mmol/mol had not retinopathy. 58 patients developed proliferative retinopathy. In Cox hazard regression analysis wHbA1c categories, puberty but not sex were associated with development of background retinopathy whereas only wHbA1c categories were associated with proliferative retinopathy. Onset before puberty was associated with prolonged time to appearance of background retinopathy.

Conclusion: There is a strong positive association between long term mean wHbA1c measured from diagnosis and rate of appearance of background retinopathy but with time background retinopathy occur in the majority of patients in spite of excellent glycaemic control. Diabetes onset before puberty requires longer duration to develop background but not proliferative retinopathy.

1039

Prevalence and progression of diabetic retinopathy in 499 type 1 diabetic pregnancies

A. Vambergue[1,2], J. Bourry[1], H. Courteville[3], E. Merlen[1], F. Baudoux[1], J. Labreuche[4], P. Dereulle[5,2];
[1]Department of Diabetology, CHRU, [2]University of Lille, [3]Department of Ophtalmology, CHRU, [4]Department of Public Health, CHRU, [5]Department of Obstetrics, CHRU, Lille, France.

Background and aims: 1) to study the prevalence of diabetic retinopathy during pregnancy in women with type 1 diabetes 2) to document the progression during pregnancy and factors associated with this progression.

Materials and methods: We studied a cohort of 499 type 1 diabetic pregnancies followed in the same centre from 1997 to 2015. Management followed the French guidelines. Retinal examination was performed by one ophthalmologist: each trimester in the absence of retinopathy, each month in case of retinopathy at first examination. Diabetic retinopathy was classified according to the ETDRS. Progression was defined as at least one stage of deterioration (apparition or aggravation of the retinopathy).

Results: The mean age was 29.7±4.8 years with duration of diabetes of 13.6±8.1 years. The metabolic control was improved during pregnancy. At inclusion 69.7% of women had normal fundus photography, 23.8% a nonproliferative diabetic retinopathy (NPDR) and 6.4% a proliferative diabetic retinopathy (PDR). The progression of retinopathy occurred in 21.8% women (apparition in 24.4% and aggravation in 15.9%). The regression rate at 1 years' post-partum was 9.3%. Women who

demonstrated progression had a higher preconceptional, 1st and 2nd trimester HbA1c ($p<0.05$, $p< 0.01$ and $p<0.01$) compared to the women without progression. Additionally, the drop in HbA1c was greater between preconception and first trimester ($p<0.01$), between first and third trimester ($p<0.001$), and between preconception and the lower HbA1c during pregnancy ($p<0.001$) among the women who had progression. After multivariate analysis, risk factors for retinopathy progression were duration of diabetes > 10 years ($p<0.0001$), nulliparity ($p<0.05$), and absence of retinopathy before pregnancy ($p<0.001$).
Conclusion: This study highlights the ongoing risk of retinopathy progression during pregnancy among women with type 1 diabetes. Our study reinforces other published works that found a progression of retinopathy associated with a more important fall in HbA1c level during pregnancy and validates the need for close follow up, especially in women with risk factors.

Quantitative measurement of retinal thickness in diabetic retinopathy and qualitative correlation between the retinal thickness and visual acuity

K. Shah[1], A. Gandhi[1], S. Natarajan[2], N. Wadhwa[3];
[1]Diabetes and Thyroid Centre, Mumbai, [2]Aditya Jyot Eye Hospital, Mumbai, [3]AUW Global, Delhi, India.

Background and aims: The conventional practice of assessing the macula for its thickness, involving slit-lamp biomicroscopy, fundus photography, and fluorescein angiography, is less sensitive to subtle changes and is limited to provide qualitative findings. Optical Coherence Tomography (OCT) provides a rapid and non-invasive method to assess retinal structures at a microscopic level. Macular edema remains the most common reason for intervention by ophthalmologists in patients with diabetes confronting visual loss and the degree of macular thickening is significantly correlated with visual acuity. Measuring macular edema is therefore of major importance in imaging patients with Diabetic Macular Edema (DME)
Materials and methods: We conducted a prospective evaluation across 100 patients with Type 2 Diabetes (T2DM) with DR (184 eyes) to assess the grade of DME by a comprehensive ophthalmologic examination to analyze retinal thickness, morphology and presence of vitreo-macular traction using OCT and correlate the macular thickness to Best Corrected Visual Acuity (BCVA) by utilizing the dilated fundus photography, fluorescein angiography and OCT. Statistical analyses were performed using independent t-test and Chi-Square test
Results: OCT precisely differentiated 4 types of DME, namely Type 1, 2, 3 and 4 which were simple (n=11), diffuse without cyst (n=33), cystoid (n=48), and vitreomacular traction (n=8) respectively. There was a significant correlation between OCT and Fundus Fluorescein angiography (FFA) ($p< 0.00001$) and Best Corrected Visual Acuity (BCVA) across macular thickness range <200 to > 500 μm. ($p< 0.00001$). 50 patients were detected with the retinal thickness > 400 μm with 16 patients with retinal thickness <200 μm. The worst BCVA (> 20/62.5) was observed in 6 patients with retinal thickness > 500 μm with the best reported BCVA (20/20-20/30) was in 17 patients with retinal thickness <200 μm
Conclusion: Our study with a triple correlates (OCT, FFA and BCVA) provides insights to the early prediction of diabetic maculopathy defined according to the Early Treatment Diabetic Retinopathy Study classification. The association between these parameters would prove useful in monitoring disease progression and identifying parameters that affect visual function. The increased macular thickness may be an earliest predictor to detect the onset of diabetic retinopathy in association with other correlates. This could help increase the reliability and precision to accurately predict the prognosis in patients with DME and help determine an appropriate therapeutic approach especially in early stages when structural changes are not yet evident with the conventional techniques

Calcium dobesilate prevents the oxidative stress and inflammation induced by diabetes in the retina of db/db mice

P. Bogdanov[1], C. Solà-Adell[1], J. Sampedro[1], M. García-Ramírez[1], C. Hernández[1], C. Pasquali[2], R. Simó[1];
[1]Vall d'Hebron Research Institute, Barcelona, Spain, [2]Vifor Pharma, Geneva, Switzerland.

Background and aims: Calcium Dobesilate (CaD) is beneficial in early stages of diabetic retinopathy (DR), but its mechanisms of action remains to be elucidated. The aim was to investigate the effect of CaD on proinflammatory cytokines and oxidative stress.
Materials and methods: db/db mice were randomly assigned to daily oral treatment with CaD (200 mg/Kg/day) or vehicle for 15 days. Biomarkers of oxidative stress (dihydroethidium, malondialdehyde), NF-κB, and proinflammatory cytokines (IL-1β, IL-6, IL-8, TNF-α, MCP-1) were examined in the retina by immunohistochemical analysis. Mitochondrial manganese superoxide-dismutase (MnSOD) was measured by Western blot. Cultures of human retinal endothelial cells (HRECs) were used for complementary experiments.
Results: CaD significantly reduced the biomarkers of oxidative stress and ameliorated the downregulation of MnSOD in the retina of db/db mice. In addition, CaD prevented the increase of NF-κB, IL-6, IL-8, TNF-α and MCP-1 induced by diabetes. These effects were associated with a significant reduction of vascular leakage. CaD inhibited the activation of NF-kβ induced by IL-1β by preventing IKKB-α phosphorylation in HRECs and reduced the upregulation of IL-6 and IL-18 induced by TNF-α in a dose-dependent manner.
Conclusion: Our results suggest that antioxidant and antinflammatory effects are crucial in accounting for the effectiveness of CaD for treating DR.

Increased plasma concentrations of vascular endothelial growth factor 165 and vascular endothelial growth factor 165b in diabetes patients with diabetic retinopathy

E.R.B. Petersen[1,2], D.A. Olsen[3], H. Christensen[3], I. Brandslund[3,2];
[1]Clinical Biochemistry and Pharmacology, Odense University Hospital, [2]Institute of Regional Health Reseach, University of Southern Denmark, Odense, [3]Clinical Immunology and Biochemistry, Lillebaelt Hospital, Vejle, Denmark.

Background and aims: Diabetic retinopathy (DR) is the most frequent cause of blindness among younger adults in the western world. No blood biomarkers exist to detect DR. We therefore speculated if the plasma concentration of vascular endothelial growth factor $(VEGF)_{165b}$ and $VEGF_{165}$ could be early markers of retinal damage. The aim of the study was to measure the plasma concentration of $VEGF_{165}$ and $VEGF_{165b}$ and to investigate whether the plasma concentration of $VEGF_{165b}$ and $VEGF_{165}$ in diabetes patients with DR differed from the plasma concentration of $VEGF_{165b}$ and $VEGF_{165}$ in control persons and in diabetes patients without DR.
Materials and methods: A digital ELISA assay ($VEGF_{165b}$) using a Simoa HD-1 Analyzer (Quanterix©, Lexington, MA 02421, USA) and a conventional ELISA assay ($VEGF_{165}$) (QuantiGlo ELISA, RnD Systems, Abingdon, OX14 3NB, UK) were applied on a cohort of type 1 and type 2 diabetes patients characterised with DR (n=466) and without DR (n=144) as well as on a sex and aged matched control group (n=169). The diabetes patients without DR consisted of a group of diabetes patients with HbA1c ≤ 5.5% (n=77) and a group of patients with HbA1c ≥ 9.7%

(n=67). The patients with DR were divided in a group of patients with DR at time of inclusion into the cohort (n=270) and in a group of patients who developed DR during follow-up (n=196).
Results: $VEGF_{165}$ was statistical significantly increased in patients with DR, both in the group of patients with DR at time of inclusion into the cohort (40 ng/L, $p < 0.001$) and in the group of patients who developed DR during follow-up (35 ng/L, $p = 0.02$) compared to the control group (31 ng/L). Further, $VEGF_{165}$ was increased in the group of diabetes patients with HbA1c ≥ 9.7% (40 ng/L, $p < 0.01$). $VEGF_{165b}$ was increased in diabetes patients with DR at time of inclusion into the cohort (19 pg/L, $p < 0.001$) and in diabetes patients developing DR during follow-up (16 pg/L, $p = 0.06$) compared to the control group (13 pg/L).
Conclusion: We determined the plasma concentration of $VEGF_{165}$ and $VEGF_{165b}$ by ELISA and a digital ELISA method, respectively. Plasma $VEGF_{165}$ and $VEGF_{165b}$ were increased in diabetes patients with DR, and $VEGF_{165}$ was also increased in diabetes patients with high HbA1c without DR. These findings support the existing knowledge on the mechanism of $VEGF_{165}$ and $VEGF_{165b}$ in DR but the difference between the groups was not large enough to identify patients at risk.

Plasma glutamine and glutamic acid are potential novel biomarkers for predicting long-term clinical outcomes of diabetic retinopathy

S. Rhee[1], E. Jung[2], H. Park[2], S. Jeong[3], K. Kim[4], S. Chon[1], S.-Y. Yu[4], J.-T. Woo[1], C. Lee[2];
[1]Department of Endocrinology and Metabolism, Kyung Hee University Hospital, [2]Department of Bioscience and Biotechnology, Konkuk University, [3]Statistics Support Department, Kyung Hee University Hospital, [4]Department of Ophthalmology, Kyung Hee University Hospital, Seoul, Republic of Korea.

Background and aims: Some diabetic patients experience few or no complications despite a long disease duration. We identified differences in plasma metabolites in type 2 diabetes patients with and without diabetic retinopathy (DR) and a disease duration of 15 years or more.
Materials and methods: From September 2014 to July 2015, a cohort of 183 elderly type 2 diabetes patients was established. Their clinical data and biospecimens were collected in accordance with the guidelines of the Korean Diabetes Association and the National Biobank of Korea, and DR phenotypes were identified by ophthalmologic specialists. Plasma metabolites were profiled with a comprehensive metabolomic approach using gas chromatography time-of-flight mass spectrometry and ultra-performance liquid chromatography-quadrupole time-of-flight mass spectrometry with multivariate statistical analyses.
Results: For metabolite analysis, 32 case-control sets with adjusted clinical variables were selected. The mean age of the subjects was 66.4 years and mean diabetes duration was 22.2 years. Metabolomic analysis revealed various amino acids, organic compounds, and carbohydrates that differed between age- and sex-matched non-diabetic controls and diabetic subjects. Among these metabolites, glutamine and glutamic acid were identified as the most accurate biomarkers for the presence of DR in subjects. ROC analysis showed a high diagnostic value of glutamine (AUC = 0.671), glutamic acid (AUC = 0.656), and the ratio between the two (AUC = 0.742) for DR. The results were consistent in validation analyses.
Conclusion: Our study suggests that glutamine, glutamic acid, and their ratio may be useful as new biomarkers for predicting the prognosis of DR in elderly type 2 diabetes patients.

Circulating extracellular vesicles from diabetic and healthy subjects show different miRNA patterns

A. Mazzeo, E. Beltramo, C. Gai, T. Lopatina, M. Trento, M. Porta;
Dept of Medical Sciences, University of Turin, Torino, Italy.

Background and aims: We previously demonstrated that extracellular vesicles (EV) derived from mesenchymal stem cells (MSC) cultured in high glucose and/or hypoxia are able to enter retinal pericytes, causing their detachment from substrate and migration, and stimulating angiogenesis in vitro. Our present hypothesis is that circulating EV in diabetes may influence small vessel homeostasis, and that molecular differences can be identified in EV from healthy controls and diabetic subjects, with/without microvascular complications. The aim of this study was the molecular characterization and comparative analysis of EV derived from healthy and diabetic subjects with and without microvascular complications, and their influence on pericyte detachment and angiogenesis.
Materials and methods: EV were extracted from plasma of 4 type 1 diabetic patients with microvascular complications (nephropathy and retinopathy) (CDM, sex: 1F/3M, age: 48.0±16.3, disease duration: 22.5±10.2), 4 without complications (DM, sex: 1F/3M, age: 44.5±8.1, disease duration: 21.0±9.6) and 4 healthy controls (noDM, sex: 1F/3M, age 39.0±9.2). EV expression of surface molecules was measured by FACS. microRNA (miRNA) content was evaluated by Taqman Human MicroRNA Arrays - cards A and B, which allow detection of 754 different miRNAs. Human retinal pericyte (HRP) detachment was evaluated by cell counting after 24 hr exposure to EV. Proliferation and apoptosis were measured in HRP still attached to culture wells. In vitro angiogenesis in HRP-endothelial cell co-cultures was analyses by tube formation in Matrigel after 48 hr EV exposure.
Results: FACS analysis of surface molecules showed no significant changes between groups. Only miR-106a was increased in the DM compared with the noDM group ($p<0.05$), while 10 miRNAs differed between the noDM and CDM groups. Five of them, with anti-angiogenic properties (miR-150, miR-155, miR-342-3p, let-7-g, miR-1243), were decreased, and 5, with pro-angiogenic properties (miR-17, miR-106a, miR-484, miR-580, miR-21*), were increased ($p<0.05$, all). As regards CDM vs DM subjects, 7 miRNAs were significantly modulated: 2 decreased (miR-30b, miR-21*) and 5 increased (miR-139-5p; miR-342-3p; miR-150; miR-24; miR-1243) ($p<0.05$, all). EV from CDM subjects increased HRP detachment (+21.7%, $p<0.05$ vs noDM), while EV from DM subjects had no effect. HRP which remained attached to wells showed no signs of apoptosis. Moreover, EV from CDM subjects increased the formation of vessel-like structures in vitro in comparison with EV from healthy controls ($p< 0.001$).
Conclusion: These observations suggest that EV patterns may be different in diabetic patients, with or without complications, compared to healthy subjects. In particular, an imbalance between miRNAs with pro- and anti-angiogenic functions could lead to abnormal microvascular proliferation, and contribute to proliferative diabetic retinopathy. Further studies could provide predictive options for diagnostic purposes and tools for the treatment of vessel abnormalities in diabetes.

Lixisenatide protects the neurovascular unit in diabetic retinopathy

K. Acunman[1], M. Kolibabka[1], N. Dietrich[1], A. Schlotterer[1], T. Fleming[2], P. Wohlfart[3], H.-P. Hammes[1];
[1]Universitätsmedizin Mannheim, Mannheim, [2]Universitätsklinikum Heidelberg, Heidelberg, [3]Sanofi-Aventis Deutschland GmbH, Frankfurt, Germany.

Background and aims: Diabetic retinopathy is a disease of the entire neurovascular unit (NVU), with the pathogenic hallmarks of vasoregression, neuronal dysfunction and glial activation. GLP-1 receptor agonists are beneficial, not only in the treatment of diabetes and its complications, but also in several neurodegenerative and neuroinflammatory diseases. In this study we analyse the effects of the GLP-1 receptor agonist lixisenatide on the neurovascular unit in a rat model of diabetic retinopathy.
Materials and methods: Streptozotocin-induced diabetic Wistar rats were treated with Lixisenatide (150 μg/kg body weight) for 12 weeks (DC+Lixi). Untreated animals served as controls (DC). Vasoregression was quantified using retinamorphometry (QRM) for pericytes (PC) and acellular capillaries (AC). Neuroretinal function was assessed with multifocal-electroretinography (mfERG). Glial activation was analysed with western blots for GFAP (Müller glia) and Cd74/Iba1 whole mount immunofluorescence staining (microglia). Methylglyoxal was quantified using HPLC-MSMS.
Results: Lixisenatide prevented pericyte dropout (1885±42.7 vs 2120±35.9 PC/mm²; DC vs DC+Lixi; p<0.01) as well as formation of acellular capillaries (64.7±4.8 vs 88.5±4.8 AC/mm²; DC vs DC+Lixi; p<0.01). Neuronal function of the inner retina improved upon treatment with Lixisenatide (b-wave amplitude: 0.87±0.15 vs 1.46 ±0.06 μV/segment; DC vs DC+Lixi; p<0.01). GFAP was significantly decreased in the Lixisenatide groups (0.28±0.04 vs 0.14 ±0.04 mean AU; DC vs DC+Lixi; p<0.05) indicating reduced Müller glia activation. Microglial activation was also markedly reduced in treated animals (20.1±1.5 vs 7.5±1.6 $Cd74^+$ microglia/mm²; DC vs DC+Lixi; p<0.01). Lixisenatide treatment showed no effects on retinal methylglyoxal levels (12.0 vs 10.2 pmol/mg; DC vs DC+Lixi; n.s.), bodyweight (372±26 vs 367±23 g; DC vs DC+Lixi; n.s.) or HbA1c (12.5±1.1 vs 12.0±1.3 %; DC vs DC+Lixi; n.s.).
Conclusion: In this study we demonstrate the beneficial effects of Lixisenatide on the neurovascular unit in the diabetic retina. Lixisenatide protects from vasoregression, neuronal dysfunction and glial activation independently of metabolic effects proving its efficiency in the treatment of diabetic microvascular complications.

MicroRNA 124a inhibits microglial migration and activation

J. Lin[1], A. Schlotterer[1], M. Dannehl[1], B. Kraenzlin[2], S. Hoffmann[2], N. Gretz[2], H.-P. Hammes[1];
[1]University of Heidelberg, 5th Medical Department, [2]University of Heidelberg, Center of Medical Research, Mannheim, Germany.

Background and aims: MicroRNAs (MiR) are a family of regulatory molecules involved in many physiological processes, including differentiation and activation of cells of the immune system. MiR-124 is a small non-coding RNA molecule with ~21 nucleotides. It is the most abundant microRNA expressed in neuronal cells. However, it is unknown if miR124 plays an important role in regulating microglial migration and activation in retinas with neurodegenerative disease. To investigate the effect of miR124 on microglia, we intravitreally administered miR124 to polycystin-2 transgenic rats, a model of polycystic kidney disease (PKD) assiociated with retinal neurodegeneration, and characterized the Impact on microglial activation.
Materials and methods: In vitro experiment: BV2 cells were transfected with control microRNA, MiR-124a and its inhibitor for 24 hours. Transwell migration assay was performed by using a culture insert of polyethylene terephthalate (PET) with a membrane of 8μm pore size. Cells from 10x random fields were quantified under microscope. In vivo experiment: Male PKD transgenic rats at 8weeks and 10 weeks old were twice intravitreally injected with microRNA 124 and its inhibitor. Eyes were enucleated at 12 weeks. Microglial and retinal vessels were labelled for CD74 and Lectin. Leica SP8 confocal microscope and Leica Application Suite X software were used for taking images and quantification.
Results: MicroRNA 124 not only inhibits microglial migration in vitro, but also suppressed microglial activation in vivo. The number of CD74 positive microglial cells increased in the deep layer of retina and significantly reduced after microRNA 124 treatment compared with the control group.
Conclusion: MicroRNA 124 inhibits microglial migration and activation in vivo and in vitro.

Effects of bariatric surgery on retinal microvascular architecture

R.J. Tapp[1,2], M. Soinio[3], C.Y. Cheung[4,5], J. Hannukainen[3,6], H. Karlsson[3,6], T.Y. Wong[4,7], A.D. Hughes[8], P. Salminen[3], P. Nuutila[3,6], P. Sahota[2], E. Vesti[3], A. Viljanen[9];
[1]The University of Melbourne, Melbourne, Australia, [2]Leeds Beckett University, Leeds, UK, [3]Turku University Hospital, Turku, Finland, [4]Singapore Eye Research Institute, Singapore, Singapore, [5]Chinese University of Hong Kong, Hong Kong, Hong Kong, [6]University of Turku, Turku, Finland, [7]Duke-NUS Graduate Medical School, Singapore, Singapore, [8]University College London, London, UK, [9]Medilaser LCC, Turku, Finland.

Background and aims: Retinal microvasculature changes reflect damage from obesity, hypertension, diabetes and other chronic disease processes. The impact of bariatric surgery induced weight loss on preclinical changes in the microvasculature are relatively unknown. We hypothesised that weight loss following bariatric surgery would be associated with improved structural changes in the retinal microvasculature, specifically with a reduction in retinal arteriolar narrowing and venular widening.
Materials and methods: The study included 22 obese subjects scheduled for bariatric surgery (laparoscopic Roux-en-Y gastric bypass or a sleeve gastrectomy) and 15 lean, age-matched controls. Ophthalmic examination, including fundus photography, was performed at baseline and 6 months. The retinal microvasculature was analysed quantitatively using a semi-automated computer program.
Results: Mean weight loss at 6 months was 26 kg ± 8 kg, (p<0.001) in the bariatric surgery group. The central retinal artery equivalent arteriolar (CRAE) increased (Mean and SE: 136 ± 1.4 μm to 141 ± 1.4 μm, p <0.012) and the central retinal vein equivalent (CRVE) decreased (from 203 ± 1.9 μm to 197 ± 1.9 μm, p <0.046) in the bariatric surgery group by 6 months, with no change in CRAE (from 137 ±1.5 to 135 ± 1.2, p=0.222) or CRVE (195 ± 2.1 to 193 ± 2.2, p=0.550) in the control group. The arteriolar to venular ratio increased in the bariatric surgery group (from 0.67 ± 0.01 to 0.72 ± 0.01, p=0.002), with no change in the control group (from 0.71 ± 0.01 to 0.70 ± 0.01, p=0.550) at 6 months. No change was observed for tortuosity, branching angles or fractal dimension.
Conclusion: The findings suggest obesity-related impairments in retinal arteriolar narrowing and venular widening are reversible after bariatric

surgery inducing weight loss. The capacity for the retinal microvasculature to improve following bariatric surgery, furthers our understanding of the plasticity of the retinal microvasculature, early in the disease course.

Thiamine transporters and hyperglycaemia-induced damage in human retinal cells

E. Beltramo, A. Mazzeo, M. Porta;
Dept Internal Medicine, University of Turin, Torino, Italy.

Background and aims: Thiamine, a co-factor for transketolase and other glycolytic enzymes, counteracts high glucose-induced damage in microvascular cells *in vitro* and prevents progression of retinopathy and nephropathy in diabetic animals. Impaired thiamine availability may facilitate metabolic damage, and diabetes might be considered a thiamine-deficient state, if not in absolute terms, at least relative to the increased requirements deriving from accelerated glucose metabolism in non-insulin dependent tissues prone to complications. Renal loss via proximal tubules, resulting in reduced thiamine/transketolase activity, has been described in diabetic patients. We previously described 2 single nucleotide polymorphisms (SNPs), rs12694743 and rs6713116, located in the SLC19A3 gene encoding for the thiamine transporter THTR2, and associated with resistance to development of proliferative diabetic retinopathy and end-stage renal disease in type 1 diabetic subjects. The protective effects of these SNPs may work either through loss of function, decreasing the discharge of thiamine, or gain of function, by increasing its uptake in target tissues. The objective of this work was to investigate if, in human retinal cells, a diabetic-like microenvironment is able to modulate the expression of the two thiamine transporters THTR1 and THTR2 and their transcription factor Sp1.
Materials and methods: Human retinal pericytes (HRP), human microvascular endothelial cells (HMEC) and human Műeller cells (MIO-M1) were cultivated for 8 days in physiological glucose (NG), stable high glucose (HG) or intermittent physiological/high glucose conditions (intHG) (n=6). To investigate substrate influence on the expression of transporters, cells were also cultured in thiamine-deficient medium (noT) or in high thiamine conditions (50μmol/l, HT) (n=6). THTR1, THTR2 and Sp1 mRNA expression was checked by relative quantitative RT-PCR and protein expression by Western blotting.
Results: Our results show that both transporters and Sp1 are expressed in HRP, HMEC and MIO-M1, THTR1 being more expressed than THTR2 in all cases. THTR2 and Sp1 mRNA expression decreased in HRP cultured in HG and intHG (THTR2: -20.8 and -36.1% respectively, $p<0.05$ vs NG; Sp1: -17.1 and -19.9%, $p<0.05$), while THTR1 expression was unchanged. On the contrary, THTR2 mRNA expression increased in HMEC (+29.7%, $p<0.05$) and MIO-M1 cells cultured in intHG (+36.4%, $p<0.05$). Protein expression checked by Western blotting confirmed these results. Different thiamine concentrations did not influence THTR1, THTR2 or Sp1 expression.
Conclusion: Diabetic-like conditions are able to modulate the expression of thiamine transporters in retinal cells. However, THTR2, which appears to be the most affected, is regulated in opposite directions in pericytes on one side, and endothelial and Műller cells on the other. Pericytes are the first cells to be affected by early diabetic retinopathy; therefore, decreased expression of THTR2 in these cells may lead to reduced intracellular availability of thiamine, with consequent metabolic damage due to accumulation of toxic metabolites. On the contrary, increased expression of THTR2 in the surrounding cells may be interpreted as an attempt to counteract glucose-induced damage, by stimulating thiamine uptake.

The 'fatty kidney': crosstalk of renal sinus fat with glomerular cells under the influence of the hepatokine fetuin-A

D.I. Siegel-Axel[1,2], R. Wagner[1,2], M. Guthoff[1], J. Machann[3], S. Nadalin[4], N. Stefan[1,2], A. Fritsche[1,2], M.A. Saleem[5], F. Schick[3], F. Fend[6], A. Königsrainer[4], N. Heyne[1], H.-U. Häring[1,2], E. Schleicher[1,2];
[1]Department of Internal Medicine, Medical Clinic IV, Division of Endocrinology, Diabetology, Angiology, Nephrology and Clinical Chemistry, [2]Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Center Munich at the University of Tübingen, [3]Department of Diagnostic and Interventional Radiology, Section on Experimental Radiology, [4]Department of General Visceral and Transplantation Surgery, University of Tübingen, Tübingen, Germany, [5]Bristol Royal Hospital for Children, Paediatric Renal Medicine, University of Bristol, Bristol, UK, [6]Institute of Pathology and Neuropathology, University ofTübingen, Tübingen, Germany.

Background and aims: We previously identified the fatty liver-derived hepatokine fetuin-A to induce pro-inflammatory signalling in perivascular fat cells (PVFC). Renal sinus fat (RSF) is a perivascular fat compartment located around the renal vessels potentially adversely impacting on renal function. In this study, we hypothesized that fetuin-A may impair renal function in NAFLD by proinflammatory signalling in RSF cells (RSFC).
Materials and methods: RSF was quantified by MRI and liver fat content by ^{1}H-MR spectroscopy in 449 individuals at risk for type-2 diabetes. Impaired renal function was assessed by the determination of uACR. To study the crosstalk of fetuin-A with RSF, human RSFC, endothelial cells (EC) from specimens of kidney transplantation donors and a human podocyte cell line (PO) were used. RSFC, EC and/or PO were cocultured in transwell systems for 6-72 h ±600 μg/ml human fetuin-A. Protein secretion was quantitated by Luminex analysis and mRNA expression by realtime PCR. Macrophages and microvessels in renal fat resections were stained by standard immunohistochemistry methods.
Results: While RSF and fetuin-A did not associate with uACR in subjects without NAFLD (n=212; beta=0.04, p=0.94 and n=88, beta=-0.09, p=0.41) positive correlations were found between RSF and fetuin-A with uACR in subjects with NAFLD (n=105; beta=0.40, p=0.0005 and n=41; beta=0.3, p=0.05). In cocultures without fetuin-A, RSFC downregulated proinflammatory and upregulated regenerative factors in EC/PO. Proinflammatory expression levels in RSFC were higher than in PVFC. Coculture of RSFC with EC/PO downregulated IL-6/-8 and MCP-1 expression, induced HGF in EC and decreased TGF-β in PO. Fet-A/palmitate increased IL-6/-8 and MCP-1 in RSFC potentially. HGF was even inhibited. Downstream of Fet-A/palmitate-induced TLR4 activation, NFκB- and JNK-mediated signalling was involved. Fet-A-treated RSFC inverted the benign effects on EC and PO from an anti- to a proinflammatory status. HGF, IL-8, MCP-1, ICAM-1 and ALCAM expressions were stimulated in EC, IL-6/-8 in PO. TGF-β was slightly reduced. In RSF resections, M1/M2 macrophages and many microvessels could be detected.
Conclusion: In vitro, treatment of RSFC with elevated fetuin-A doses inverted the benign effects of RSFC on glomerular cells from a reduced into an induced unhealthy proinflammatory status indicating a Janus-faced characteristic of RSFC. Analysis of our cohort indicates that RSF, particularly in conjunction with fatty liver, may influence renal function in apparently healthy individuals. Taken together, the crosstalk of the fatty liver and the kidney via RSF may adversely affect renal (patho)physiology.

Lifetime dietary macronutrient intake ratios alter kidney function and structure into old age

A.K. Fotheringham[1], S.M. Solon-Biet[2], A.C. McMahon[2], W.O. Ballard[3], K. Ruohonen[4], D.J. Borg[1], D. Raubenheimer[2], D.G. Le Couteur[2], S.J. Simpson[2], J.M. Forbes[1];
[1]Mater Research UQ, Brisbane, [2]Charles Perkins Centre, The University of Sydney, Sydney, [3]School of Biotechnology and Biological Sciences, The University of Sydney, Sydney, Australia, [4]Cargill Aqua Nutrition, Sandnes, Norway.

Background and aims: Chronic kidney disease is prevalent in diabetes (DKD) affecting ~30% of patients, increasing their risk for stroke and cardiovascular disease. DKD is a progressive disorder where changes in glomerular filtration rate (GFR) and structural abnormalities such as tubulointerstitial fibrosis (TIF) and glomerulosclerosis (GS) can predict progression. Despite dietary protein restriction appearing in guidelines for advanced DKD management, the influence of macronutrients on kidney function and structure over the course of ageing has not been investigated. Hence, in this study we use a novel geometric framework to assess the long term effects of macronutrient combinations on kidney function and structure in ageing.
Materials and methods: Male and female C57 mice (N=4/group) were fed *ad-libitum,* 1 of 25 experimental diets that varied across a spectrum of protein (5-60%), carbohydrate (20-75%) and fat (20-75%), at low, medium or high energy contents. At 15 months of age (late middle age), organs and blood were collected. TIF and GS were assessed histologically, whilst serum cystatin C was used as a surrogate for GFR. Blood urea and ions were analysed by COBAS. Risk factors for DKD (body composition, glucose tolerance, systolic (SBP) and diastolic (DBP) blood pressure, and lipids) were assessed just prior to death by gold standard techniques. Using a geometric framework, we produced 4-dimensional models (general additive models) to visualise and quantify the impacts of macronutrient consumption, as both main effects and interactions on each of the DKD factors of interest. Statistical analysis was performed using the mgcv package for R.
Results: Serum cystatin C ranged from 126 to 1006 ng/ml, and was negatively correlated with dietary protein intake (P<.0001), whereby GFR was decreased with lower protein intake. GFR was not influenced by dietary consumption of fat or carbohydrate. A spectrum of TIF was observed in kidney sections (0.5 to 9%). Lower protein consumption in the context of either a high fat or high carbohydrate intake predicted greater TIF (P=0.0005, P= 0.016, respectively). GSI tended to be greater with higher fat intake in the context of lower protein or carbohydrate, although this did not reach significance (p=.083). When lifetime dietary intake of protein was lower, coupled with high fat or increased caloric intake, GFRs were lower and kidney fibrosis was increased in conjunction with increased adiposity (P=.16 and P=.01). Surprisingly, long term consumption of macronutrient combinations which increased SBP or DBP, elevated plasma LDL cholesterol or triglycerides or resulted in glucose intolerance, did not associate with decreased GFR or kidney structural damage.
Conclusion: This framework shows that both individual macronutrients in isolation and their relative combinations affect risk factors for DKD over a lifespan. Overall lower protein intake in conjunction with higher consumption of fat, or calories, results in a phenotype with the lowest GFR and the most kidney structural damage as assessed by TIF and GSI.

Relation between renal vitamin D-endocrine system and RANK/RANKL-signalling pathway in diabetes nephropathy: effect of vitamin D_3 treatment

D. Labudzynskyi[1], I. Shymanskyy[1], S. Savosko[2], L. Bonnet[3];
[1]Department of Vitamin and Coenzyme Biochemistry, Palladin Institute of Biochemistry of the National Academy of Sciences of Ukraine, [2]Department of Histology and Embryology, O.O.bogomolets National Medical University Academy of Sciences of Ukraine, Kyiv, Ukraine, [3]INSERM, UMR 1062, Marseille, France.

Background and aims: Substantial deficiency of vitamin D_3 (D_3) and disruption in the functioning of D_3-endocrine system may play a crucial role in the development of diabetic nephropathy, but the precise mechanism is not fully explored. Growing evidence suggests that receptor activator of nuclear factor κB (RANK)/RANK ligand-signaling pathway can be involved in the development of various renal diseases and close association may exist with D_3-associated regulatory processes. We, therefore, investigated the relationship between the changes in renal vitamin D-endocrine system and RANK/RANKL-singaling pathway in diabetes nephropathy and estimated the effect of vitamin D_3 treatment.
Materials and methods: Type 1 diabetes was induced in male C57BL/J6 mice (23.0 ± 1.6 g) by i.p. injection of high dose of STZ (150 mg/kg b.w.). After 2 weeks of STZ-induced diabetes mice were treated with or without vitamin D_3 (15 IU/mouse per os, for 8 weeks). Serum $25OHD_3$ was assessed by ELISA. The mRNA expression of D_3-endocrine system components and pro-inflammatory cytokines was measured by RT-qPCR. Levels of VDR, RANK and RANKL were detected by immunoblotting. VDR and RANK localization in kidney tissue was visualized using immunohistochemistry. Histological features were assessed by H&E staining.
Results: Serum level of $25OHD_3$ was found to be reduced to 24.6 ± 2.1 in diabetes vs. 40.3±2.8 nmol/L in control, indicative of diabetes-induced D_3 deficiency ($p< 0.05$). D_3 deficiency correlated with abnormalities in D-endocrine system as are evident from decreased levels of cubulin, megalin and CYP24A1 mRNAs and increased expression of CYP27B1 and DBP mRNAs. It was also shown that diabetes induced more than 2-fold decrease in VDR protein level in kidney tissue of diabetic mice vs. control ($p<0.05$). These changes were accompanied by upregulation of the expression of key pro-inflammatory markers in kidney tissue: nuclear factor κB (NF-κB)/p65, IL-6, IL-1β, and TNF-α. Diabetes-related inflammation and failures in D_3-endocrine system were shown to be associated with overexpression of RANKL and RANK proteins (1.6- and 1.4-fold respectively vs. control, $p<0.05$). Given that RANKL is referred to as an upstream effector of the NF-κB activation, it can be implicated in the mechanism of impaired genomic regulation of cytokines expression as an underlying effector of diabetic nephropathy. Full restoration of $25OHD_3$ content and partial normalization of kidney tissue structure were achieved by D_3 treatment. Vitamin D_3 administration caused a partial normalization of D-endocrine system that led to VDR-mediated decrease in mRNA expression of pro-inflammatory cytokines as well as protein levels of RANK and RANKL in renal tissue of diabetic animals.
Conclusion: The present study confirmed that to a large extent diabetes-induced kidney abnormalities can be associated with the upregulation of RANK/RANKL signaling pathway and NF-κB-mediated expression of pro-inflammatory cytokines that correlated with insufficient vitamin D_3 availability and VDR downregulation. Our results can explain protective VDR-mediated effects of vitamin D_3 against diabetes-induced kidney injury through RANK/RANKL signaling pathway.

Baseline characteristics in PRIORITY study: proteomics and mineralocorticoid receptor antagonism for prevention of diabetic nephropathy in type 2 diabetes

N. Tofte, on behalf of the PRIORITY study group;
Steno Diabetes Center Copenhagen, Gentofte, Denmark.

Background and aims: The urinary proteomics based classifier CKD273 has been shown to retrospectively identify normoalbuminuric

diabetic patients who progress to overt kidney disease. In the PRIORITY (Proteomic prediction and Renin angiotensin aldosterone system Inhibition prevention Of early diabetic nephRopathy In TYpe 2 diabetic patients with normoalbuminuria) trial, the aim is to confirm that CKD273 can predict microalbuminuria prospectively, and to test whether mineralocorticoid receptor antagonism (MRA) delays progression to microalbuminuria. Here we report the association between CKD273 and traditional risk factors for diabetic nephropathy at baseline.

Materials and methods: PRIORITY is an investigator-initiated, prospective, randomized, double blind, placebo-controlled multicentre clinical trial and observational study in normoalbuminuric type 2 diabetic patients. Patients are stratified into high-or low risk groups based on CKD273. Patients in the high risk group are assigned to spironolactone 25 mg once daily or placebo, whereas the low-risk group is followed on standard care. The trial continues until September 2018, following patients for up to 4.5 years. The primary endpoint is development of microalbuminuria.

Results: In total 2277 type 2 diabetic patients have been screened over a time period of 2.5 years and 1811 are included from 15 sites. Table 1 shows the baseline characteristics. 224 (12.4%) have the high-risk CKD273 pattern. The high- and low-risk populations differ statistically in terms of gender, age, diabetes duration, UACR and eGFR however the differences are numerically small. Univariate regression analyses of CKD273 vs each baseline variable demonstrated weak associations (R^2 of 0.03, p <0.0001) for the strongest correlations with UACR and eGFR respectively. In a logistic regression model predicting CKD273 risk strata, including all baseline variables, eGFR and UACR remain statistically significant (p < 0.0003) with an AUC of 0.70 (95 % CI: 0.65, 0.74).

Conclusion: Classical risk factors for diabetic kidney disease differ only slightly between high and low risk patients based on the urinary proteomics based risk classifier CKD273 in type 2 diabetes, suggesting it provides additional information to the measures already available in the clinic. The potential added value will be tested in this prospective study.

Variable \	Included N=1811	Low-risk N=1587	High-risk N=224	P-value (high vs. low)

Adiponectin receptor agonist, AdipoRon, protects cultured podocytes against lipopolysaccharide-induced inflammation and apoptosis

S. Lindfors[1], H. Nisén[2], T. Mirtti[1], J. Tienari[3], S. Lehtonen[1];
[1]Department of Pathology, University of Helsinki, [2]Department of Urology, Helsinki University Hospital, [3]Department of Pathology, University of Helsinki and Helsinki University Hospital, Helsinki and Hyvinkää, Finland.

Background and aims: Chronic inflammation has emerged to play a significant role in the pathogenesis of diabetic kidney disease. Several diabetes-associated factors can induce chronic inflammation, such as bacterial lipopolysaccharides (LPS) in the serum. On the other hand, type 2 diabetes is often accompanied with lowered serum levels of adiponectin hormone. As adiponectin has anti-inflammatory effects, its deficiency or downregulation of its receptor may support chronic inflammation and predispose podocytes to cellular injury and development of albuminuria. The aim of this study is to investigate whether the first small-molecule agonist of the adiponectin receptor, AdipoRon, protects cultured podocytes from LPS-induced inflammation and cell death.

Materials and methods: Human kidney samples were obtained from surgical nephrectomies and were taken from the nonmalignant part of the kidney. Paraffin sections were stained with AdipoR1 antibody and positive staining area (%) within 10 glomerular sections per patient was quantified by HistoQuant software. Differentiated human podocytes (AB8/13) were pre-treated with AdipoRon or vehicle for 2 hours and exposed to LPS for additional 1 or 24 hours. Culture media was collected after 24 hours and secreted cytokines were measured by ELISA. Protein levels of cleaved caspase-3, p-JNK and p-IκBα were measured from cell lysates by quantitative immunoblotting.

Results: We found that Adiponectin receptor 1 (AdipoR1) is strongly expressed in human glomeruli and especially in podocytes. In females, patients with type 2 diabetes (n=11) had 14% less AdipoR1-positive area in comparison to non-diabetic controls (n=16) (p<0.05). In men, no difference was observed between type 2 diabetes patients (n=23) and non-diabetic controls (n=24). The average age did not differ between the groups. Downregulation of renal AdipoR1 expression has been previously observed in albuminuric rodent models of type 2 diabetes, indicating that it may play a role in the development of diabetic kidney complication.

In the in vitro studies, we found that 24-hour LPS stimulation caused 2-fold increase in the expression of cleaved caspase-3 (p<0.001) in cultured podocytes, and was restored back to the level of the control by AdipoRon (p<0.001). This indicates that AdipoRon prevents LPS-induced apoptotic cell death. Simultaneously, LPS stimulation caused 3-fold upregulation (p<0.01) of the secretion of tumor necrosis factor-α (TNF-α), which was reduced by 41% by AdipoRon (p<0.01). As TNF-α has pro-apoptotic and pro-inflammatory effects, the anti-apoptotic effects of AdipoRon are likely mediated via lowering inflammation. In line with this, we found that 1-hour LPS stimulation upregulated phosphorylation of JNK (Thr183/Tyr185) and IκBα (Ser32/36), which was prevented by AdipoRon. The JNK and NFκB pathways, which are activated by phosphorylation of JNK and IκBα, respectively, are known to mediate inflammatory responses and cell survival.

Conclusion: Our results suggest that activating the adiponectin receptor by AdipoRon is a potent way to alleviate inflammation and apoptosis of podocytes. Further studies are needed to investigate whether AdipoRon could prevent inflammation-related glomerular injury in vivo.

The phosphodiesterase inhibitor cilostazol reduced the risk of chronic kidney disease in type 2 diabetes without diabetic kidney disease

Y.-B. Ahn[1], J.-S. Yun[1], S.-A. Cha[1], S.-H. Ko[1], S.-A. chang[2], H. Son[2], S.-H. Ko[1];
[1]The Catholic University of Korea, Suwon, [2]The Catholic University of Korea, Seoul, Republic of Korea.

Background and aims: The purpose of this study was to investigate a possible association between the use of cilostazol (a phosphodiesterase type 3 inhibitor) and the development of chronic kidney disease (CKD) through a post-hoc analysis of a cohort of patients with type 2 diabetes
Materials and methods: From January 2000 to December 2006, 620 patients with type 2 diabetes without diabetic kidney disease (estimated glomerular filtration rate [eGFR] > 90ml/min/1.73m2 and normoalbuminuria [24-hour urine albumin excretion < 30mg/day by consecutive two or more measurements]) were enrolled. The indications for cilostazol use were patients who were over 40 years of age or who had additional cardiovascular risk factors (a family history of cardiovascular disease, hypertension, smoking, dyslipidemia) or had a symptom with intermittent claudication and peripheral artery disease in one or both limbs. The eGFR was measured more than once every year to check the patients' renal function. New-onset CKD was defined as a decreased eGFR of < 60 ml/min/1.73m^2 using a Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation. A logistic regression model was used to estimate the adjusted odds ratio with 95% confidence intervals of incident CKD associated with cilostazol use both overall and by cumulative duration of use.
Results: The mean age and duration of diabetes were 54.5 ± 8.3 years and 6.9 ± 5.6 years, respectively. The baseline eGFR and albumin excretion rate were 101.9 ± 8.1 and 10.1 ± 6.7 mg/day. The median follow-up time was 12.1 years. During the study, 86 patients (13.9%) progressed to CKD. After adjusting for multiple confounding factors, the use of cilostazol was significantly associated with a reduced risk of incident CKD (adjusted OR 0.49, 95% CI 0.26-0.93; P = 0.028). A duration-response relation was also observed. The use of cilostazol for more than 10 years associated with a reduced risk of CKD (adjusted OR 0.50, 95% CI 0.25-0.98; P = 0.044). When the duration-response was considered as a continuous variable, the significant association between cilostazol and the development of CKD remained (adjusted OR 0.94 per one year cilostazol use, 95% CI 0.89-0.99; P = 0.017).
Conclusion: The results of this study showed that the use of cilostazol, a phosphodiesterase inhibitor, was associated with a reduced risk of new-onset CKD. In fact, a longer duration of cilostazol use tended to decrease the risk of new-onset CKD.
Disclosure: **Y. Ahn:** None.

Resistant starch ameliorates advanced glycation endproduct-induced albuminuria in a mouse model of type 2 diabetes

M. Snelson, S.M. Tan, K. Sourris, G. Higgins, R. Lindblom, V. Thallas-Bonke, M.E. Cooper, M.T. Coughlan;
Department of Diabetes, Monash University, Melbourne, Australia.

Background and aims: Long-term excess intake of dietary advanced glycation endproducts (AGEs) contributes to chronic renal injury. Recent research implicates gut dysbiosis in the progression of diabetic nephropathy, however, the role of dietary AGEs in gut dysbiosis and renal injury in the context of diabetes has not yet been explored. The aim of this study was to investigate whether excess consumption of dietary AGEs cause gut dysbiosis, exacerbating renal injury in a mouse model of type 2 diabetes. A secondary aim was to elucidate whether a high fibre diet (resistant starch), may be protective against diabetic nephropathy via altering gut homeostasis.
Materials and methods: Six week old diabetic mice (db/db) (BKS.Cg-Dock7m+/+Leprdb/J) on a C57BL/KsJ background and age-matched non-diabetic control mice (db/m) were randomised (n=12/group) to receive a low AGE (LAGE, unbaked rodent chow) or a high AGE diet (HAGE, baked at 160°C for 1 hour), with or without 25% resistant starch (RS) for 10 weeks. All diets were isocaloric. 24-hour urine was collected for the assessment of albuminuria. At 15 weeks of age, mice were fasted and an oral glucose tolerance test (2g/kg lean body mass) was performed. At 16 weeks of age, intestinal permeability was assessed in vivo by the clearance of FITC-labelled dextran (500mg/kg body weight). Glycated haemoglobin was assessed using a Roche cobas b101 analyser.
Results: The high AGE diet exacerbated albuminuria in db/db mice (874.4±154.8 vs 536.2±96.5μg/24h, P<0.05, db/db HAGE vs db/db LAGE), and this AGE-induced increase in albuminuria was attenuated by RS (874.4±154.8 vs 515.5±71.9μg/24h, P<0.05, db/db HAGE vs db/db HAGE + RS). Db/db mice had increased gut permeability compared to db/m mice (2.38±0.32 vs 1.05±0.11μg/ml, P<0.01, db/db LAGE vs db/m LAGE). Furthermore, the high AGE diet increased gut permeability of db/db mice (3.43±0.43 vs 2.38±0.32μg/ml, P=0.06, db/db HAGE vs db/db LAGE), an effect not observed in RS-fed db/db mice (2.38±0.32 vs 2.86±0.35μg/ml, P>0.05, db/db LAGE vs db/db LAGE+RS). Following OGTT, db/db mice had a higher glucose AUC (74.08±5.98 vs 17.54±2.32 mmol/L x min, P<0.05, db/db LAGE vs db/m LAGE) and glycated haemoglobin (10.47±1.96 vs 4.06±0.12, P<0.05, db/db LAGE vs db/m LAGE) compared to db/m mice. Neither the high AGE diet nor the resistant starch supplemented diets influenced glycaemic control in db/db or db/m mice, as reflected by OGTT AUC (74.08±5.98 vs 75.29±6.45 vs 75.29±6.45 vs 72.64±7.16 mmol/L x min, P>0.05, db/db LAGE vs db/db LAGE+RS vs db/db HAGE vs db/db HAGE+RS), or glycated haemoglobin (10.61±0.46 vs 9.65±0.55 vs 10.98±0.67 vs 10.58±0.67 % glycated haemoglobin, P>0.05, db/db LAGE vs db/db LAGE+RS vs db/db HAGE vs db/db HAGE+RS).
Conclusion: A high AGE diet led to increased intestinal permeability, which was associated with worsening albuminuria in db/db mice. Resistant starch was protective against high AGE induced albuminuria in db/db mice, effects which are not dependant on changes in glucose homeostasis. These preliminary studies support the notion that dietary AGEs contribute to renal disease via alterations in gut homeostasis and suggest a potential role for resistant starch as a renoprotective agent.

One-year eGFR decline rate is a good predictor for prognosis of renal failure in patients with type 2 diabetes

S. Meguro[1], J. Nojima[1,2], N. Ohkawa[3], M. Furukoshi[4], T. Kawai[5], H. Itoh[1];
[1]Nephrology, Endocrinology, and Metabolism, Keio University, [2]Internal Medicine, Eiju General Hospital, [3]Asahi Kasei Pharma Corporation, [4]Asahi Kasei Corporation, [5]Internal Medicine, Saiseikai Central Hospital, Tokyo, Japan.

Background and aims: Patients who lose renal function faster than the average age-related decline in eGFR tend to progress to ESRD. Progressive renal decline was defined as an eGFR loss of ≥ 3.3% per year, but the calculation of this annual average renal decline rate requires lifelong observation. In this study, we used a data smoothing technique to analyze eGFR trajectories and successfully identified starting points of meaningful eGFR decline.
Materials and methods: All type 2 diabetes patients seen between June 2001 and October 2014 were candidates for this study. Among these patients, subjects whose eGFR was measured more than twice in a half-year for more than three years were included. Patients with no eGFR examination more than a year during the study period, or a mean eGFR < 60 mL/min/1.73 m^2 at baseline were excluded. We performed a smoothing technique called locally weighted regression method to reduce the fluctuation in eGFR trajectory. Every eGFR value was smoothed ($eGFR_{monthly\ smoothing\ data}$) and average $eGFR_{monthly\ smoothing\ data}$ in every half-year was calculated for each patient ($eGFR_{half\ year}$). We calculated each 1-year eGFR decline rate from the difference between each $eGFR_{half\ year}$ value and that of the previous year. We also used the maximum value of $eGFR_{half\ year}$ for ROC analysis. The endpoint was defined as a decline of $eGFR_{half\ year}$ to less than half of eGFR at baseline.

Results: A total of 2533 patients with type 2 diabetes were included in this study. The mean eGFR at baseline was 77.1 ± 13 mL/min per 1.73 m^2. The mean follow-up period was 9.1 ± 3.0 years. During the follow-up period, 85 (3.4%) patients reached the endpoint. When we performed ROC analysis for the endpoint, AUC of 1-year eGFR decline rate was 0.949. We examined the predictive value of the cut-off value of 7.5%, and found a sensitivity of 98.8% and specificity of 82.3%. The AUC of albuminuria at baseline was 0.684 and that of mean eGFR at baseline was 0.576. When we analyzed the cumulative renal endpoint incidence in subjects with a 1-year eGFR decline rate ≥ 7.5% with the Kaplan-Meier method (Figure), the average survival period was 98 months, and only 1 (0.05%) patient whose 1-year eGFR decline rate was always < 7.5% reached an endpoint.

Conclusion: The predictive accuracy of the smoothed 1-year eGFR decline rate for renal prognosis is high compared with other indicators. In cases where the 1-year eGFR decline rate is ever greater than 7.5%, the prognosis may be poor.

ADIPOQ gene polymorphisms and changes in renal function in a cohort from the community, the prospective D.E.S.I.R. study

F. Fumeron[1,2], A. Pikelaiti[1,2], A. Nicolas[1,3], B. Balkau[4], M. Marre[1,5], G. Velho[1], R. Roussel[1,5];
[1]INSERM UMRS1138, Centre de Recherche des Cordeliers, Paris, [2]Univ Paris Diderot, Sorbonne Paris Cité, Paris, [3]Univ Pierre et Marie Curie, Sorbonne Universités, Paris, [4]INSERM, CESP Centre for research in Epidemiology and Population Health, U1018, Villejuif, [5]Dept. Of Diabetology, Endocrinology and Nutrition, APHP, Paris, France.

Background and aims: High adiponectin levels are associated with diabetic nephropathy. Polymorphisms of the adiponectin gene (*ADIPOQ*) have been associated with nephropathy, both in type 1 and type 2 diabetes. Nevertheless, it is not known whether *ADIPOQ* polymorphisms are associated with renal function in the general population. We evaluated whether *ADIPOQ* polymorphisms were associated with changes in renal function in a community cohort, the D.E.S.I.R. (Data from Epidemiological Study on Insulin Resistance Syndrome) study.

Materials and methods: The D.E.S.I.R. study, a prospective cohort from the general population, recruited 5,212 men and women from western France, in the age range 30-65 years. Among those with a 9-year follow-up, 4220 born in mainland France were genotyped for 4 *ADIPOQ* polymorphisms (rs2241766, rs266729, rs17300539 and rs1501299). Adiponectin levels were measured by radioimmunoassay in a sample of 250 subjects. Estimated glomerular filtration rate (eGFR) was calculated according to the "Modification of Diet in Renal Disease" formula (MDRD). Progression towards chronic kidney disease (CKD) during follow-up was defined by an eGFR below 60 ml/min/1.73 m^2 on at least one follow-up visit. We have also considered the criterion "Certain Drop in eGFR" as proposed by the Kidney Disease Improving Global Outcomes (KDIGO) group.

Results: Progression towards CKD (defined as eGFR<60 ml/ min/1.73 m^2) during follow-up was observed in 225 participants. The KDIGO criterion "Certain Drop in eGFR" of CKD progression was fulfilled by 251 participants during follow-up. We observed an association between the *ADIPOQ* rs2241766 SNP (+45T>G) and CKD progression defined by the KDIGO criterion. The +45G carriers had a lower risk of progression with an odds-ratio of 0.61 (95% CI 0.43-0.86, p=0.006, by logistic regression, adjusted for sex, age, and body mass index). Change in eGFR during the follow-up was also associated with +45T>G polymorphism. The +45G allele was associated with a lower decrease in eGFR after 9 years (-6.76, -5.38, -4.35 ml/min/1.73 m^2 in TT, TG and GG genotypes, respectively, p=0.014, by linear regression adjusted for sex, age, BMI). These results remained significant after exclusion of people with diabetes, at baseline or at follow-up. The +45G allele was associated with higher adiponectin levels (p=0.003, ANCOVA adjusted for sex, age, BMI, glycemic status). No association was found between renal parameters and the other *ADIPOQ* polymorphisms.

Conclusion: The *ADIPOQ* +45G allele associated with higher adiponectin levels was negatively associated with progression towards CKD in this community-based cohort. The same allele has been positively associated with nephropathy in our previous studies in people with type 1 and type 2 diabetes. This supports the hypothesis of opposite roles of adiponectin in renal function according to the clinical and metabolic background. High adiponectin levels may be beneficial in healthy subjects.

Correlation of diabetic nephropathy with platelet hyperactivity, von Willebrand factor, protein S and protein C activity in patients with type 1 diabetes

K. Sarkisova[1], M. Shestakova[1,2], I.R. Jarek-Martynowa[2], A. Ilyin[2], L. Nikankina[2], L. Chirkova[2], M. Shamkhalova[2];
[1]I.M. Sechenov First Moscow State Medical University, [2]Endocrinology Research Centre, Moscow, Russian Federation.

Background and aims: Diabetes is associated with accelerated atherosclerosis and an increased risk of clinical cardiovascular disease. However, little is known about platelet activation as a risk factor for cardiovascular disease in DM1 patients with nephropathy. The aim of this study was to assess the impact of level of fasting plasma glucose, HbA_1c, glomerular filtration rate (GFR), albumin excretion rate (AER) on the platelet activity, endothelial dysfunction and the physiological anticoagulant activity in patients with DM1.
Materials and methods: Study has been reviewed by the Local Ethics Committee it has been performed in accordance with the ethical standards laid down in the Helsinki Declaration. We examined 60 patients with DM1 (age 28,1±6,5, HbA_1c 9,1±1,8%). With normoalbuminuria AER in the morning urine <20 mg/L (n=38); microalbuminuria AER <199 mg/L(n=17); macroalbuminuria AER ≥200 mg/L (n=5). On the background euglycemia (fasting plasma glucose ≤6,5 (5,7±1,06) mmol/l), and hyperglycemia (fpg ≥12 (13,2±2,35) mmol/l) were measured induced platelet aggregation (IPA) in whole blood using ADF, arachidonic acid, ristocetin, thrombin (tRaP-6), collagen by multiple electrode platelet aggregometry (Multiplate); physiological anticoagulants (protein S, protein C, AT-III), and von Willebrand factor was determined by ELISA; GFR by standard EPI formula. Statistical analysis was performed with SPSS 22,0 for Windows, $p<0.05$.
Results: Platelet aggregation using ADF, arachidonic acid, ristocetin was significantly increased on the background of hyperglycemia compared with euglycemia (p=0,01, p=0,02, p=0,016 respectively) (W-test). Platelet aggregation using ADF was higher in patients with macroalbuminuria 82,0 [61,0;86,0] compared with microalbuminuria patients 47,5 [38,7; 68,2], p=0,014 (U-test). von Willebrand factor was higher in patients with microalbuminuria 0,76 [0,54;1,04] and with macroalbuminuria 0,77 [0,58; 0,85] compared with normoalbuminuria patients 0,47 [0,28; 0,59],p=0,01 (U-test). Protein S activity was significantly increased in group with GFR 45-59 ml/min/1.73 m^2 80,3[68,1; 97,2] compared with group with GFR ≥60 ml/min/1.73 m^2 103,8[87,4; 109,9], p=0,021 (U-test). Protein C activity was significantly increased in group with GFR 45-59 ml/min/1.73 m^2 114,5 [95,3; 122,1] compared with group with GFR ≥60 ml/min/1.73 m^2 138,9 [124,2; 158,5], p=0,007 (U-test). Platelet aggregation using ADF was correlated negatively with GFR (r=-0,253;p=0,03). Level of HbA_1c was correlated positively with increased platelet aggregation using arachidonic acid (r=0,299;p=0,03) and protein C activity (r=0,375;p=0,02).
Conclusion: Hyperglycemia, increased level of HbA_1c, diabetic nephropathy are associated with platelet hyperactivity and endothelial dysfunction which may increase the risk of adverse cardiovascular and cerebrovascular events. An increase in the activity of physiological anticoagulants in later stages of nephropathy may be a compensatory reaction of the organism for the hypercoagulable condition in patients with DM1.

The assessment of relationship of osteopontin with vascular complications progression and the risk of adverse outcomes in patients with long-term type 1 diabetes

M. Arutyunova[1], A. Glazunova[1], I. Klephortova[1], S. Martynov[1], O. Manchenko[1], I. Ulianova[1], A. Ilyin[1], N. Goncharov[1], G. Katziya[1], M. Shamkhalova[1], M. Shestakova[1,2];
[1]Endocrinology Research Centre, [2]I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation.

Background and aims: To investigate the association between osteopontin (OPN) and vascular complications of diabetes, and the risk of adverse events developments in patients with long-term type 1 diabetes mellitus (DM1)
Materials and methods: The study included 156 patients with long-term DM1 (more than 20 years). We have estimated the renal status, severity of cardiovascular pathology, and frequency of adverse outcomes such as: doubling the level of creatinine, reaching the terminal stage of chronic kidney disease (CKD), developing nonfatal myocardial infarction, stroke, amputation, urgent hospitalization, death within 5 years of observation.
Results: Serum OPN was higher in persons with terminal stage of CKD who are on dialysis therapy and who underwent renal transplantation (TP), and lower was - in patients without CKD. The differences were statistically significant: between a group of people without CKD and patients with CKD 1-4, dialysis patients and those, who underwent TP (p=0.0027; p=0.0246; p=0.0249, respectively). In patients with albuminuria, the level of OPN was also significantly higher than in individuals with normoalbuminuria (49.9 ng/ml [24.3, 67.85] vs 28.1 ng/ml [12.4, 46.7]; p = 0.005). Elevated serum levels of OPN were associated with young patients (r=-0.249; p=0.048), low body mass index (BMI) (r=-0.267; p=0.020), increased albuminuria (r=0.42; p=0.0104), serum level of C-reactive protein (r=0.426;p=0.0378), left ventricular hypertrophy - LVMI (r=0,257; p=0,0279), vitamin D deficiency (r=-0.224; p=0.0280). The relationship of OPN with the ADMA marker was found (r=0.290; p=0.0103). According to the OPN serum concentration level, patients were divided into 3 groups: the 1st group of OPN 5-17 ng/ml, the 2d group 17.1-59.0 ng/ml, the 3d group 59.1 -145, 6 ng/ml. Groups 1 and 2 were differed in the degree of calcification of the coronary arteries, such was identificated with using of a multispiral computed tomography of heart with Agatston index definition (p=0.048), groups 1 and 3 were differed with respect to BMI (p=0.003), the level of albuminuria (p=0.010), vitamin D (p=0.047) and ADMA (p=0.013), and groups 2 and 3 - by BMI (p=0,012), albuminuria (p=0,018) and ADMA (p=0,021). The development of adverse events during the 5-year follow-up period (28.2%) was associated with a higher value of the OPN (50.6 ng/ml [23.8, 62.2] vs 38.9 ng/ml [16, 51.2]; p=0.010).
Conclusion: The study demonstrates the diagnostic value of serum OPN not only in verification of specific for diabetes cardiovascular and renal pathology, which has already got formed, but also in predicting the risks of progression of late diabetic complications and mortality of patients with long-term CD1 flow.

The detoxifying capacity of carnosine in vitro and in renal cells

V. Peters[1], C.P. Schmitt[2], B. Singler[1], P. Nawroth[3], T. Fleming[3], A. Amberger[4], K. Klika[5], J. Zschocke[4], T. Weigand[1];
[1]Division of Metabolic Diseases, University of Heidelberg, [2]Division of Paediatric Nephrology, University of Heidelberg, [3]Division of Endocrinology, University of Heidelberg, Heidelberg, Germany, [4]Division of Human Genetics, Medical University Innsbruck, Innsbruck, Austria, [5]Molecular Structure Analysis, German Cancer Research Center (DKFZ), Heidelberg, Germany.

Background and aims: Methylglyoxal (MG) is a reactive carbonyl species that accumulates under diabetic conditions and essentially contributes to diabetic complications. Carnosine has previously been described as a quencher of reactive metabolites and to mitigate long term diabetic

complications such diabetic nephropathy. We therefore analyzed the mode and detoxification capacity of carnosine against MG in cell free environment and cultured renal cells.
Materials and methods: Interactions of carnosine and MG were evaluated spectrophotometrically and by NMR analysis of the formed adducts. Carnosine dependent reduction of MG induced AGE and CEL formation of from human serum albumin was measured by ELISA and Western Blot. Renal cells were incubated with increasing carnosine to MG ratios and incubation times; cell viability was measured by MTT assay. Putative carnosine transporters were quantitated by qPCR, intracellular carnosine uptake by radiolabeled carnosine-uptake assay.
Results: NMR studies revealed the formation of oligo/polymeric products of MG, catalyzed by carnosine. The addition of carnosine (≥100:1 to MG) and anserine (≥200:1 to MG) reduced the formation of AGEs ($p \leq 0.05$) and CEL ($p \leq 0.05$). In renal cells, carnosine (0 to 5 mM) did not restore MG impaired cell viability (0 to 1 mM) in short- and long-term incubation experiments. Neither cellular SOD and GPx expression, nor SOD activity or GSH levels were altered by carnosine addition. Putative carnosine transporters were only expressed in tubular cells and uptake of radiolabeled carnosine was very low (0.04±0.02% in tubular cells and 0.05±0.02% in mesangial cells after 24h).
Conclusion: Carnosine interacts with MG in vitro by catalyzing the formation of MG oligo- and polymers .This action, however, in cultured renal cells does not result in protection from MG induced toxicity, i.e. does not increase cell viability or elements of the cellular stress protection system. Intracellular carnosine uptake is low, carnosine to MG ratios required to induce protective effects are not reached. Intracellular carnosine metabolism and compartmentalization should now be analyzed. These results suggest high importance of internal carnosine metabolism.

The new, volatile biomarkers of chronic kidney disease and coexisting type 2 diabetes

P. Miarka[1], B. Grabowska[2], M. Skowron[2], A. Pietrzycka[3], I. Sliwka[4]; [1]Department of Nephrology, Medical College, Jagiellonian University, [2]Institute of Nuclear Physics Polish Academy of Sciences, [3]Medical College, Jagiellonian University, Faculty of Pharmacy, [4]Department of Nephrology, Institute of Nuclear Physics Polish Academy of Sciences, Krakow, Poland.

Background and aims: Chromatographic studies on breath composition are aimed at finding volatile markers useful for medical diagnostics or in screening investigations. Studies leading to the development of screening breath tests are especially important for the diagnostics of chronic kidney disease (CKD) and type 2 diabetes mellitus (T2DM). The aim of the presented study was to confirm diagnostic usefulness of chosen volatile compounds detected in breath, which are suggested as potential biomarkers of renal dysfunction and diabetes.
Materials and methods: Breath samples were collected from 20 patients with CKD. Among these 20 patients, all with CKD, 10 patients had also T2DM or glucose intolerance. The control group, consisting of 6 women and 4 men. All exhaled air samples were analyzed using gas chromatograph (Agilent 6890GC) coupled with mass spectrometer (5975MSD). Thermal desorption was applied as the enrichment method.
Results: Patients were characterized by increased creatinine, urea, homocysteine (Hcy) and glutathione (GSH) levels. Liver enzymes values, lipid levels and inflammation markers remained within normal limits. The group of patients with CKD and diabetic nephropathy had significantly different kidney function parameters ($p<0.05$). Diagnostically promising results were obtained for trimethylamine (TMA) and sulphur compounds. TMA was detected only in CKD patients. Higher breath concentrations of methanethiol (MeSH) were observed in CKD patients with coexisting diabetes than in patients with renal dysfunction only or in the healthy group. There was a tendency of increasing MeSH concentration in breath with increasing total glutathione in plasma ($r=0.53$, $p=0.0026$). Also, a trend of increasing dimethylsulfide (DMS) levels detected in breath was noticed with an increase of hydrogen sulfide concentration in plasma ($r=0.74$; $p=0.00001$) as well as with aspartate aminotransferase (AST), ($r=0.61$; $p=0.001$).
Conclusion: The presented results suggest the possibility of applying TMA, MeSH, and DMS detection in breath as diagnostic methods.

Mitochondrial dysfunction defines a population of young people with type 1 diabetes at risk of kidney disease

J.M. Forbes[1], N. Flemming[1], D. McCarthy[1], K. Boot[2], N. D'Silva[3], L. Gallo[1], D.R. Thorburn[4], A. Russell[5], D. Johnson[5], G. Morahan[6], T. Jones[7], J. Couper[8], K. Donaghue[9], M. Hodson[10], T. O'Moore-Sullivan[3]; [1]Mater Research Institute - The University of Queensland, Brisbane, [2]David Serisier Biobank, Mater Health Service, Brisbane, [3]Diabetes and Endocrinology, Mater Health Service, Brisbane, [4]Murdoch Children's Research Institute, Melbourne, [5]Metro South Health, Brisbane, [6]Harry Perkins Institute of Medical Research, Perth, [7]Telethon Kid's Institute, Perth, [8]Women's and Children's Hospital, Adelaide, [9]Children's at Westmead, Sydney, [10]Metabolomics Australia - The University of Queensland, Brisbane, Australia.

Background and aims: Recent evidence suggests that kidney disease in Type 1 diabetes (T1D) develops much earlier than previously appreciated. In adolescents with type 1 diabetes (T1D), the highest tertile of urinary albumin-to-creatinine ratio (uACR), a marker of endothelial dysfunction, predicts renal and cardiovascular disease risk. Another factor implicated in the development of diabetic kidney disease (DKD) is mitochondrial dysfunction. The objective of this study was to examine the relationships between mitochondrial function, uACR and estimated glomerular filtration rate (eGFR) in young people with T1D.
Materials and methods: In this cross-sectional study, adolescents and young adults with T1D were recruited [n=100; 20.0±2.8 yrs; M:F-54:46, HbA_{1c}-66.1(12.3) mmol/mol; diabetes duration-10.7 ±5.2 yrs; BMI-24.5(5.3) kg/m^2]. Mean uACR was determined from 3 morning urine samples collected from each study participant. The study population was then divided into uACR tertiles. Lower (uACR ≤0.66 mg/mmol; n=33) and middle (uACR 0.67-1.16; n=33) tertiles were defined as having low-moderate risk of future DKD and those in the upper tertile (uACR ≥1.17; n=34) as having the highest risk. SeaHorse XF analyser was used for mitochondrial functional assays in circulating leukocytes. Urinary metabolomics by LC MSMS, GCMS and HPLC measured central carbon metabolites, nucleotides, fatty and amino acids.
Results: A majority (99.7%) of participants had hyperfiltration [CKD_{EPI} eGFR, 135.0(13.8) ml/min/m^2) and individuals in the upper tertile of uACR had the highest median eGFR (P <0.031 vs low risk tertile; age, gender and diabetes duration adjusted). In a generalized linear model which included HbA_{1c}, BMI, diabetes duration, sex and age, a significant inverse relationship was identified between eGFR-CKD_{EPI} and logACR in the upper tertile, as compared with both lower risk tertiles (vs middle, $P=9.8\times10^{-5}$; vs lower, $P=2\times10^{-16}$). Mitochondrial function (ATP dependent respiration) in circulating leukocytes, was decreased in individuals in the higher uACR tertile, compared with the two lower uACR tertiles ($P=0.008$). Multivariate modelling of urinary metabolites identified a signature which separated individuals in the upper uACR tertile from the lower risk tertiles.
Conclusion: Young individuals with type 1 diabetes and higher risk of DKD have mitochondrial dysfunction and an inverse relationship

between GFR and uACR. These features are similar to those in individuals with progressive kidney disease, warranting further investigation.

Exome-chip association analyses for diabetic nephropathy and estimated glomerular filtration rate in Chinese patients with type 2 diabetes

C.Y.Y. Cheung[1], C.H. Lee[1], C.S.M. Tang[2], A. Xu[1], K.W. Au[1], C.H.Y. Fong[1], K.H.M. Kwok[1], W.S. Chow[1], Y.C. Woo[1], M.M.A. Yuen[1], K.C.B. Tan[1], T.H. Lam[3], H.F. Tse[1], P.C. Sham[4], K.S.L. Lam[1];
[1]Department of Medicine, The University of Hong Kong, [2]Department of Surgery, The University of Hong Kong, [3]School of Public Health, The University of Hong Kong, [4]Department of Psychiatry, The University of Hong Kong, Pokfulam, Hong Kong.

Background and aims: Diabetic nephropathy (DN) is the leading cause for end stage renal disease. Despite evidence showing that genetic susceptibility plays a role in the development of DN, the genetic determinants of DN remains poorly understood. This study aimed to identify novel single nucleotide polymorphisms (SNPs) associated with DN and a quantitative measure of renal function, the estimated glomerular filtration rate (eGFR), among Chinese patients with type 2 diabetes.
Materials and methods: Exome-chip association analyses for DN and eGFR were conducted by genotyping 1689 DN cases and 1227 non-DN controls from the Hong Kong West Diabetes Registry (HKWDR). DN cases were defined as subjects with the presence of either microalbuminuria or macroalbuminuria, as indicated by the patient's urinary albumin-to-creatinine ratio in two random urine samples, collected within 6 months, according to the American Diabetes Association criteria; or having an abnormal eGFR<60 mL/min/1.73m^2. Those with normoalbuminuria and an eGFR≥60 mL/min/1.73m^2 were classified as non-DN controls. All subjects were genotyped using the custom Asian Exomechip. Single variant association analyses were conducted on 77,343 and 78,026 SNPs for DN and eGFR, respectively. The associations of SNPs with DN and eGFR were examined by multiple logistic and linear regression analyses, respectively, with adjustment for age, sex, duration of diabetes and presence of hypertension.
Results: A total of 7 SNPs located in 6 loci showed evidence of association with DN ($P<1x10^{-4}$). The strongest association was identified at rs7315438 ($P=8.32x10^{-6}$; OR[95%CI]: 0.76[0.68-0.86]), an intergenic variant located between the *TBX3* and *MED13L* genes. A suggestive association was also identified at rs9313307 ($P=5.07x10^{-5}$; OR[95%CI]: 1.46[1.22-1.75]), located upstream of the *TENM2*. In the analysis for eGFR, 12 SNPs located in 10 loci were associated with eGFR at $P<1x10^{-4}$. The *TENM2* rs9313307, which also demonstrated an association with DN, was found to be significantly associated with eGFR ($P=7.04x10^{-7}$; β[95%CI]: -0.2[-0.28, -0.12]). Several low-frequency missense variants at *ZKSCAN2* (rs61746620; P=9.75x10-6; β[95%CI]: -1.67[-2.41, -0.93]), *BRICD5* (rs199775669; $P=6.20x10^{-5}$; β[95%CI]: -1.64[-2.43, -0.84]), and MUC17 (rs150088438; $P=7.53x10^{-5}$; β[95%CI]: -0.88[-1.32, -0.44]) also demonstrated suggestive associations with eGFR.
Conclusion: We have identified the associations of several novel loci with DN and/or eGFR in the exome-chip association analyses among Chinese patients with type 2 diabetes. Although genome-wide significance was not found for any of the identified SNPs, several genes, such as *TBX3*, *TENM2* and *MUC17,* are potential functional candidates for DN and altered eGFR. Further replication studies in independent cohorts would serve to validate our findings.

Interleukin-21 receptor (IL-21R) blockade reduces the development of albuminuria in a uninephrectomised db/db mouse model of diabetic nephropathy

A. Seth, L. Burke, S. Madalli, H. Brant, L. Liang, S. Heasman, R. Ettinger, M. Coghlan, C. Moreno Quinn, D.J. Baker;
CVMD, MedImmune, Cambridge, UK.

Background and aims: Chronic kidney disease (CKD) encompasses a range of disorders affecting kidney structure and function that affect an estimated 10% of the world's population. Current treatments are limited to blockade of the renin-angiotensin system, however, the identification of novel mechanisms contributing to CKD provide the potential for new classes of therapies. Here we explore a role for blocking interleukin-21 receptor (IL-21R) signalling in a murine model of diabetic nephropathy (DN). IL21R is a type I cytokine receptor and has been detected on glomeruli and tubules in both mouse and man. IL21R has been reported to play a role in intrarenal T-cell accumulation and is upregulated in murine models of DN. Similarly, genetic perturbation of IL21R signalling has protective effects against kidney disease in murine models of accelerated autoimmune disease.
Materials and methods: Here we utilise the uninephrectomized type 2 diabetic *db/db* mouse model to test the effect of a blocking murine IL21R-Fc fusion protein (mIL21R-Fc) on markers of CKD. Mice underwent uninephrectomy at 7 weeks of age and were randomised by urine albumin to creatinine ratio (UACR) at 15 weeks of age. mIL-21R-Fc (400ug/mouse 3x week; n=14) or control (n=14) was administered intraperitoneally (i.p.) from 16-21 weeks of age. Blood and urine was collected at 15, 18 and 20 weeks, and terminal tissues were collected at 21 weeks of age. Plasma glucose, plasma creatinine, urine albumin, and urine creatinine were measured to determine *in vivo* efficacy of mIL21R-Fc on renal function. Protein levels of kidney damage markers and cytokines were also assayed *ex vivo* in parallel with an immunohistochemical assessment of glomerular damage.
Results: At 15 weeks of age the UACR levels were 245 mg/g ± 21 for the control group and 249 mg/g ± 35 for the mIL21R-Fc group. Treatment with mIL21R-Fc significantly attenuated the progression of albuminuria at 18 and 20 weeks compared to vehicle control (% change in UACR; treatment 27% ± 9 versus control 47% ± 9 at 18 weeks; treatment 24% ± 9 versus control 65% ± 14 at 20 weeks, p = 0.035). These therapeutic effects were associated with a reduction in renal protein levels of the inflammatory cytokine macrophage inflammatory protein 3alpha (MIP-3a; control 130 pg/ml ± 18 v treatment 78 ± 6 pg/ml p=0.041). mIL21R-Fc also reduced renal vascular endothelial growth factor (VEGF) protein levels (control 6 ± 1 pg/ml versus treatment 4.1 ± 0.6 pg/ml p=0.014, n=9-12). mIL21R-Fc did not affect histopathological scoring of glomerular damage and no differences in blood urea nitrogen (BUN) or plasma glucose were detected between treatments.
Conclusion: In summary, blockade of IL-21R signalling attenuates albuminuria in a diabetic nephropathy model and may act by reducing MIP-3a levels. MIP-3a is a chemokine that has been reported to attract T lymphocyte, and previous reports that intrarenal $CD4^+$ T cell accumulation occurs via an IL-21R-dependent pathway support this interpretation. Silencing VEGF signalling has been reported to improve DN in mice suggesting that IL-21R blockade may also act by reducing VEGF signalling. Blockade of IL-21R signalling may provide a novel pathway for the treatment of diabetic nephropathy.

Renal TNF-alpha-induced protein 2 is altered in diabetic nephropathy

F. Barutta, S. Bellini, G. Bruno, G. Gruden;
Medical Sciences, University of Turin, Turin, Italy.

Background and aims: Diabetic nephropathy (DN) is characterised by increased glomerular permeability to proteins. Hyperglycemia, hypertension, and inflammatory processes are believed to play a key role in the pathogenesis of the complication by inducing podocyte injury. The cytosolic protein TNF-α-Induced Protein 2 (TNFAIP2), also known as B94, is induced by TNF-α, an inflammatory cytokine implicated in the pathogenesis of DN, and by retinoic acid, a key regulator of podocyte phenotype. This raises the possibility that TNFAIP2 may play a role in DN and represent a new target for intervention; however, there is no information on TNFAIP2 in diabetic or other kidney diseases. Our aim was, thus, to establish if TNFAIP2 expression is altered in DN and to investigate if DN-related insults modulate TNFAIP2 in cultured podocytes.
Materials and methods: Human kidney biopsies: TNFAIP2 protein expression was studied in kidney biopsies from type 2 diabetic patients (n=6) and control non-diabetic subjects (n=6) by immunohistochemistry. Experimental diabetes: diabetes was induced in eight-week-old male C57BL6 mice by intraperitoneal injection of streptozotocin at a dose of 55 mg/kg in citrate buffer. Control animals were injected with citrate buffer alone. Diabetic (DM n=15) and control (ND n=15) animals were euthanized 14 weeks following induction of diabetes and expression of TNFAIP2 was studied by either immunohistochemistry or immunofluorescence in the renal cortex. Prior to sacrifice, blood samples were taken and urine collected over 18-hours for urinary albumin concentration measurement by ELISA. In a subgroup of animals, glomeruli were isolated using a modified Dynabead method and TNFAIP2 levels assessed by real time PCR and immunoblotting. In vitro experiments: cultured podocytes were exposed to high glucose (25 mM), mechanical stretch (10% elongation), TNF-α (50 ng/mL), or retinoic acid (1μM) for various time periods and TNFAIP2 expression analysed real-time PCR and immunoblotting. Control cells were studied in parallel.
Results: Only few glomerular cells stained positively for TNFAIP2 in normal human kidney biopsies, but immunostaining for TNFAIP2 was significantly enhanced in patients with DN (ND: 1.42±0.44; DM: 7.21 ±1.35; mean ± SD; $p<0.05$ DM vs. ND). In mice, blood glucose, glycated albumin, and albumin excretion rate were significantly higher in the presence of diabetes, confirming the development of DN. Glomerular TNFAIP2 expression was significantly increased in diabetic mice compared to controls as assessed by immunohistochemistry (ND: 2.00±0.18; DM: 6.09±0.66; mean ± ESM; $p<0.05$ DM vs. ND) and real time PCR (ND: 037±0.05; DM: 1.04±0.17; $p<0.05$ DM vs. ND). Furthermore, podocytes were the predominant glomerular cell type expressing TNFAIP2 as suggested by staining distribution and confirmed by immunostaining for TNFAIP2 and podocin on serial cortex sections. Cultured podocytes constitutively express TNFAIP2 at both mRNA and protein level. TNFAIP2 expression was enhanced in podocytes exposed to high glucose (vehicle: 1.00±0.01; HG: 2.60±0.36, $p<0.01$), TNF-α (vehicle: 1.00±0.01; TNF-α: 2.31±0.24; $p<0.01$), and retinoid acid (vehicle: 1.00 ±0.1; RA: 1.75±0.06; $p<0.01$), while no changes were observed in podocytes exposed to mechanical stretch.
Conclusion: Glomerular TNFAIP2 expression was enhanced in both human and experimental DN, particularly in podocytes. Furthermore, DN-related insults increased TNFAIP2 expression in podocytes, providing a potential underlying mechanism of TNFAIP2 overexpression.

Atg5 deficiency in endothelial cells contributes to the development of IL-6 dependent endothelial to mesenchymal transition and kidney fibrosis

T. Yuta[1], S.M. Lee[1], Z. Dongqing[1], K. Kanasaki[1,2], D. Koya[1,2];
[1]Diabetology and Endocrinology, Kanazawa Medical University, Kahoku-Gun, [2]Anticipatory Molecular Food Science and Technology, Kanazawa Medical University, Kahoku-Gun, Ishikawa, Japan.

Background and aims: Autophagy is a catabolic process that preserves cellular homeostasis via autophagic clearance. Dysregulation of autophagy is well known contributor in the development of organ dysfunction. There is considerable understanding of the molecular and biological functions of autophagy in pathophysiological conditions. There are some reports showing autophagy deficiency contributes to endothelial dysfunction in patients with diabetes. However, the role of autophagy within the vasculature is ambiguous.
Materials and methods: In this study to test the role of autophagy within endothelium, we utilized human microvascular endothelial cells (HMVECs) and endothelial specific Atg5 knockout mice ($atg5^{endo}$, Atg5f/f; Cdh5Cre/+). HMVECs were treated with Atg5 siRNA and $atg5^{endo}$ mice were treated with streptozotocin (STZ) or high fat diet (HFD).
Results: Inhibition of autophagy in human microvascular endothelial cells (HMVECs) and in the endothelial specific $atg5^{endo}$ mice are associated with the induction of IL-6 and increased rate of endothelial-to-mesenchymal transition (EndMT), which contributes in kidney fibrosis. IL-6 secretion was remarkably higher in Atg5 siRNA-transfected HMVECs culture medium; neutralization of IL-6 by specific antibody completely inhibited EndMT in Atg5 siRNA-transfected HMVECs. Atg5 siRNA-transfected HMVECs exhibited significantly enhanced TGF-β/p-Smad3 signaling; unexpectedly EndMT in Atg5 siRNA-transfected HMVECs was independent from TGF-β/p-Smad3 pathway revealed by specific neutralizing antibody experiment. Similar to the in vivo data, $atg5^{endo}$ mice displayed kidney fibrosis when compared to littermate control associated with higher level of plasma IL-6, induction of EndMT, and increased TGF-β/p-Smad3 levels. Such fibrosis in $atg5^{endo}$ mice was accelerated when mice were either treated STZ or fed with HFD.
Conclusion: These results revealed that the essential role of autophagy in endothelial cell homeostasis and the disruption of such endothelial autophagy could lead to IL-6 dependent EndMT and kidney fibrosis associated with diabetes and metabolic syndrome.

Targeting the C5a-C5aR1 signalling axis in diabetic kidney disease

M.T. Coughlan[1], S.M. Tan[1], E.I. Ekinci[2], M. Snelson[1], S.A. Penfold[1], G.C. Higgins[1], R.S. Lindblom[1], K.C. Sourris[1], V. Thallas-Bonke[1], G. Jerums[2], A. Skene[3], D.A. Power[4], R.J. MacIsaac[5], M.E. Cooper[1], T.M. Woodruff[6];
[1]Department of Diabetes, Monash University, Melbourne, [2]Department of Medicine, The University of Melbourne, Melbourne, [3]Department of Anatomical Pathology, Austin Health, Melbourne, [4]Department of Nephrology, Alfred Health, Melbourne, [5]Departments of Endocrinology and Diabetes, St Vincent's Hospital, Melbourne[6]Laboratory of Neuroinflammation, The University of Queensland, Brisbane, Australia.

Background and aims: The complement system plays a central role in the activation of innate immunity, inflammation and tissue remodelling. The complement activation fragment C5a is the most potent pro-inflammatory effector molecule of the complement system. Although previous studies indicate an association between activation of complement and diabetic kidney disease (DKD), the role of C5a and its receptor, C5aR1, in mediating injury in the kidney in diabetes has yet to be determined. The aim of this study was to investigate the role of complement C5a and its receptor, C5aR1 in the development of diabetic kidney disease.
Materials and methods: The spontaneously diabetic Ins2-Akita mouse model was used to characterise the changes in complement activation products associated with DKD (n=8 mice/group). Streptozotocin-induced diabetic C57BL/6 mice were treated with the highly selective

C5aR1 antagonist, PMX-53 (2mg/kg/day), in drinking water for 24 weeks (n=8-15 mice/group). Kidney injury was assessed by urine albumin excretion. Complement was examined by qRT-PCR, ELISA or immunohistochemistry (IHC). C5a was measured in plasma from patients with diabetes (n=16) or non-diabetic controls (n=40) by ELISA. C5aR1 was determined in renal biopsies from patients with DKD (n=23) and non-diabetic controls (healthy donors, n=6) by IHC.

Results: Ins2-Akita mice displayed upregulated gene expression of C5 (1.27±0.31 vs 6.35±2.10 AU; p=0.05) and C5aR1 in the renal cortex (0.95±0.08 vs 1.34±0.11 AU; p=0.02) compared to wildtype littermates. Urinary C5a was increased in Ins2-Akita mice (50±9 vs 151±32 pg/24 hr, p<0.01). Blockade of C5a-C5aR1 signalling with PMX-53 resulted in decreased urinary albumin in diabetic mice when compared to vehicle-treated diabetic controls (83±18 vs 30±9 μg/24 h; p=0.02). Plasma levels of C5a were increased in patients with type 1 diabetes compared to age-matched non-diabetic controls (110±23.5 vs 35±2ng/ml; p<0.0001). Examination of C5aR1 in human kidney by IHC revealed upregulation in the glomeruli and tubulointerstitium of renal biopsies from subjects with DKD compared to non-diabetic controls (15.7±1.8 vs 5.1±1.9; p=0.003).

Conclusion: The C5a-C5aR1 signalling axis is activated in human and mouse DKD. A pilot study using PMX-53 indicates that blockade of C5a-C5aR1 signalling attenuates albuminuria in experimental diabetes. Further studies are required to validate C5aR1 as a therapeutic target in diabetic kidney disease.

PS 092 Novel aspects of classical risk factors

1068

Prognostic value of glycosuria amount during hyperglycaemia in patients with type 1 diabetes and risk for diabetic nephropathy (DN)

M. Marre[1], C. Carpentier[2], K. Mohammedi[1], N. Belhatem[1], B. dulybouhanick[3], V. Rohmer[2], P. Rodien[2], A. Bumbu[1], S. Hadjadj[4], R. Roussel[1], L. Potier[1], G. Velho[5], S. Dubois[2];
[1]Diabetology, Bichat Hospital, AP-HP, Paris, [2]CHU Angers, Angers, [3]CHU Rangueil, Toulouse, [4]Diabetology, CHU Poitiers, Poitiers, [5]INSERM U1138, Paris, France.

Background and aims: Only a fraction of T1DM patients with poor glycemic control develop DN due to selective haemodynamic changes, maybe in tubulo-glomerular feed-back. We examined the prognostic value of changes produced by hyperglycemia in Glomerular Filtration Rate (GFR) and solute clearances (glucose, lithium, sodium, total osmols) in T1DM patients at risk for DN: glomerular hyperfiltration (hyperGFR), and/or microalbuminuria (Urinary Albumin Excretion (UAE) 30-300mg/24 h) compared to low risk controls (normal GFR and UAE).

Materials and methods: In 1990-92, 108 T1DM patients without DN attending a University Hospital were screened for microalbuminuria and hyperGFR (>mean+ 2SD of age-matched healthy controls; ^{51}CrEDTA plasma disappearance technique). 32 underwent renal tests described below: 21 at high risk for DN (9 with isolated hyperGFR, 11 with microalbuminuria, including 4 with both), and 11 at low risk (normal GFR and UAE despite poor glycaemic control, including 6 with T1DM duration >20 years). GFR and Effective Renal Plasma Flow (ERPF, Iodothalamate and Hippurate infusion techniques), Fractional Clearances (Fract Cl) of glucose, lithium (marker of proximal tubular reabsorption), sodium, and total osmols were measured during 2 clamp-periods in the same test: normoglycaemia, then hyperglycaemia. Follow-up was until 2016, with time to occurrence of DN (UAE>300mg/24h), eGFR<60 mL/min/1.73m^2, End Stage Renal Disease, or all-cause death as primary end point.

Results: At baseline, 53 patients were at high risk (36 with hyperGFR, 10 with microalbuminuria, 7 with both), and 55 ones at low risk. The participants to renal tests at high risk were comparable to low risk ones for age (32(SD13) years), sex ratio (53% women), T1DM duration (median15 (interquartiles 9-22) years), and HbA1c (9.1 (2.1)%), all representative of the whole cohort. Glycaemia rose similarly in both groups from 6.1(2.0) to 15.6(5) mM. Their GFR and ERPF were similar in normoglycaemia (139(31) and 631(219) mL/min/1.73m$^{2)}$. On hyperglycaemia, GFR increased by 4(median, ranges -6, 18)% and ERPF by 6(-7, 24)% in the high risk group, vs decreases of -6(-13, 1)% for GFR and 1(-15,6)% for ERPF in the low risk group (p<0.05 for both). On hyperglycaemia, glycosuria was twice lower in the high risk group than in the low risk one (0.341(0.247) vs 0.611(0.435) mmol/min; p<0.05), with reduced changes in Fract Cl of glucose (2.2(1.5)x10^{-3} vs 5.1(3.9) x10^{-3}(p< 0.01), lithium (-1.1(30.1)vs +32 (47); p<0.05), osmols (124(166) vs 284(267); p< 0.05), and sodium (-0.54(39) vs +35(62); p=0.06).Participants with isolated hyperGFR and those with microalbuminuria were not different. At follow-up (median duration 22 (interquartiles 12-26) years), 15 high risk patients underwent primary end points, vs 6 low risk ones (OR 3 .47 (95% CI 1.14-11.96; p=0.03 after adjustments on age, sex, T1DM duration, and follow-up duration).

Conclusion: Reduced glycosuria during hyperglycaemia is a risk for DN in T1DM patients.

Serum uromodulin predicts a decline in kidney function independently from the presence of type 2 diabetes

E. Brandtner[1], A. Leiherer[1], A. Muendlein[1], C.H. Saely[2], K. Geiger[1], A. Mader[3], P. Schwerzler[3], P. Fraunberger[4], H. Drexel[5];
[1]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, [2]Academic Teaching Hospital Feldkirch, Feldkirch, Austria, [3]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [4]Medical Central Laboratory, Feldkirch, Austria, [5]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: Uromodulin is the most abundant protein excreted in urine. Low uromodulin has been found to be associated with type 2 diabetes (T2DM) as well as with chronic kidney disease (CKD). Whether it also predicts a future decline in kidney function is not known and is addressed in the present study.
Materials and methods: We measured serum uromodulin in 529 patients undergoing coronary angiography for the evaluation of established or suspected coronary artery disease (CAD).
Results: Uromodulin was lower in patients with T2DM than in non-diabetic subjects (148±70 vs. 171±79; p=0.001) and significantly correlated with estimated glomerular filtration rate (eGFR; r=0.242, p<0.001) and, inversely, with the albumin creatinine ratio (ACR; r=-0.120, p=0.012). It was significantly lower in patients with CKD (eGFR <60 ml/min/1.73 m^2) than in those with normal kidney function (72±29 vs. 169±76 ng/ml; p<0.001), and also in patients with albuminuria than in patients without increased albumin excretion (149±72 vs. 168±78 ng/ml; p=0.008). Further, uromodulin at baseline was significantly lower in patients who developed an eGFR <60 ml/min/1.73 m^2 during 4 years of follow-up compared to those who did not (127±42 vs. 180±79ng/ml, p=0.003). It was inversely associated with declining eGFR even after full adjustment including ACR, baseline CAD and the presence of T2DM (OR=0.354 [95%CI 0.131-0.957], p=0.041). The inclusion of uromodulin to a basic prediction model for CKD increased the model performance (C-statistic 0.844 vs. 0.804, p=0.049).
Conclusion: In conclusion, we for the first time show that serum uromodulin predicts a decline in kidney function independently from conventional risk factors including T2DM.

Normoalbuminuric renal impairment in type 2 diabetes is associated with a high risk of death. The Renal Insufficiency And Cardiovascular Events (RIACE) study

G. Pugliese[1], A. Solini[2], E. Orsi[3], E. Bonora[4], C. Fondelli[5], R. Trevisan[6], M. Vedovato[7], F. Cavalot[8], O. lamacchia[9], S. Morano[1], A. Nicolucci[10], G. Penno[2];
[1]La Sapienza University, Rome, [2]University of Pisa, Pisa, Italy, [3]IRCCS Cà Granda - Ospedale Maggiore Policlinico Foundation, Milan, [4]University and Hospital Trust of Verona, Verona, [5]University of Siena, Siena, [6]Azienda Ospedaliera Papa Giovanni XXIII, Bergamo, [7]University of Padua, Padua, [8]University of Turin, Orbassano, [9]University of Foggia, Foggia, [10]Center for Outcomes Research and Clinical Epidemiology (CORESEARCH), Pescara, Italy.

Background and aims: Nonalbuminuric renal impairment has become the prevailing phenotype of diabetic kidney disease (DKD) in patients with type 2 diabetes and an estimated glomerular filtration rate (eGFR) <60 ml/min/1.73m^2, though a few data are available on death rate in these individuals. This study aimed at assessing the rate and determinants of all-cause death in the nonalbuminuric phenotype, as compared with the albuminuric ones.
Materials and methods: The Renal Insufficiency And Cardiovascular Events (RIACE) Italian Multicenter Study is an observational, prospective, cohort study enrolling 15,773 consecutive non-dialytic patients with type 2 diabetes in 2006-2008 in 19 outpatients Diabetes Clinics in Italy. Baseline cardiovascular risk factors, complications and treatments were recorded. Based on baseline albuminuria and eGFR, patients were classified as having: no DKD (nonalbuminuric non-chronic kidney disease, CKD), albuminuria alone (albuminuric non-CKD), reduced eGFR alone (nonalbuminuric CKD), or both (albuminuric CKD). Vital status on October 31, 2015 was retrieved for 15,656 patients (99.26%).
Results: After a follow-up of 7.4±2.1 years, death rate was 31.0 per 1,000 person-years (95% CI 30.01-32.04). There was a gradual increase in crude mortality rates from nonalbuminuric non-CKD (19.87 [18.87-20.86]) to albuminuric CKD (90.25 [83.41-97.08]), with a higher death rate for nonalbuminuric CKD (61.49 [56.59-66.40]) than for albuminuric non-CKD (36.79 [34.23-39.35]). Unadjusted HRs were 1.696 (95% CI 1.528-1.883), 3.020 (2.630-3.467), and 5.366 (4.623-6.227) for albuminuric non-CKD, nonalbuminuric CKD, and albuminuric CKD, respectively. Differences between albuminuric non-CKD and nonalbuminuric CKD disappeared after adjustment for age and multiple confounders. Trends were similar in males and females. However, when patients were stratified by age, in the youngest category (<55 years) subjects with nonalbuminuric CKD had the highest crude mortality rates and unadjusted and adjusted HRs, even higher than subjects with albuminuric CKD. In normoalbuminuric subjects with an eGFR <45 ml/min/1.73m^2, especially with low albuminuria (10-29 mg/day), risk was higher than in microalbuminuric and similar to macroalbuminuric individuals with preserved eGFR. At recursive partitioning and amalgamation analysis, prevalent CVD and lower HDL cholesterol were the most relevant correlates of mortality in all phenotypes. Other correlates differed among DKD phenotypes; albuminuria >8.3 mg/day and higher waist circumference were associated with a higher likelihood of death in the nonalbuminuric form.
Conclusion: Mortality risk is elevated in nonalbuminuric renal impairment, particularly so in younger individuals and in those with an eGFR <45 ml/min/1.73m^2 and low albuminuria. Correlates of death partly differ from those of the albuminuric phenotypes.

1071

Nonalbuminuric diabetic kidney disease in type 1 diabetes: association with the risk of major vascular outcomes and all-cause mortality

M. Garofolo, E. Russo, R. Miccoli, D. Lucchesi, L. Giusti, V. Sancho Bornez, G. Daniele, G. Penno, S. Del Prato;
Endocrinology and Metabolism, University of Pisa, Pisa, Italy.

Background and aims: Different diabetic kidney disease (DKD) phenotypes has been described not only in type 2, but also in type 1 diabetes. Despite improvements in care, individuals with type 1 diabetes, mostly those with DKD, have higher mortality and reduced life expectancy (LE) compared with the general population. Recently, a prognostic model to assess the risk of major outcomes and all-cause death in type 1 diabetes has been developed from data of the EURODIAB Prospective Complication Study (PCS). Here we evaluated the association of different DKD phenotypes with the EURODIAB PCS risk score and with all-cause mortality in a cohort of 774 type 1 diabetic individuals.
Materials and methods: The EURODIAB PCS absolute risk, stratified as low- (LR, score up to 15), intermediate- (IR, score 16 to 20), and high- (HR, score 20 or higher), the distribution of the different DKD phenotypes [no DKD, stages 1-2 DKD, nonalbuminuric stage ≥3 DKD (Alb-

DKD), albuminuric stage ≥3 DKD (Alb+DKD)] and all-cause mortality in a mean follow-up of 8.25±2.34 years (median 7.58 years, IQR 6.47-9.73) have been evaluated in a cohort of 774 individuals with type 1 diabetes belonging to a single center (men/women 52.6/47.4%, 40.2 ±11.7 year-old with a mean diabetes duration of 19.3±12.2 years and HbA1c of 7.83±1.18%, 62.1±12.9 mmol/mol). Adjudications of DKD phenotypes were made by blinded investigators.

Results: Out of 774 subjects, 692 (89.4%) had no DKD, 53 (6.8%) had DKD stages 1-2, 17 (2.2%) had Alb-DKD stage ≥3 and 12 (1.6%) had Alb+DKD stage ≥3. Risk score distribution was: LR n. 466 (60.2%), IR n. 205 (26.5%) and HR n. 103 (13.3%) in the whole cohort, and LR n. 461 (62.9%), IR n. 195 (26.6%) and HR n. 77 (10.5%) after exclusion of 41 type 1 diabetic individuals (5.3%) who already had major outcomes. Prevalence of subjects with high score was: no DKD, 9.1%; DKD stages 1-2, 34.0%; Alb-DKD, 64.7%; Alb+DKD, 91.7% ($p<0.0001$). All cause mortality increased through DKD phenotypes: no DKD, 3.0%; DKD stages 1-2, 15.1%, HR 4.504 (95%CI: 1.992-10.186); Alb-DKD, 29.4%, HR 8.573 (3.222-22.815); Alb+DKD, 50.0%, HR 20.683 (8.292-51.587) (Kaplan-Meier, logrank $p<0.0001$). Accounting in Cox regression for age (HR 1.070; 1.044-1.098, $p<0.0001$) and sex (men: HR 1.922; 0.969-3.813, $p=0.061$), HRs for all-cause mortality compared to no DKD were: DKD stages 1-2, 3.841 (1.686-8.750, $p=0.001$); Alb-DKD, 2.970 (1.018-8.662, $p=0.046$); Alb+DKD, 7.441 (2.781-19.911, $p<0.0001$). In a second Cox model, accounting for sex and the EURODIAB score (intermediate risk: HR 3.346, 1.201-9.321, $p=0.021$; high risk: HR 11.736, 4.437-31.044, $p<0.0001$), HRs for all-cause mortality compared to no DKD were: DKD stages 1-2, 2.571 (1.113-5.939, $p=0.027$); Alb-DKD, 2.772 (0.968-7.943, $p=0.058$); Alb+DKD, 4.584 (1.691-12.421, $p=0.003$). Trends in trajectories of both Kaplan-Meier analysis of all-cause mortality as well of each model of the Cox regression were confirmed after exclusion of the 41 individuals who have had previous MACE.

Conclusion: In type 1 diabetes, the Alb-DKD phenotype has a prevalence of 2.2% and accounts for 20.7% of all DKDs and is independently associated with an increased risk of major vascular outcomes and an high all-cause mortality rate, to the same extent as the albuminuric stages 1-2 DKD. The highest risk and the highest mortality rate were observed in Alb+DKD. Intensive cardiovascular prevention strategies should be applied to these subjects.

Diabetes Kidney Disease (DKD) severity classifications and therapy impact in a real-world setting across 5EU/US

V. Higgins, A. Leith, M. Kelly, A. Ellams;
Adelphi Real World, Bollington, UK.

Background and aims: The strong correlation between type 2 diabetes mellitus (T2DM), cardiovascular and renal complications is well documented and by addressing multifactorial risks, it is claimed that diabetes-related complications can be reduced. This analysis explores the co-existence of these conditions amongst T2DM patients, clinical versus physician-driven diabetes kidney disease (DKD) severity label assignment and subsequent impact on therapy class choice by DKD severity stratification.

Materials and methods: Data were drawn from the 2016 Diabetes Disease Specific Programme in the US and EU. Diabetes specialists and primary care physicians (PCPs) completed forms for the next 10 consulting T2DM patients, including current antidiabetic therapy, HbA_{1c}, estimated glomerular filtration rate (eGFR) test value, physician-reported diagnosis of DKD (categorized as [1] mild renal or [2] moderate/severe renal), congestive heart failure (CHF) and body mass index (BMI) derived from weight and height reporting. Physicians did not report eGFR stages or BMI classifications and these were retrospectively applied to the data based on clinical criteria. DKD labelling via derived eGFR scores was defined as stages 1-5. Obesity labelling via BMI was ≥30 kg/m^2.

Results: A total of 352 specialists, 501 PCPs, and 8,523 T2DM patients were included across US and 5EU. Of these, 41% had T2DM-only, 30% T2DM+obesity, 14% T2DM+DKD (eGFR stage 1-5), 13% T2DM+DKD+obesity and only 1% with T2DM+DKD+obesity+HF. 28% of patients had an eGFR-confirmed DKD diagnosis compared to only 9% of patients receiving a physician-confirmed DKD diagnostic label. When comparing the physician severity labelling vs. eGFR score, 33% of patients were not classified with the same DKD stage. When looking at which therapy class is prescribed at which eGFR stage, there is evidence of some contraindicated usage across DKD stages in a real-world setting predominantly with metformin, sulfonylurea (SU) and dipeptidyl peptidase-4 inhibitors (DPP-4i) therapy classes.

Conclusion: DKD prevalence is high amongst T2DM patients in a real-world setting, with around two-thirds of DKD patient cases not being recognized by the physician according to derived eGFR staging. As a result, there is evidence that some contraindicated therapy options may be being prescribed at various DKD stages. Further education around DKD severity classifications could address these issues.

Evolution of renal function in type 2 diabetics: a retrospective study of the last 12 years

C. Ferrinho[1], R. Fonseca[1], C. Bello[1], F.S. Santos[1], C. Gouveia[1], J.S. Duarte[1], J. Azinheira[2], C. Vasconcelos[1];
[1]Endocrinologia, Diabetes e Metabolismo, Centro Hospitalar Lisboa Ocidental, [2]Patologia Clínica, Centro Hospitalar Lisboa Ocidental, Lisboa, Portugal.

Background and aims: Albuminuria is associated with progression to chronic kidney disease, is a strong predictor of cardiovascular risk and is associated with an increase in all-cause and cardiovascular mortality. It is more relevant in patients at higher risk, such as type 2 diabetics. Our aim was to evaluate the variation of the renal function rate in type 2 diabetic patients, between 2005 and 2016, considering albuminuria and other potentially relevant factors, such as the duration of the disease, presence of comorbidities and treatments.

Materials and methods: Retrospective observational study in 1031 consecutive patients with type 2 diabetes mellitus followed for at least three years. We collected 39 clinical, laboratory and therapeutic variables from our electronic dataset. A total of 7371 determinations of albuminuria/creatininuria ratio were performed in our lab and estimated GFR (eGFR) was based on the CKD-EPI formula. Patients younger than 18 years, with other types of diabetes, impaired kidney function at first determination (eGFR < 60 mL/min/1.73 m^2) or transplanted were excluded. Results are presented by median and standard error. We applied descriptive statistics methods, Pearson's correlations, Student T test for continuous variables and the chi-square in the categorical variables.

Results: A total of 1031 patients were evaluated, with a predominance of female gender (59.3%). The initial age of the patients was 62.5 ± 0.3 years. The mean follow-up time was 5.9 ± 0.8 years. The first albuminuria was 12.4 ± 9.7 mg/mg and the eGFR decreased an initial value of 87.0 ± 0.4 to 74 ± 0.6 mL/min/1.73m^2. There was great prevalence of comorbidities: dyslipidemia (97.1 %), hypertension (91.7%), retinopathy (64.1%), obesity (41.8%) and mortality in this period was 5.8% (60 patients) and there were 22.7% dropouts. We found significant correlations between the eGFR variation and

the initial albuminuria ($p<0.01$), age ($p<0.01$) and HbA_{1c} ($p=0.01$). During follow-up we found correlations with mean albuminuria ($p<0.01$) and blood pressure, but especially mean pulse pressure ($p<0.01$). Patients who died were older ($p<0.01$), had lower inicial eGFR ($p<0.01$) and larger decline of eGFR ($p<0.01$).

Conclusion: Albuminuria is associated with the risk of progression to chronic kidney disease, with the initial and the mean value being significantly associated with a higher rate of decline in renal function (eGFR). The same for the initial blood pressure values and their control during the follow-up (median= 6 years).The mortality in our group was low and associated with initial age, with eGFR and its decline, but not with albuminuria or other laboratorial variables in the study population.

Decreased plasma kallikrein activity is associated with kidney function decline in patients with type 1 diabetes

M.-A. Härma[1,2], I. Toppila[1,2], K. Uusi-Rauva[1,2], V. Harjutsalo[1,2], C. Forsblom[1,2], P.-H. Groop[1,2], M. Lehto[1,2], the FinnDiane Study Group;
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, [2]Abdominal Center Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland.

Background and aims: Kallikreins are serine proteases that release kinins from kininogens and may be involved in the renin-angiotensin-aldosterone system by converting prorenin into renin. It has been suggested that kallikreins and kinins, through protease dependent signaling, may play a role in the pathogenesis of kidney disease. We therefore measured plasma kallikrein (KK) activity in patients with type 1 diabetes (T1D) with various stages of diabetic nephropathy (DN). We also assessed the genetic impact of the plasma KK cofactor gene KNG1 and the upstream Factor XII gene F12.

Materials and methods: Plasma KK activity was determined with a chromogenic assay (S-2302, Haemochrom Diagnostica) in 297 patients with T1D. All patients were investigated as part of the Finnish Diabetic Nephropathy (FinnDiane) Study. DN was determined based on urinary albumin excretion rate (AER): normal AER (<30 mg/24 h; n=166), microalbuminuria (≥30 and <300 mg/24 h; n=41), macroalbuminuria (≥300 mg/24 h; n=38), and end-stage renal disease (ESRD; dialysis or transplantation; n=52). Renal function (eGFR) was estimated by the CKD-EPI equation. Genotypic information for the F12 and KNG1 genes was obtained from the FinnDiane GWAS study.

Results: Plasma KK activity decreased by advancing stage of DN: normal AER (median 2.59 [IQR 1.39-4.10]), microalbuminuria (2.04 [1.22-3.35]), macroalbuminuria (1.44 [0.96-2.83]), and ESRD (1.34 [0.71-1.72]; p=1.23e-05). The activity was lower in patients on dialysis compared to patients with kidney transplant (p=0.009). Notably, the plasma KK activity differed by genotypes of the common functional variants F12 rs1801020 ($p=7.16\times10^{-15}$) and KNG1 rs5030062 (p=0.001) in such a way that carriers of the rs1801020 minor (A) and the rs5030062 major (A) alleles had in general lower plasma KK activity as shown below. The activity correlated positively with eGFR ($r_s=0.34$; $p=2.72\times10^{-9}$), and this association remained after adjustment for age, sex, diabetes duration, waist circumference, HbA_{1c}, and with the two functional variants and their interaction (β=0.20 [95% CI 0.08-0.31], p=0.0006).

Conclusion: Plasma KK activity decreases with advancing stages of kidney disease and correlates positively with eGFR in patients with T1D. We also show that the plasma KK activity is associated with functional genetic variants, that have previously been linked to circulating Factor XII, renin and aldosterone protein levels. Whether plasma KK by itself influences the development of DN remains to be elucidated.

Hypertriglyceridaemia, diabetic nephropathy and coronary heart disease in type 1 diabetes: Simple association or causal relationship?

L. Stechemesser[1], C. Forsblom[2,3], N.M. Panduru[4], I. Toppila[2,3], M.-R. Taskinen[5], R. Weitgasser[6], P.-H. Groop[2,3];
[1]Internal Medicine 1, Paracelsus Medical University Clinic, Salzburg, Austria, [2]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, [3]Abdominal Center Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland, [4]2nd Clinical Department, Diabetes Nutrition and Metabolic Diseases Chair, "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania, [5]Heart and Lung Centre, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland, [6]Department of Medicine, Diakonissen-Wehrle Hospital, Salzburg, Austria.

Background and aims: Dyslipidemia is a major risk factor for diabetic nephropathy and coronary heart disease (CHD), the most common causes of premature death in type 1 diabetes (T1D). Data whether hypertriglyceridemia is causally related to these diabetic complications are scarce. We therefore investigated in patients with T1D, if hypertriglyceridemia is causally related to diabetic nephropathy and CHD.

Materials and methods: This cross-sectional analysis was part of the prospective, ongoing Finnish Diabetic Nephropathy Study (FinnDiane). Between 1994 and 2015 data were obtained from 4481 T1D patients in more than 80 hospitals or health centers across Finland. The potentially causal effect of triglycerides on CHD and stages of nephropathy was explored using Mendelian Randomization (MR) and a genetic risk score (GRS) based on 96 SNPs associated with triglycerides in the literature. The strength of MR is to create a form of a randomized controlled trial. Based on triglycerides, which are strongly affected by genetic variants, patients have been randomly allocated to different groups before birth. Follow up period started at birth and ended at the study visit when clinical endpoints were evaluated (>41 years of follow-up). MR analysis was performed using the GMM estimation of structural mean models for binary and the two-stage least squares method for continuous outcome.

Results: In the entire cohort there were 47.8% females, age was 41±12.7 yrs, diabetes duration 25.1±13.1 yrs, and HbA1c 8.4±1.4%. CHD was present in 8.3% of the patients, 18% had CKD stage 3-5, 12.5% microalbuminuria, 13.8% macroalbuminuria and 9.7% ESRD. GRS was associated with triglycerides ($p<0.001$), and the association remained significant after adjustment for LDL-C and multiple combinations of LDL-C, HDL-C, total cholesterol, ApoA1 and ApoB, sex, age, BMI and systolic blood pressure ($p<0.001$). Triglycerides ($p<0.001$) but not GRS ($p=0.464$) was associated with eGFR. However, instrumental variables regression showed no causal effect of triglycerides on eGFR ($p=0.470$). Triglycerides ($p<0.001$) and GRS ($p=0.002$) was associated with CHD. Notably, MR showed a causal effect of genetically elevated triglycerides on CHD with a 2.5-fold elevated risk for each SD-elevation of logTriglycerides.

Conclusion: In addition to confirming that triglycerides are associated with CHD, our data also suggest that there is a causal link between triglycerides and CHD in patients with T1D. In contrast, we found no causal relationship between triglycerides and diabetic nephropathy in this population.

Reduced levels of anti-ageing hormone Klotho are associated with microalbuminuria and predict renal function decline in patients with type 2 diabetes

N. Fountoulakis, G. Maltese, N. Keswani, G. Viberti, L. Gnudi, J. Karalliedde;
Cardiovascular Division, King's College London, London, UK.

Background and aims: Soluble Klotho (sKlotho) is a circulating anti-ageing hormone involved in phosphate metabolism which is renoprotective in animal studies. We have previously demonstrated in type 1 diabetes mellitus an association between microalbuminuria (MA) and reduced levels of sKlotho. It is unknown if sKlotho predicts renal function decline in type 2 diabetes mellitus (T2DM) patients with preserved renal function and there is limited data on sKlotho levels in T2DM patients with MA. The primary aim of our study was to investigate if sKlotho predicts renal function decline in T2DM patients with relatively preserved renal function.

Materials and methods: We studied 101 patients (60% male) with T2DM, mean age (range) 60.3 years (40-82), duration of diabetes mean ± SD, 9.8±6.6 years, and estimated glomerular filtration rate (eGFR)>45 ml/min (mean eGFR 90.4± 19.7 ml/min) with and without residual MA on renin angiotensin system (RAS) blockade. Patients were followed up for a median (range) of 8 years (3-12 years) at Guy's Hospital London with standardised clinical and biochemical measurements. eGFR was determined using the Chronic Kidney Disease Epidemiology Collaboration equation. For each patient, a linear regression model of time on eGFR was created, and slope of the regression line was used to estimate changes in eGFR over time. sKlotho, serum phosphate (sPhos), calcium (sCa) and Fibroblast growth factor 23 (FGF-23) were measured from stored samples collected at baseline. The primary endpoint was >50% decline in eGFR from baseline and/or death.

Results: Of the cohort 21% (n=21) reached the primary endpoint. Cox regression analysis showed that baseline sKlotho level independently predicted the primary endpoint after adjustment for risk predictors including MA, HbA1c, sPhos, sCa, FGF-23, blood pressure (BP) variables, and baseline eGFR (Hazard Ratio per 10-pg/mL increase, 0.47; 95% CI, 0.24-0.98; $P=0.04$). Patients with residual MA (n=55) and without MA (n=46) did not have any significant differences in age, duration of diabetes, FGF-23, sPhos, sCa, eGFR, and glycaemic control. MA patients had higher systolic BP (SBP) and body mass index (BMI) and significantly lower levels of sKlotho median, interquartile range (IQR), 184.7 (131.2 to 274.6) pg/ml compared to patients without MA 231.3 (175.5 to 290.8) pg/ml $p=0.01$ and this significant difference remained after adjustment for SBP, BMI and other variables. Patients in the lowest quartile of sKlotho had significantly faster annual rate of eGFR decline, median (IQR) of -3.3 (-4.5 to - 1.7) ml/min/year compared to the highest quartile, -1.4 (-2.8 to 0.02) ml/min/year, independent of other risk factors in multivariate analyses, $p=0.03$.

Conclusion: We demonstrate in T2DM patients with relatively preserved renal function, reduced levels of sKlotho are associated with MA and predict significant renal function decline. The role of sKlotho as a novel bio-marker of renal dysfunction and potential treatment target for renoprotection in T2DM requires further evaluation.

Fructosamine 3-kinase and glyoxalase 1 polymorphisms and their association with development of vascular complications in diabetes: a 10-year follow-up study

J. Škrha jr.[1,2], M. Flekač[1], E. Horová[1], A. Muravská[2], M. Kalousová[2], M. Prázný[1], J. Škrha[1];
[1]Third Department of Medicine, First Faculty of Medicine, Charles University and General University Hospital in Prague, [2]Institute of Medical Biochemistry and Laboratory Diagnostics, First Faculty of Medicine, Charles University and General University Hospital in Prague, Prague, Czech Republic.

Background and aims: Advanced glycation end-products are key players in the pathogenesis of long-term vascular complications in diabetes. Fructosamine 3-kinase (FN3K) and glyoxalase 1 (GLO1) are crucial enzymes preventing excessive glycation processes. The aim of our study was to evaluate an association of FN3K (rs3848403, rs1056534) and GLO1 (rs4746) polymorphisms with development of chronic vascular changes in diabetes.
Materials and methods: Totally, 467 subjects with diabetes were enrolled within the study - 128 Type 1 /T1D/ aged 45 ± 14 yrs and 339 Type 2 /T2D/ aged 64 ± 11 yrs. Mean duration of the study was 10 years. DNA analysis was performed using RealTime PCR and Taqman genotyping method for allelic discrimination (FN3K polymorphisms) or PCR-RFLP method (GLO1 polymorphism). Both at the beginning and at the end of the study basic anthropometrical data, glycated hemoglobin HbA_{1c} (in IFCC units), glomerular filtration rate (using CKD-EPI formula) and (micro)albuminuria (albumin/creatinine ratio) were assessed, and macrovascular endpoints were recorded. χ^2 test was used to compare the qualitative data.
Results: Diabetes control expressed by HbA_{1c} was improved during the study both in T1D and T2D (T1D: 70 ± 14 vs 62 ± 10 mmol/mol, p<0.0001; T2D: 64 ± 20 vs 57 ± 15 mmol/mol, p<0.0001). Glomerular filtration rate was significantly increased in T1D (108 ± 24 vs 122 ± 27 mL/min/1.73 m^2, p<0.0001), whereas no change was observed in T2D (107 ± 28 vs 108 ± 36 mL/min/1.73 m^2, NS). A new development of diabetic nephropathy was observed in 6 % of T1D and 13 % of T2D, whereas 12 % of T1D and 16 % of T2D transformed from micro- to normoalbuminuria. Such improvement was observed neither in retinopathy nor neuropathy. Genotype frequencies of rs3848403, rs1056534 and rs4746 polymorphisms followed the expected frequencies according to Hardy-Weinberg equilibrium and did not differ between T1D and T2D. In T1D FN3K (rs3848403) TT genotype with mutated T allele was significantly associated with development of diabetic nephropathy (p<0.04) or a new microvascular endpoint (new nephropathy, retinopathy or neuropathy) (p<0.02). Such association was not present in T2D. Similarly, FN3K (rs1056534) CC genotype without mutated G allele was significantly associated with development of diabetic nephropathy in T1D (p<0.02), but not in T2D. There was not observed any association of GLO1 rs4746 polymorphism with the development of either micro- or macrovascular damage.
Conclusion: Our 10-year follow-up study showed improvement in diabetes treatment and partial regression of diabetic nephropathy. While FN3K polymorphisms rs3848403 and rs1056534 may have some functional effect in the development of diabetic angiopathy, especially in T1D, the role of GLO1 rs4746 polymorphism is disputable and other factors will act in this scenario.

Haemorheologic assessment for screening diabetic nephropathy in type 2 diabetes

S. Lee, J. Kim, K. Park, J. You, M. Kim, J. Nam, J. Park, C. Ahn, K. Kim; Yonsei University, Seoul, Republic of Korea.

Background and aims: Hemorheologic alterations or changes in blood viscosity have been suggested to play a role in the pathogenesis of diabetic microvascular complications. We measured various hemorheologic parameters in type 2 diabetes patients and assessed their possible role as a diagnostic tool for diabetic nephropathy.
Materials and methods: Four hundred-seventy patients with type 2 diabetes were included in this study. Hemorheologic parameters, including erythrocyte deformability, elongation index (EI), critical shear stress (CSS), and aggregation index (AI) were measured using microfluidic hemorheometer. Various metabolic parameters were assessed from fasting blood samples and urinary albumin to creatinine ratio was used to assess diabetic nephropathy.
Results: There were significant differences in Elongation index at 3 Pascal (EI at 3Pa), Fibrinogen/EI, and shear stress among patients in different stages of chronic kidney disease (all p<0.05), EI at 3 Pa, Fibrinogen/EI, and shear stress significantly differed among the groups. Fibrinogen/EI differed between normal or CKD 1 and CKD 2 patients. In multiple regression analysis, Fibrinogen/EI at 3Pa was an independent predictor of albumin to creatinine ratio independent of age, ESR, hematocrit, HbA1c, and body mass index (ß=0.101, p<0.05). Also, critical time, critical stress, fibrinogen/EI at 3Pa, CSS/EI et 3Pa, ad fibrinogen/CSS at 3Pa were significantly different among patients at different stages of diabetic nephropathy (all p< 0.05). Among the variables, Fibrinogen/EI at 3Pa showed area under the ROC curve of 0.721, suggesting 860 mg/dL% as a cut off point for diabetic nephropathy with the sensitivity of 74% and specificity of 62%.
Conclusion: Fibrinogen/EI is a sensitive parameter measured via point-of-care testing for screening diabetic nephropathy in patients with type 2 diabetes.

Biomarkers associated with progression of renal disease in type 1 diabetes

M. Colombo[1], E. Valo[2], S. McGurnaghan[3], L. Blackbourn[3], R.N. Dalton[4], D. Dunger[5], P.H. Groop[2], P.M. McKeigue[1], C. Forsblom[2], H.M. Colhoun[3,6], SDRNT1BIO Investigators, FinnDiane Study Group;
[1]Usher Institute of Population Health Science and Informatics, University of Edinburgh, Edinburgh, UK, [2]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, Finland, [3]The Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, [4]WellChild Laboratory, King's College London, London, [5]Department of Paediatrics, University of Cambridge, Cambridge, [6]Department of Public Health, NHS Fife, Kirkcaldy, UK.

Background and aims: To identify biomarkers associated with and/or predictive of progression of renal disease in subjects with type 1 diabetes mellitus (T1DM).
Materials and methods: The study comprised 926 patients with T1DM recruited from diabetes clinics and primary care into the Scottish Diabetes Research Network Type 1 Bioresource (SDRNT1BIO) and 315 patients recruited as part of the FinnDiane project. FinnDiane participants were oversampled for albuminuria. Retrospective and prospective clinical record measures of risk factors, eGFR and albuminuria and direct measures of eGFR and albuminuria were available. Progression of renal disease was evaluated by approximating eGFR trajectories for each patient by a linear slope and by defining a rapid progressors category by dichotomizing the linear slope according to a threshold of a loss of more than 3 ml/

min/1.73^2 per year. Biomarkers were measured in non-fasting serum samples using the Luminex platform (30 protein biomarkers) and mass spectrometry (94 metabolites). We investigated associations with eGFR slopes through linear regression where each biomarker was evaluated independently in models adjusted for age, sex and diabetes duration. A cross-validated forward selection approach was adopted to create the sparsest panel of biomarkers that would improve prediction.
Results: After setting a Bonferroni-corrected significance threshold of 4x10^{-4}, 17 protein markers and 10 metabolites showed significant association with eGFR slopes beyond age, sex, diabetes duration and study day eGFR (strongest associations with Kidney Injury Molecule-1 (KIM-1) beta=-0.37 (95% CI -0.42, -0.31), CD27 antigen beta=-0.39 (-0.47, -0.31), Alpha-1 Microglobulin beta=-0.30 (-0.36, -0.23)). These associations were also present when considering the binary rapid progressors outcome. KIM-1 was still significantly associated with eGFR slopes and rapid progression even after further adjustment for BMI, systolic blood pressure, diastolic blood pressure, HbA_{1c}, HDL, total cholesterol, smoking status and categorical albumin:creatinine ratio (ACR). Serum KIM-1 was shown consistently to be the most strongly associated biomarker, and was the most predictive marker in forward selection. When predicting rapid progression, KIM-1 alone increased the predictive performance of a model adjusted for age, sex, diabetes duration and study day eGFR, from an AUC of 0.703 to 0.762.
Conclusion: Serum KIM-1 is the biomarker most associated with rapid eGFR loss in patients with diabetes and significantly improves its prediction above clinical data.

Individuals with impaired glucose tolerance have a higher risk to develop chronic kidney disease over ten years than individuals with impaired fasting glucose

S.G.J. Diurlin, B. Daka, U. Lindblad, M.I. Hellgren;
Dep. of Primary Health Care, Institute of Medicine at Sahlgrenska Academy, Gothenburg, Sweden.

Background and aims: Impaired fasting glucose (IFG) and impaired glucose tolerance (IGT) are insulin resistance states but differing in the tissue aetiology of the insulin resistance. In summary, individuals with IFG suffer primarily from beta cell insufficiency, while individuals with IGT suffer primarily from insulin resistance in muscle tissue. The aim of this study was to explore the difference in development of chronic kidney disease stage 3 (CKD) between individuals with IFG and IGT over ten years.
Materials and methods: A random sample of 2816 individuals, 30-75 years old, in a middle-sized town in South-west of Sweden, were examined in a longitudinal study. All participants performed an oral glucose tolerance test and were examined by three specially educated nurses with blood pressure, body weight and height. IFG and IGT were defined by WHO criteria. Blood tests were drawn for S-creatinine and morning urine was collected for urine albumin and creatinine. After a mean follow-up time of 9.7 (7.8-11.6) years 1327 of the original participants were re-examined following the same protocol. In this study we addressed individuals with IFG (n=29) and IGT (n=24) in both examinations. CKD stage 3 was defined by estimated glomerular filtration rate (eGFR) ≤60 ml/min/1.73m^2 according to CKD -epi.
Results: During follow-up a decrease in eGFR was observed in the study population (mean=6.1 ml/min, SD=11.9). At baseline 2.1 % (n=28) of all subjects (n=1327) had chronic kidney disease stage 3, while there at follow-up was an increase to 8.3 % (n=109). The decrease in eGFR was greater in those with IGT when compared to those with IFG; Δ eGFR (IGT-IFG)= 8.5 ml/min, P= 0.003, CI= 2.8-14.2. There was in particular a significant difference between individuals with IFG and those with IGT considering the development of chronic kidney disease stage 3 after ten years, OR = 24.3, P= 0.016, CI= 1.8-327. These differences were still significant after adjustments for age, sex and eGFR at baseline.
Conclusion: Subjects with IGT are at higher risk to develop nephropathy when compared with subjects with IFG. Thus, it is particularly important to identify individuals with IGT to implement lifestyle interventions and when indicated also treatment with pharmaceuticals to prevent the development of nephropathy.

Non-alcoholic fatty liver disease significantly predicts future decline in kidney function in angiographied coronary patients

C. Lins[1], A. Vonbank[2], D. Zanolin[1], A. Leiherer[1], A. Schuler[2], A. Muendlein[1], P. Rein[2], A. Mader[3], P. Schwerzler[3], H. Drexel[4], C.H. Saely[2];
[1]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, [2]Academic Teaching Hospital Feldkirch, Feldkirch, Austria, [3]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [4]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is associated with insulin resistance, type 2 diabetes (T2DM), and an increased risk of cardiovascular events. A potential association of NAFLD with the decline of kidney function over time has not been investigated yet and is addressed in the present study.
Materials and methods: We prospectively investigated a series of 981 consecutive patients referred to coronary angiography for the evaluation of established or suspected coronary artery disease (CAD). NAFLD was diagnosed using the validated fatty liver index, and the glomerular filtration rate (eGFR) was calculated both at baseline and after a follow-up period of 4 years.
Results: At baseline, in patients with NAFLD (n=447; 45.6% of the study cohort) the prevalence of T2DM and of the metabolic syndrome was higher (32.7 vs. 18.8 %; p<0.001 and 72.9 vs. 23.0%; p<0.001, respectively), whereas eGFR was similar (73.2±20.0 vs. 72.9±21.3 ml/min/1.73 m^2; p=0.812) when compared to subjects who did not have NAFLD. Prospectively, NAFLD significantly predicted a decline in eGFR after adjustment for age, gender, and eGFR at baseline (F=8.97; p=0.003) and after further adjustment for smoking, LDL cholesterol, T2DM and the MetS (F=7.35; p=0.007).
Conclusion: We conclude that NAFLD significantly predicts a decline in kidney function over 4 years independently of baseline kidney function in angiographied coronary patients.

1082

Serum galectin-3 predicts progressive kidney disease in type 2 diabetes

K.C.B. Tan, S.W. Shiu, Y. Wong;
Department of Medicine, The University of Hong Kong, Hong Kong, Hong Kong.

Background and aims: Galectin-3, a member of the multifunctional galectin family, acts a broad-spectrum biological response modifier and is involved in tissue fibrosis, immunity, and inflammatory response. Recent evidence suggests that galectin-3 may play a role in the development of diabetic and non-diabetic nephropathies and serum level of galectin-3 may serve as a biomarker of inflammation and renal fibrosis. We have therefore evaluated whether serum galectin-3 level can predict progressive kidney disease in patients with type 2 diabetes.

Materials and methods: Galectin-3 was measured in the baseline serum samples by ELISA in 590 type 2 diabetic patients with estimated glomerular filtrate rate (eGFR) >30 mL/min/1.73m^2. Progressive kidney disease was defined as a doubling of the serum creatinine concentration, dialysis or transplant during follow up.
Results: 126 subject developed progressive kidney disease over 7.5 ± 4.4 years of follow up. At baseline, serum galectin-3 level significantly correlated with serum creatinine level and eGFR. Subjects with deterioration in renal function had higher baseline serum galectin-3 level than those whose renal function remained stable (9.07 ± 3.02 ng/ml vs 7.73 ± 2.18, p<0.01). Serum galectin-3 was a significant independent predictor of progressive kidney disease even after adjustment for age, gender, smoking, baseline eGFR, systolic blood pressure, HbA1c and duration of diabetes (p= 0.004, odds ratio 1.163, 95% CI 1.049-1.289).
Conclusion: Elevated serum galectin-3 level was associated with progression of diabetic kidney disease in type 2 diabetes and galectin-3 may be a potential useful biomarker to predict renal deterioration.
Disclosure: **K.C.B. Tan:** None.

1083

Components of metabolic syndrome and their causality for diabetic nephropathy

I. Toppila[1,2], E. Valo[1,2], C. Forsblom[1,2], N. Sandholm[1,2], P.-H. Groop[1,2], the FinnDiane Study Group;
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, [2]Abdominal Center Nephrology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland.

Background and aims: The metabolic syndrome (MetS) is a risk factor for diabetic nephropathy (DN), and the individual components of the MetS are associated with DN. However, whether these components are casually related to the pathogenesis of DN is unknown. This work therefore assesses potential causality.
Materials and methods: The study includes 4,533 participants with Type 1 Diabetes (T1D) from the FinnDiane Study. The data on five components of the MetS; systolic blood pressure (SBP), HDL cholesterol (HDL), triglycerides (TG), and waist circumference (WC) were measured at the baseline visit. Fasting glucose (FG) was not measured as all patients had T1D. All participants were genome-wide genotyped. Risk SNPs for components of the MetS were identified from publicly available GWASs. Genetic risk scores (GRS) for each patient were computed for each of the components (including FG). DN was defined as a case-control phenotype: controls as patients with normal albumin excretion rate (n=2,012), and cases as patients with macroalbuminuria or ESRD (n=1,161), using the latest available data (1,360 patients with DN status not compatible with case or control definition were used for GRS quality evaluation only). For the analyses the Multivariate Mendelian randomization (MR) and two-stage least-squares (2SLS) estimation on individual level phenotype/genotype data was used. The first-stage regression was defined as linear multivariate multiple regression using control patients only, and the second-stage was defined as logistic univariate multiple regression, using the predicted values of the risk factors from the model of the first-stage as independent variables. Risk factors demonstrating significant estimates for the second-stage were considered causal for DN.
Results: The created GRSs were strongly associated with the corresponding traits ($P_{GRS\text{-}SBP}=4.6\times10^{-5}$ to $P_{GRS\text{-}HDL}=2.4\times10^{-45}$), and explained approximately 0.4-4.5% of the trait variation. Some GRSs showed significant inter-correlations (GRS_{FG} vs. GRS_{TG}, r=-0.06, $p=4.4\times10^{-5}$ and GRS_{HDL} vs. GRS_{TG}, r=-0.31, $p=2.3\times10^{-104}$), and associations with other risk factors (GRS_{TG} associated with HDL, p=0.02), suggesting plausible pleiotropic genetic effects. GRS_{WC} was also directly associated with DN independently of other GRSs (OR=2.3 for each SD increase in GRS_{WC}, p=0.002). At the second stage of the MR analyses, only genetically predicted WC was associated with the DN outcome (OR=1.22 for each cm increase in genetically predicted WC, p=0.003), demonstrating a causal effect on DN. This association remained even when the first and second stage models were adjusted for sex and age at the baseline visit (OR=1.23, p=0.003).
Conclusion: Components of the MetS partially share genetic background. However, only genetically determined waist circumference seem to be causal for DN, whereas the other components of the MetS demonstrated no significant causal effects. Improving the quality of GRSs by using results from population-specific GWAS studies and/or increasing the number of included risk SNPs will most likely improve the power to find also other factors casually related to DN in the future.

Reduced sublingual endothelial glycocalyx in type 1 diabetic patients with diabetic nephropathy

S.A. Winther[1,2], M. Frimodt-Møller[1], E.H. Zobel[1], T.W. Hansen[1], P. Rossing[1,3];
[1]Complications Research, Steno Diabetes Center Copenhagen, Gentofte, Copenhagen, [2]Novo Nordisk A/S, Maaløv, [3]Faculty of Health, University of Copenhagen, Copenhagen, Denmark.

Background and aims: Glycocalyx is a glycoprotein layer that lines and protects the inner surface of the capillary endothelium. Damage to the glycocalyx may be an early stage in development of microvascular complications in diabetes. Insight into the function and thickness of glycocalyx in vivo, has been limited by the lack of easy and non-invasive quantification tools. The development of capillaroscopy has made it possible to visualize the sublingual capillaries by sidestream dark field imaging. Capillaroscopy estimates the dimensions of the glycocalyx by measuring the sublingual perfused boundary region (PBR). Our aim was to evaluate the glycocalyx thickness non-invasively in type 1 diabetic patients with different levels of historical and current albuminuria.
Materials and methods: Cross-sectional study including 77 type 1 diabetic patients stratified by history of normoalbuminuria (<30 mg/g) (n=26; age (mean±SD) 55.5±11.2 years; 34.6% women); microalbuminuria (30-299 mg/g) (n=27; 62.2±9.3 years; 48.2% women); and macroalbuminuria (>300 mg/g) (n=24; 57.5±9.9 years; 54.2% women). Glycocalyx thickness was assessed by 5 measurements with the GlucoCheck device (GlucoCheck BV, Maastricht, The Netherlands), an in vivo non-invasive hand-held microscope generating video recordings of the sublingual capillaries. The endothelial glycocalyx thickness was estimated from the PBR in capillaries with a diameter range of 5 to 25 μm. Higher PBR indicates smaller glycocalyx width. Urinary albumin-to-creatinine ratio (UACR) was measured in three morning samples.
Results: In normo-, micro-, and macroalbuminuric patients PBR was 2.30±0.22 μm, 2.32±0.25 μm, and 2.49±0.35 μm, respectively. The differences between normo- and macroalbuminuric patients (p=0.020) and micro- and macroalbuminuric patients (p=0.042) were significant, whereas the difference between normo- and microalbuminuric patients was not (p=0.74). After adjustment for age, sex, HbA_{1c}, diabetes duration and systolic blood pressure, the differences between normo- and macroalbuminuric patients (p=0.018) and micro- and macroalbuminuric patients (p=0.004) remained significant. In pooled (n=77) multivariate linear regression, higher level of current UACR (p=0.0007) and longer diabetes duration (p=0.026) were associated with a higher PBR.
Conclusion: In type 1 diabetic patients with a history of macroalbuminuria, measurements with the non-invasive GlucoCheck device revealed significantly higher PBR, suggesting an impaired glycocalyx, compared to patients with normo- or microalbuminuria. Moreover, higher current level of albuminuria was associated with higher PBR.

Early pregnancy clinical risk factors for preeclampsia in women with type 1 and type 2 diabetes

S.K. Nørgaard[1,2], M. Vestgaard[1,2], B. Asbjornsdóttir[1,2], L. Ringholm[3], P. Damm[1,4], E.R. Mathiesen[1,2];
[1]Center for Pregnant Women with Diabetes, Rigshospitaltet, Copenhagen, [2]Department of Endocrinology, Rigshospitalet, Copenhagen, [3]Steno Diabetes Center Copenhagen, Gentofte, [4]Department of Obstetrics, Rigshospitalet, Copenhagen, Denmark.

Background and aims: To assess the prevalence of pregnancy-induced hypertensive disorders and to identify early clinical, modifiable predictors of preeclampsia in women with type 1 and type 2 diabetes.
Materials and methods: A population-based cohort study of 494 women with pre-existing diabetes (307 type 1 and 187 type 2 diabetes) within a population of 2 million inhabitants, included at their first antenatal visit at 11±6 gestational weeks (mean±SD) from 2012 to 2016. Predictors of preeclampsia present at first antenatal visit were sought identified.
Results: At the first antenatal visit HbA1c was 6.9±2.3 % (51±10 mmol/mol) vs. 6.8±2.6 % (49±14 mmol/mol) and blood pressure 120 ±12/76±8 mmHg vs. 122±14/79±10 mmHg, (p=0.16/p=0.001) in women with type 1 and type 2 diabetes, respectively. Preeclampsia developed in 40 women at 36±3 gestational weeks with delivery 8±9 days later. The prevalence of preeclampsia was 8% (9% vs. 7%) and gestational hypertension 8% (9% vs. 6%). Univariate analysis identified nulliparity, presence of retinopathy or diabetic nephropathy including microalbuminuria and increasing blood pressure as predictors of preeclampsia. At the first antenatal visit, presence of diabetic microangiopathy (nephropathy, microalbuminuria and/or retinopathy) and diastolic blood pressure, were independently, positively associated with the development of preeclampsia, while neither diabetes type or HbA1c were associated with preeclampsia in this group of women with pre-existing diabetes and comparable good glycemic control.
Conclusion: At the first antenatal visit, diastolic blood pressure was the only independent, potentially modifiable risk factor for preeclampsia, in women with pre-existing diabetes regardless of diabetes type.

Role of cardiovascular autonomic activity in hypertension associated with obesity

S. Chiheb, A. Rezki, I. Banu, C. Pillegand, E. Cosson, P. Valensi;
Service Endocrinologie Diabétologie Nutrition, Hôpital Jean Verdier, Bondy, France.

Background and aims: We previously reported that a defect in vagal activity detected by cardiovascular autonomic reflex tests was associated with a higher rate of hypertension in patients with type 1 or type 2 diabetes, and that vagal activity is often depressed in the non diabetic obese population. Muscle sympathetic activity was found to be greater in hypertensive obese patients compared to normotensive ones. The aim was here to examine the relations between hypertension and cardiac autonomic nervous system activity in obese or overweight patients with normal (NGT), impaired glucose tolerance (IGT) or type 2 diabetes (T2D).
Materials and methods: We included 81 patients (38 NGTs, 28 IGTs and 15 T2Ds), including 25 with well-controlled hypertension. All of them were free of cardiovascular history. Central and peripheral blood pressure was assessed by applanation tonometry (SphygmoCor®). Cardiac sympathetic activity (LF-HR), vagal activity (HF-HR) and sympatho-vagal balance (LF/HF-HR) were determined by spectral analysis of heart rate variations at a controlled breathing rate during 6 minutes (Task Force Monitor® digital plethysmography).

Results: HF-HR, LF-HR and LF/HF-HR did not differ significantly according to glucose status. Compared with normotensive patients, hypertensive patients were older (60.0±12.8 *vs* 40.5±10.5 years, p<0.0001), had similar BMI(35.7±6.6 *vs* 36.4±5.3 kg/m^2) and HbA1c levels (5.89 ±1.15 *vs* 5.61±0.72%), higher systolic and diastolic blood pressure, higher heart rate, lower HF-HR and LF-HR (p<0.01 to p<0.0001). In multivariate analysis hypertension was associated with LF-HR and HF-HR independently of age, BMI and glucose status.
Conclusion: The present data suggest that among overweight or obese patients cardiac vagal and sympathetic activity is lower in those with hypertension whatever their glucose status. Changes in autonomic activity might be involved in hypertension.
Disclosure: **S. Chiheb:** None.

Disrupted patterns of blood pressure in patients with type 1 diabetes

R. Lithovius[1,2], D. Gordin[1,2], C. Forsblom[1,2], M. Saraheimo[1,2], V. Harjutsalo[1,2], P.-H. Groop[1,2];
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, [2]University of Helsinki and Helsinki University Hospital, Helsinki, Finland.

Background and aims: Hypertension is a major risk factor for microvascular complications and cardiovascular disease in patients with type 1 diabetes. However, the office-based blood pressure (BP) measurements may not accurately reflect real diurnal BP variation and does not identify disrupted patterns of BP. Therefore, Ambulatory Blood Pressure Monitoring (ABPM) may provide more accurate estimates of BP variability and, thus, lead to better hypertension control. The aim of the study is to estimate the presence of disrupted patterns of blood pressure (sustained, white-coat and masked hypertension) in patients with type 1 diabetes.
Materials and methods: This study comprised 126 patients with type 1 diabetes [52% men, mean age 43.6 ± 10.4 years and diabetes duration 26.0 ± 9.7 years] from the Finnish Diabetic Nephropathy Study (FinnDiane). The thresholds for hypertension of the office based measurement was ≥140/90 mmHg and for the 24-h ABPM ≥130/80 mmHg. Masked hypertension was defined as normal office BP, but elevated ABPM, and white-coat hypertension as elevated office BP, but normal ABPM. 24h ABPM, central BP and pulse wave velocity (PWV) were measured simultaneously by a non-invasive brachial oscillometric device (Mobil-O-Graph).
Results: Of the cohort, 37% were normotensive and 33% hypertensive (of them 45% were untreated), while 5.5% had white-coat and 24% masked hypertension (of them 47% were untreated). Although patients with masked hypertension had similar office systolic BP as those who were normotensive, 24-h systolic BP did not differ from those with sustained hypertension (p=0.1). Markers indicating arterial stiffness, (i.e. 24-h central BP and PWV) were higher in patients with masked hypertension than in those with normotension (p <0.0001).
Conclusion: Detailed evaluation of blood pressure by ABPM identifies one-quarter of the patients with masked hypertension which is associated with arterial stiffness. Further studies are needed to evaluate whether masked hypertension predict micro- and macrovascular complications in patients with type 1 diabetes.

Blood pressure variability in individuals with and without (pre)diabetes: the Maastricht study

T. Zhou[1,2], A.A. Kroon[1,2], K.D. Reesink[2,3], M.T. Schram[1,2], A. Koster[4,5], N. Schaper[1,2], P.C. Dagnelie[5,6], C.J. van der Kallen[1,2], S.J.S. Sep[1,2], C.D.A. Stehouwer[1,2], R.M.A. Henry[1,2];
[1]Dept. of Internal Medicine, Maastricht University Medical Centre +, [2]Cardiovascular Research Institute Maastricht, [3]Dept. of Biomedical Engineering, Maastricht University, [4]Dept. of Social Medicine, Maastricht University, [5]Care and Public Health Research Institute, [6]Dept. of Epidemiology, Maastricht University, Maastricht, Netherlands.

Background and aims: The mechanisms underlying the associations between (pre)diabetes and cardiovascular disease (CVD) are incompletely understood. We hypothesize that greater blood pressure variability (BPV) may underlie this association, as greater BPV is associated with (incident) CVD. However, data on BPV in (pre)diabetes is scarce. Therefore, we investigated the association between (pre)diabetes and within-visit, 24-hour and 7-day BPV.
Materials and methods: Cross-sectional data from The Maastricht Study (N=3451, 1924 with normal glucose metabolism [NGM], 511 with prediabetes, and 975 with type 2 diabetes [T2DM], 51% men, aged 60±8 years), an observational population-based cohort study enriched with individuals with T2DM. As BPV-indices, we determined standard deviation (SD) for within-visit BPV (n=3244), average real variability (ARV) for 24-hour BPV (n=2699), and SD for 7-day BPV (n=2259) (by office, 24-hour ambulatory, and 7-day home blood pressure measurements, respectively). We additionally analyzed 24-hour BPV divided into day (09:00h - 21:00h) and night (01:00h - 06:00h). Differences in BPV as compared to NGM were assessed with multiple linear regression, adjusted for age, sex, mean systolic or diastolic BP, smoking status, alcohol use, BMI, prior CVD, lipid profile, use of lipid-modifying and antihypertensive medication, and estimated GFR.
Results: In T2DM, the average systolic/diastolic values of within-visit, 24-hour and 7-day BPV were: 4.8/2.6, 10.5/7.3 and 10.4/6.5mmHg, respectively and in prediabetes 5.0/2.6, 10.3/7.0 and 9.4/5.9mmHg, respectively. Adjusted analyses showed that T2DM was associated with greater nocturnal systolic BPV (ARV 0.42mmHg [95%CI: 0.05 - 0.80]) and greater 7-day systolic BPV (SD 0.76mmHg [0.32 - 1.19]) as compared to NGM. Prediabetes was associated with greater within-visit systolic BPV only (SD 0.35mmHg [0.06 - 0.65]) as compared to NGM.
Conclusion: Both prediabetes and T2DM are associated with greater very-short to mid-term BPV. Nevertheless, the slightly greater BPV seen in both prediabetes and T2DM as compared to NGM suggest that very-short to mid-term BPV may explain not more than a small part of the increased CVD risk associated with glucose metabolism status. These findings do not detract from the fact that very-short to mid-term BPV is substantial and important in individuals with and without (pre)diabetes.

Expression of neutrophil elastase and myeloperoxidase mRNA in patients with newly diagnosed type 2 diabetes

S.K. Biswas[1], M. Ferdous[1], S. Chhoden R[1], M. Ali[1], S. Jasmin[1], S.M.K. Alam[1], M. Fariduddin[2], M.I. Arslan[1];
[1]Department of Biochemistry & Molecular Biology, Bangabandhu Sheikh Mujib Medical University (BSMMU), [2]Department of Endocrinology, Bangabandhu Sheikh Mujib Medical University (BSMMU), Dhaka, Bangladesh.

Background and aims: Neutrophil elastase (NE) and myeloperoxidase (MPO) enzymes actively participate in the formation of neutrophil extracellular trap and protect us from infection by killing pathogens. The impaired activity of NE and MPO may lead to impaired host defense against infection, and exaggerated activity of these enzymes may induce chronic inflammation. Importantly, diabetes mellitus (DM) is known to be associated with impaired host defense and chronic low-grade inflammation. Previous studies in DM found both higher and lower levels/activities of NE and MPO proteins in the serum or leukocytes. The present study was therefore aimed to explore the expressions of NE and MPO mRNA in the peripheral blood leukocytes (PBL) in patients with newly diagnosed type 2 DM.
Materials and methods: A total of 104 subjects were recruited from those who came for diabetes screening at our medical university. Subjects were grouped as control (normoglycemic) and diabetes based on their fasting blood glucose and HbA1c levels following ADA criteria. Subjects with previous history of DM and those suffering from complications of DM, chronic liver and kidney diseases, infection, inflammatory disease and malignancy were excluded. Insulin levels were measured by chemiluminescent microparticle immunoassay. Insulin resistance and beta cell functions were calculated. Total RNA from PBL was extracted and converted to cDNA by standard method. The mRNA levels of NE and MPO genes were quantified relative to reference gene beta-actin by quantitative real-time PCR. Gene expression data were analyzed by comparative Ct method, and expressed as percentage of reference gene.
Results: The control (n=65) and diabetes (n=39) groups were found similar in terms of sex distribution (m=57, f=47) and BMI. However, compared to control group the diabetes group was found aged (34±6 versus 46±8 yrs; $p<0.001$) with elevated systolic and diastolic BP ($p<0.01$). Fasting glucose, HbA1c and CRP levels were found significantly elevated in diabetes compared to control group ($p<0.01$). Fasting insulin levels were found similar between control (10.8±5.7), and diabetes (10.7±6.9 μU/mL) groups. However, HOMA-IR values [median (IQR)] were found 2.0 (1.3-3.1) for control and 3.6 (2.2-6.3) for diabetes groups ($p<0.001$); and HOMA-%B values were found 147% (108-234) for control and 45% (22-69) for diabetes groups ($p<0.001$). The NE mRNA expression was found significantly decreased in diabetes [0.29% (0.12-0.64)] compared to control group [0.45 (0.18-1.99); p=0.039]. Similarly, the MPO mRNA expression was also found significantly decreased in diabetes [0.09 (0.02-0.22)] compared to control group [0.16 (0.03-0.48); p=0.023]. The NE and MPO mRNA levels showed a negative trend with fasting glucose levels in all subjects (r= - 0.17, p=0.08 and r= - 0.16, p=0.10, respectively). However, the NE or MPO mRNA levels did not show any significant correlation with HbA1c, fasting insulin, HOMA-IR and HOMA-%B neither in diabetes group nor in all the study subjects.
Conclusion: The NE and MPO mRNA levels decrease in patients with newly diagnosed type 2 DM and show a negative trend with fasting glucose level. This finding may be considered as a probable molecular mechanism of increased susceptibility to infection in DM.

Relationship of chronic vascular complications with beta cell dysfunction and insulin resistance in newly-diagnosed type 2 diabetes. The VNDS Study

M. Dauriz[1], M. Trombetta[1], L. Santi[1], M. Boselli[1], C. Brangani[1], I. Pichiri[1], D. Travia[1], V. Cacciatori[1], C. Negri[1], V. Stoico[1], R.C. Bonadonna[2], E. Bonora[1];
[1]Department of Medicine, Division of Endocrinology, Diabetes and Metabolism, University of Verona School of Medicine and Hospital Trust of Verona, Verona, [2]Department of Medicine, Division of Clinical and Experimental Medicine, University and Azienda Ospedaliera Universitaria of Parma, Parma, Italy.

Background and aims: Type 2 diabetes (T2D) is a heterogeneous disorder resulting from the variable combination of impaired insulin sensitivity (IS) and defective beta-cell function (BF). Severe chronic vascular complications that ensue from exposure to chronic (sub)diabetic hyperglycemia may be present long before overt diabetes is ultimately diagnosed and they may be associated with the underlying pathogenic phenotype. This study aimed at assessing the prevalence of vascular complications and their relationships with beta cell function (BF) and insulin sensitivity (IS) defects in a large cohort of patients enrolled in the Verona Newly-Diagnosed Type 2 Diabetes Study (VNDS).
Materials and methods: In 712 GADA-negative, drug naïve, consecutive VNDS participants we measured: 1) IS, by euglycemic insulin clamp; 2) BF, by mathematical modeling of 5h-OGTT; 3) microvascular complications (MIC): diabetic retinopathy, cardiac autonomic and sensory-motor neuropathy (SMN, by biothesiometer and tendon reflexes), e-GFR_{MDRD}<60 mL/min/1.73 m^2 or albuminuria >30 mg/24h; and 4) macrovascular complications (MAC): prior cardiovascular disease, ischemic ECG, lower-limb artery stenosis or carotid stenosis >40% at US-scans. Thresholds for defective BF and IS were the 25th percentiles of BF and IS assessed with the same methods of VNDS in subjects with normal glucose regulation of the GENFIEV (n=340) and GISIR (n=386) studies, respectively.
Results: The prevalence of combined BF and IS defects was 78.9%, while that of isolated BF and IS was 10.8% and 8.8%, respectively. Overall, the prevalence of MIC and MAC was 48.2% and 18.6%. The most frequent MIC and MAC were SMN (28.5%) and prior cardiovascular disease (11%), respectively. Notably, the prevalence of isolated or combined IS and BF defects did not significantly differ between patients with and without complications. Logistic regression analysis revealed that reduced IS, older age, male sex and smoking independently predicted MAC, but not MIC, after adjusting for BMI, blood pressure, LDL-cholesterol and A1c. BF was not associated with any complication.
Conclusion: Our study showed that patients with newly-diagnosed T2D have a high prevalence of MIC and MAC, the latter being independently associated with reduced IS. These findings highlight the clinical importance of a systematic screening for chronic complications in the earliest disease stages.

Compensatory protective effect of cardiotrophin-1 on hyperglycaemic crisis

C.-J. Chang[1], H.-T. Wu[2], H.-C. Hung[3], H.-Y. Ou[4], J.-S. Wu[1];
[1]Department of Family Medicine, College of Medicine, National Cheng Kung University and Hospital, [2]Department of Family Medicine, National Cheng Kung University Hospital, [3]Department of Internal Medicine, National Cheng Kung University Hospital, [4]Department of Internal Medicine, College of Medicine, National Cheng Kung University and Hospital, Tainan, Taiwan.

Background and aims: High glucose generates reactive oxygen species (ROS), and contributes to glucotoxicity in hepatocytes. Hyperglycemia causes functional changes of the liver to promote liver injury. However, only a mild hepatic dysfunction observed in hyperglycemic crisis, implying a factor that exerts a hepatic protective effect in hyperglycemic crisis. Cardiotrophin-1 (CT-1) is a novel cytokine that modulates insulin sensitivity, and also exerts a hepatic protective activity in non-alcoholic fatty liver diseases. However, the role of CT-1 in hyperglycemic crisis-induced hepatic dysfunction remains unknown. Thus, the aim of this study is to investigate the hepatic protection effects of CT-1 in hyperglycemic crisis.
Materials and methods: Plasma CT-1 levels, and routine biochemistry were measured in 29 patients with hyperglycemic crisis before and after standard treatments. The effects of CT-1 on hepatic functions were evaluated in streptozotocin-induced hyperglycemic mice (STZ mice). HepG2 cells were used to clarify the possible mechanisms in the regulation of CT-1 expression.
Results: Plasma CT-1 concentrations were significantly decreased in subjects with hyperglycemic crisis after standard treatment, in accompanied with improved hepatic functions. Correction of hyperglycemia in STZ mice decreased the hepatic CT-1 expression. Injection of recombinant CT-1 improved hepatic dysfunctions, and liver architecture in STZ mice with increased anti-oxidative proteins, including hepatic superoxide dismutase-1 (SOD1). Moreover, CT-1 increased SOD1 expression through a STAT3-dependent pathway to decrease methylglyoxal-induced ROS production, and improved cell viability.
Conclusion: These findings highlight the protective activity of CT-1 in hyperglycemic crisis.

Impaired pulmonary function in type 2 diabetes: Is there a role for advanced glycation end-products measured by skin autofluorescence? Data form the ILERVAS project

A. Lecube[1], E. Sánchez[1], À. Betriu[2], L. Gutiérrez-Carrasquilla[1], M. Elías[2], F. Barbé[3], F. Purroy[1], M. Buti[4], E. Fernández[2], C. López-Cano[1]; [1]Endocrinology and Nutrition Department, Hospital Universitari Arnau de Vilanova, [2]Nephrology Department, Hospital Universitari Arnau de Vilanova, [3]Pneumology Department, Hospital Universitari Arnau de Vilanova, [4]Primary Care, Lleida, Spain.

Background and aims: Tissues that are rich in collagen and elastin, such as the lung, can be target of non-enzymatic glycation. Therefore, the production of advanced glycation end-products (AGEs) would collaborate in the deterioration of lung function previously described in type 2 diabetes (T2D). Our aim was to assess the relation between AGEs and pulmonary function because little information exits in these patients.
Materials and methods: For this purpose, we designed a cross-sectional study including 747 subjects from the ILERVAS project (58.1±6.4 years; 51.3% men; 6.3% with T2D) without known pulmonary disease, who underwent a baseline spirometry (Datospir©). The ILERVAS project is a interventional prospective study evaluating subclinical atherosclerosis and hidden kidney disease in subjects without previous cardiovascular disease. Restrictive pattern was defined by GOLD's guidelines pattern as forced vital capacity (FVC) <80% and forced expiratory volume in the first second (FEV1)/FVC ratio >70%. Skin autofluorescence (AF), a non-invasive assessment of subcutaneous AGEs accumulation, was measured (AGE Reader; DiagnOptics Technologies, The Netherlands).
Results: Patients with T2D showed less FVC [77.0 (38.0-114.5) vs. 91.1 (31.0-154.0) % predicted, p<0.001], FEV1 [80.1 (28.0 to 124.5) vs. 90.1 (28.0 to 143) % predicted, p=0.001], and a higher percentage of restrictive pattern (44.7% vs. 19.5%, p<0.001) compared to non-diabetic subjects. In the entire population, subjects with a restrictive pulmonary pattern showed an increased skin AF compared with subjects with normal lung function (2.3±0.6 vs. 2.0±0.5 arbitrary units, p<0.001). This difference persisted when only patients with T2D were evaluated (3.0±0.6 vs. 2.6 ±0.7AU, p=0.048). Univariate analysis showed that skin AF negatively correlated with FVC (r=-0.233, p<0.001) and FEV1 (r=-0.213, p<0.001). A multivariate regression analysis showed that skin AF (together with age, gender, BMI and packs of cigarettes per year) independently predicted FVC (R^2=0.174) and FEV1 (R^2=0.183).
Conclusion: In conclusion, skin AF is correlated with impaired pulmonary function. This is the first clinical evidence that suggest the role of AGEs as a mechanism to explain the deleterious effect of T2D in lung function.

[1]Laboratory of Molecular and Cellular Nephrology, Mossakowski Medical Research Centre Polish Academy of Sciences, [2]Laboratory of Virus Molecular Biology, University of Gdańsk - Medical University of Gdańsk, Intercollegiate Faculty of Biotechnology, Gdańsk, Poland.

Background and aims: The podocytes with their foot processes are important cellular layer of glomerular barrier involved in the regulation of glomerular permeability. Disturbance of podocytes function has a central role in the development of proteinuria in diabetic nephropathy. Retraction of the podocyte foot processes forming slit diaphragm is a common feature of proteinuria. The correlation of retraction with the development of proteinuria in not well understood. Protein kinase G type I alpha (PKGIα) is an intracellular target for vasorelaxant factors. We showed the relationship between oxidative stress, PKGIα activation, actin reorganization and changes in permeability to albumin across the filtration layer. AMPK-activated protein kinase (AMPK) is central in controlling the metabolism of glucose and fatty acid, its role in obesity and type 2 diabetes is major importance. AMPK also plays an important role in modulating of cell polarity, permeability and cytoskeleton reorganization. Here we investigated the interplay between PKGIα and AMPK signaling in cultured rat podocytes and its influence on filtration barrier permeability.
Materials and methods: We measured glomerular capillary permeability to albumin in isolated glomeruli from Wistar rats and transmembrane albumin flux in cultured rat podocytes. We examined the mutual interaction between AMPK and PKGIα activities and their influence on podocytes permeability by knocking down PKGIα and AMPK with small interference RNA (siRNA). The PKGIα-AMPK interaction was confirmed by co-immunoprecipitation and immunofluorescence. All experimental procedures were conducted in accordance with directive 2010/63/EU.
Results: Glomerular permeability to albumin and transmembrane albumin flux were decreased in the presence of AMPK activators (metformin, AICAR) or increased in the presence of PKGI activators (8-Br-cGMP, hydrogen peroxide). We demonstrated that PKGIα and AMPK mutually regulated in podocytes. We observed that PKGIα protein co-immunoprecipitated with AMPKα1 and AMPKα2 proteins. Using siRNA directed against PKGIα we also observed the activation of AMPK-dependent signaling pathways. We showed that decrease of PKGIα expression (about 56%) induced increase in basal levels of phosphorylated AMPK (from 0.536±0.012 to 0.821±0.048, n=4, P<0.05) and Acetyl-CoA carboxylase (ACC, from 0.307±0.028 to 0.635±0.032, n=4, P<0.05). The same effect was observed in the reverse procedure. Using siRNA against AMPKα2 (expression decreased by about 40%) we observed increase in basal level of phosphorylated myosin phosphatase target subunit 1 (MYPT1, from 0.160±0.001 to 0.416±0.077, n=3, P<0.05) and decrease in the phosphorylated myosin light chain 2 (MLC2, from 0.644 ±0,018 to 0.545±0.014, n=4, P<0.05). Moreover decrease of AMPKα1 expression by siRNA did not influence PKGIα activity.

Conclusion: Thus we propose that interplay between PKGIα and AMPKα2 activity regulate contraction apparatus and permeability to albumin in podocytes. Overall we have identified a potentially important new mechanism that may be injurious during diabetes in podocytes and affect filtration barrier permeability.

TRPC6 regulates the insulin effect on podocyte cytoskeleton dynamics

D. Rogacka[1], P. Rachubik[1], M. Szrejder[1], M. Rychłowski[2], S. Angielski[1], A. Piwkowska[1];
[1]Laboratory of Molecular and Cellular Nephrology, Mossakowski Medical Research Centre Polish Academy of Sciences, [2]Laboratory of Virus Molecular Biology, Intercollegiate Faculty of Biotechnology, University of Gdańsk-Medical University of Gdańsk, Gdańsk, Poland.

Background and aims: Podocytes are cells uniquely sensitive to insulin, demonstrating similarities to skeletal muscle and adipocytes with respect to insulin stimulated glucose uptake kinetics and the expression of glucose transporters (GLUTs). Recent studies have shown that insulin could dynamically remodel the actin cytoskeleton of podocytes, what was critically important in maintenance of the glomerular filtration barrier integrity. Rho family GTPases, dynamic modulators of the actin cytoskeleton, are expressed in cells forming glomerular filtration barrier. Thus changes of Rho GTPases activity may affect glomerular permeability to albumin, leading to albuminuria/proteinuria, a sign of kidney disease and important risk factor of the renal failure progression. Cumulative evidence has suggested that podocyte function and insulin signaling are central to the development of diabetic nephropathy, but the underlying mechanism is unclear. In addition, accumulating evidence suggests that TRPC6 channels are crucial mediators of podocyte calcium handling, involved in the regulation of glomerular filtration. Here we investigated whether TRPC6 is involved in insulin-dependent regulation of cytoskeleton dynamic in cultured rat podocytes.
Materials and methods: We assessed insulin-induced changes in glomerular permeability by measuring albumin flux in cultured rat podocyte. Expression and phosphorylation of proteins associated with actin cytoskeleton reorganization (PAK, Rac1/cdc42, cofilin) were confirmed in the podocytes using Western Blotting and immunofluorescence. F-actin network was labeled and visualized by fluorescence microscopy. All experiments were conducted in accordance with Directive 2010/63/EU and were approved by the Local Ethics Committee.
Results: Insulin induced the activation of proteins associated with actin cytoskeleton reorganization. We observed that insulin increased phosphorylation of PAK by about 46% (from 0.879±0.018 to 1.280±0.102, n=4, $P<0.05$) and decreased phosphorylation of cofilin (S71) by about 28% (from 1.998±0.106 to 1.450±0.033, n=4, $P<0.05$). We found that TRPC channel inhibitor SKF96365 or siRNA knockdown of TRPC6 abolished this effects and attenuated insulin-induced rearrangement of the actin cytoskeleton.
Conclusion: Taken together, our data suggest a key role of TRPC6 channels in the mediation of insulin-dependent regulation of actin dynamics in podocytes and identify a potential mechanism explaining disturbances in filtration barrier permeability in diabetes.

Diabetes induced changes in circulating and kidney mitochondrial DNA: a potential novel pathway of renal damage

A.N. Malik, A. Czajka, E.B. Thubron, C.L. Rackham, A.L.F. Austin, A. King;
Diabetes Research Group, King's College London, London, UK.

Background and aims: We recently showed that circulating mitochondrial DNA (MtDNA) levels are an independent risk marker in patients with diabetic nephropathy (DN) and proposed that diabetes induced early systemic changes in MtDNA may be involved in DN. To test this hypothesis, in the current study we investigated the early effect of diabetes on circulating and renal MtDNA levels in the Streptozotocin (STZ) induced diabetic mouse model.
Materials and methods: C57Bl/6 mice were defined as diabetic based on blood glucose levels of >20mM 4 days post STZ injection. Blood samples were obtained from control and diabetic mice after 1 week and 4 week of diabetes and kidney tissue after 4 weeks. Diabetic mice were cured using islet transplantation and subsequently cured mice were rendered diabetic by the removal of the islet graft to examine the effect of reversion to diabetes, and blood samples from cured and reverted mice were obtained. Total DNA was isolated from blood/tissue samples and absolute MtDNA copy numbers were measured using real time qPCR.
Results: MtDNA levels were significantly increased in the blood after 1 week and remained elevated after 4 weeks of diabetes, however kidneys from 4 week diabetic mice showed decreased MtDNA (n=3-6, $P<0.05$). To establish if the increased circulating MtDNA was a direct consequence of the diabetes, diabetic mice were treated by islet transplantation and this reduced their elevated circulating MtDNA to normal levels. Subsequent reversion to diabetes by the removal of the islet graft was accompanied by a concomitant increase in circulating MtDNA.
Conclusion: These data show that diabetes can directly lead to increased circulating MtDNA and that this increase can be normalised by correcting blood glucose levels. The loss of renal MtDNA in diabetic mice suggests that the increase circulating MtDNA may have originated from organs. Diabetes induced loss of renal MtDNA indicates loss of renal mitochondria which as an early event may predispose the diabetic kidney to bioenergetic deficit and contribute to the risk of DN. Furthermore, since MtDNA can act as an inflammatory molecule, the demonstration of diabetes induced increase in circulating MtDNA could explain the chronic inflammation often seen in diabetes patients. These data suggest that diabetes induced MtDNA changes may play important roles in the risk of diabetic complications and need further investigation.

The AGEs inhibitor pyridoxamine prevents kidney injury and dysfunction in mice fed high-fat high-fructose diet

M. Collino[1], F. Chiazza[1], D. Collotta[1], A.S. Cento[2], D. Nigro[2], V. Bitonto[3], J.C. Cutrin[3,4], M. Aragno[2], R. Mastrocola[2,5];
[1]Department of Drug Science and Technology, University of Turin, [2]Department of Clinical and Biological Sciences, University of Turin, [3]Department of Molecular Biotechnologies and Health Sciences, University of Turin, Turin, Italy, [4]Ininca-Conicet, Buenos Aires, Argentina, [5]Department of Internal Medicine, University of Maastricht, Maastricht, Netherlands.

Background and aims: Recent evidence suggests a key role of the local accumulation of diet-derived Advanced Glycation End-Products (AGEs) in evoking kidney injury/dysfunction associated with chronic exposure to hypercaloric diets. Pyridoxamine, a structural analog of vitamin B6 that exerts anti-glycative effect by interfering with oxidative macromolecular damage, is now in phase 3 clinical efficacy trial to delay chronic kidney disease progression in patients with type 1 diabetes. However, so far, the potential beneficial renoprotective effects of pyridoxamine in type 2 diabetes and obesity have not yet been investigated. Thus, we aimed to study the role of dietary supplementation with piridoxamine as preventive strategy to counteract the deleterious renal effects evoked by hypercaloric diet in mice.
Materials and methods: C57Bl/6J mice were fed a standard diet (SD, n = 16) or a diet enriched in fat (40%) and fructose (45%) (HFHF, n=16) for

12 weeks. At week 3, two subgroups of SD and HFHF mice started to receive pyridoxamine supplementation (150 mg/kg/day) in the drinking water. At week 12, mice were sacrificed and urine, plasma and kidneys were collected for Western blot, ELISA, histological and immunohistochemical analysis.

Results: When compared to SD mice, HFHF fed mice showed increased body weight (25,2±1,1 vs. 33,7±2,1 g, p<0,001) and impaired glucose homeostasis (fasting glycaemia 72,80±18,89 vs. 138,80±12,68 mg/dL, p<0.001). Pyridoxamine administration significantly improved fasting glycaemia (104,60±9,71 mg/dL, p<0,05) but not body weight (34,7±3,5 g). Renal function was strongly impaired by hyper-caloric supplement (serum creatinine 0.70±0.06 vs 1.13±0.15 mg/dL p<0.05; urine albumin 74.44±14.18 vs 265.07±15.43 μg/mL, p<0.001) and, most notably, pyridoxamine significantly prevented the renal function derangements (serum creatinine 0.66±0.03, p<0.05 vs HFHF; urine albumin 195.28±34.68 μg/mL, p<0.05 vs HFHF). Kidney morphology of HFHF fed mice presented strong vacuolar degeneration and loss of tubule brush border, both clearly attenuated by pyridoxamine administration. The HFHF-induced morphological and functional derangements were associated with a robust increase in the local expression of AGEs receptor (RAGE) and pro-fibrogenic markers (fibronectin, vimentin, SMAD2/3) as well as a significant activation of the pro-inflammatory NF-kB and Rho/ROCK signaling pathways. Interestingly, piridoxamine prevented the diet-induced overexpression of RAGE and pro-fibrogenic markers as well as the activation of the inflammatory signaling cascades.

Conclusion: The present study demonstrated for the first time that the administration of the anti-glycative compound pyridoxamine counteracted diet-dependent kidney injury and dysfunction by interfering with local AGEs accumulation, thus resulting in reduced activation of the pro-fibrotic and inflammatory cascades.

Arteriell stiffness and progression of cerebral white matter lesions in asymptomatic patients with type 2 diabetes and healthy controls: a 5-year cohort study

K.L. Funck[1], E. Laugesen[1,2], P. Høyem[1], B. Stausbøll-Grøn[3], W.Y. Kim[3,4], L. Østergaard[5], D. Zeidler[5], T.K. Hansen[1], P.L. Poulsen[1];
[1]Department of Endocrinology and Internal Medicine, [2]Department of Clinical Medicine, [3]MR Research Centre, Department of Clinical Medicine, [4]Department of Cardiology, [5]Center of Functionally Integrative Neuroscience, Aarhus, Denmark.

Background and aims: Stroke is a frequent and feared complication in patients with type 2 diabetes. Arterial stiffness may improve current suboptimal risk prediction in this patient group, however, studies in diabetes populations are lacking. We aimed to determine the association between arterial stiffness and the progression of cerebral white matter lesions (WML), a marker of stroke risk, in patients with type 2 diabetes and healthy controls. We tested the a priori hypothesis that progression of arterial stiffness is associated with progression of WMLs.

Materials and methods: We conducted a 5-year cohort study. Observers were blinded to patient status. Arterial stiffness and WMLs were assessed at both baseline and follow-up visits. Arterial stiffness (carotid-femoral pulse wave velocity [PWV]) was obtained by applanation tonometry. WMLs were assessed by cerebral T2-FLAIR MRI and quantified by Breteler score. WML progression was defined as an upward change in category during follow-up. Data from 49 patients newly diagnosed with type 2 diabetes and no previous history of cerebrovascular disease and 58 age- and sex-matched controls were available for analysis. At baseline, participants had a mean (±SD) age of 59±10 years and patients had a median (range) diabetes duration of 1.8 (1.0-3.2) years. Fifty-two (49%) were males.

Results: Patients with type 2 diabetes had a higher PWV than controls at both baseline (9.2±2.2 vs. 7.9±1.4m/s, p<0.01) and follow-up (9.8±2.4 vs. 8.6±1.9m/s, p=0.01). Breteler scores and WML progression were similar in the two groups (p>0.05). PWV progression was associated with WML progression in the total cohort (adjusted for age, sex, diabetes, baseline PWV and systolic blood pressure progression: OR 1.58 per 1m/s [95%CI: 1.09-2.28], p=0.02). We found no interaction between diabetes and PWV progression on WML progression.

Conclusion: PWV progression is associated with WML progression in patients with type 2 diabetes and healthy controls. PWV candidates as a new risk marker for stroke.

Carotid-femoral pulse wave progression and WML progression

WML progression OR per 1m/s increase in PWV (95% CI)

Association of mannose-binding lectin levels with progression in carotid artery intima-media thickness in type 2 diabetic patients: a 7-year follow-up

M. Kaplar[1], J. Kulcsar[1], M. Katko[1], B. Cogoi[1], R. Esze[1], M.T. Magyar[2], L. Olah[2], K. Szabo[2], K.R. Czuriga-Kovacs[2], G. Paragh[1];
[1]Department of Internal Medicine, University of Debrecen, [2]Department of Neurology, Debrecen, Hungary.

Background and aims: Mannose-binding lectin (MBL), a weak acute phase reactant protein activates the "lectin" pathway of complement system independently of the antibodies and plays an important role in the innate immunity. It has been suggested that MBL may be involved in the pathogenesis of micro- and macrovascular complications of diabetes and MBL levels may be used as a prognostic marker for these complications. Only a few data about the role of MBL in the development of subclinical atherosclerosis (carotid artery intima-media thickness - IMT) in diabetes mellitus were reported. According to these results low MBL levels enhance the progression in IMT, while high MBL levels have protective role. Our aim was to analyse a possible association between serum MBL levels and changes in IMT after a 7-year follow-up in Type 2 diabetic (T2DM) patients.

Materials and methods: Serum MBL levels (ng/ml) and IMT (mm) were measured in a total of 106 Type 2 diabetic patients (56 male and 50 female). Regarding stability of MBL serum levels they were determined once at the end of the study with a sandwich ELISA (BioPorto Diagnostics). IMT was measured at the beginning of the study and after a 7-year follow-up. It was carried out on both sides using 2D echo. Data were collected and analysed statistically using repeated measures ANOVA with Newman Keuls post-hoc tests.

Results: Progression in IMT was significantly higher in patients with absolute MBL deficiency (MBL < 100 ng/ml, n=13, ΔIMT: 0.109 ± 0.143 mm, p < 0.001) compared to those above this threshold (MBL ≥ 100 ng/ml, n=93, ΔIMT: 0.039 ± 0.134 mm, p = 0.15). Taking into consideration that thiazolidine-dions (TZD) may decrease IMT, calculations were also performed after exclusion of patients having been treated with TZD agents. In this setting progression in IMT was significant in

both groups but, with much stronger elevation in MBL deficient group (n=11, ΔIMT: 0.138 ± 0.103 mm, p < 0.001) compared to normal and elevated MBL levels group (n=67, ΔIMT: 0.039 ± 0.134 mm, p = 0.03). We also evaluated changes in IMT according to the initial IMT values. We could observe progression in patients with MBL < 100 ng/ml in both IMT < 0.8 mm and IMT ≥ 0.8 mm groups (n=8, ΔIMT: 0.122 ± 0.099 mm, p < 0.01 and n=3, ΔIMT: 0.184 ± 0.121 mm, p < 0.001, respectively). However, patients in the group of MBL levels ≥ 100 ng/ml neither with initial IMT < 0.8 mm (n=50, ΔIMT: 0.099 ± 0.106 mm, p=0.06), nor with initial IMT ≥ 0.8 mm (n=17, ΔIMT: -0.047 ± 0.146 mm, p=0.4) showed significant progression. There was no significant difference in HbA1c and lipid parameters of patients and all patients were treated with ASA 100 mg/day.

Conclusion: Our study shows that low MBL levels partially depending on the initial IMT values increase the progression of IMT in T2DM during a 7-year follow-up and MBL probably may be one of the markers for subclinical atherosclerosis.

PS 096 Complications from bench to bedside

1099

Protective effect of SOCS1-based therapy against renal and vascular oxidative stress in diabetic mice

L. Lopez-Sanz, C. Recio, S. Bernal, I. Lazaro, A. Oguiza, J. Egido, C. Gomez-Guerrero;
Renal, Vascular and Diabetes Research Lab, IIS-Fundacion Jimenez Diaz, Madrid, Spain.

Background and aims: Oxidative stress resulting from excessive production of reactive oxygen species (ROS) or impaired antioxidant defenses is a key pathogenic factor in diabetic complications, including nephropathy and atherosclerosis. Chronic activation of Janus Kinase/Signal Transducer and Activator of Transcription (JAK/STAT) signaling pathway contributes to diabetic complications by inducing genes involved in cell proliferation, fibrosis, inflammation and oxidative stress. Suppressors of cytokine signaling (SOCS) family controls both magnitude and duration of JAK/STAT pathway and has emerged as a new target for therapeutic intervention. This study investigates the beneficial effect of SOCS1-based therapies to combat oxidative stress and tissue injury in a mouse model of diabetes.

Materials and methods: Streptozotocin-induced diabetic apolipoprotein E-deficient mice received either a single dose of recombinant adenovirus expressing SOCS1 ($1x10^{12}$ viral particles/kg, i.v.) or 3 weekly injections of SOCS1 peptidomimetic (3 mg/kg/day, i.p.). After 6-10 weeks of intervention, kidney, aorta, serum and urine samples were used to evaluate clinical parameters, oxidative stress markers, morphology, and gene expression.

Results: Diabetes induction in mice resulted in a progressive alteration of the redox balance, as demonstrated by increased ROS levels and decreased antioxidant activity, which ultimately led to renal dysfunction and vascular injury. Interestingly, these molecular and pathological alterations in diabetic mice were partially reversed by SOCS1 gene transfer and, more efficiently, by SOCS1 peptidomimetic. Compared with untreated controls, kidney and aorta from mice treated with SOCS1 peptidomimetic exhibited significantly lower levels of superoxide anion (% vs control: 59±4% and 64±4%, respectively), DNA oxidation marker (44±6% and 58±8%) and NADPH oxidase subunits (Nox1, 41±6% and 36 ±3%; Nox4, 47±4% and 33±7%), along with higher levels of antioxidant genes (heme oxygenase-1, 197±22% and 238±46%; superoxide dismutase, 244±37% and 254±37%; catalase, 150 ±28% and 239±51%) and urinary total antioxidant capacity (183 ±10%). These trends remained throughout the course of the treatment period and correlated with a reduction in parameters of renal dysfunction (albuminuria, mesangial expansion and fibrosis), atherosclerosis (lesion size and lipid content) and inflammation (leukocyte infiltration and chemokine expression). In cultures of renal tubuloepithelial cells, macrophages and vascular smooth muscle cells, SOCS1 attenuated ROS generation induced by cytokines and/or high-glucose. This effect was associated with a decrease in NADPH oxidase activity and expression of catalytic (Nox1, Nox2 and Nox4) and regulatory (NoxA1 and NoxO1) subunits, and was mediated by both STAT1- and PI3K-dependent mechanisms.

Conclusion: SOCS1-based therapies have a protective role against increased oxidative stress under chronic hyperglycemia, by altering the expression of enzymes associated with the induction and resolution of oxidative stress in diabetic mice.

Novel insights into the protective role of Nrf2 activation in diabetes-associated atherosclerosis

I. Lazaro[1], L. Lopez-Sanz[1,2], S. Bernal[1,2], J. Madrigal-Matute[3], A. Oguiza[1], C. Recio[1], J. Egido[1,2], C. Gomez-Guerrero[1,2];
[1]Renal, Vascular and Diabetes Research Lab, IIS-Fundacion Jimenez Diaz, Madrid, [2]Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders (CIBERDEM), Madrid, Spain, [3]Dept. Developmental and Molecular Biology, Institute for Aging Studies, Albert Einstein College of Medicine, Bronx, USA.

Background and aims: The intertwined relationship between metabolism, oxidative stress and pro-inflammatory events in the vascular system is determinant in the pathogenesis of diabetic cardiovascular disease. Therefore, novel approaches to limit vascular inflammation and to restore redox balance are of clinical interest. Nuclear factor (erythroid-derived 2)-like 2 (Nrf2) is a stress-sensitive transcriptional regulator of genes involved in inflammatory and oxidative stress responses, and has emerged as a promising therapeutic target. This study investigates the underlying mechanisms of the protective effect of Nrf2 induction in an experimental model of diabetes-associated atherosclerosis.
Materials and methods: Streptozotocin-induced diabetic apolipoprotein E-deficient mice were randomized to receive 3 weekly *i.p.* injections of the Nrf2 activator tert-butyl hydroquinone (tBHQ, 50 mg/kg/day) or vehicle. After 6 weeks of treatment, we evaluated atherosclerotic lesions (size and composition) in the aorta and the expression levels of markers for inflammation, redox balance and autophagy.
Results: Administration of tBHQ effectively increased the number of Nrf2-activated cells within the atherosclerotic lesions of mice, colocalizing with both macrophages and vascular smooth muscle cells. Nrf2 induction by tBHQ treatment resulted in a significant decrease in the size and extension of atherosclerotic lesions in diabetic mouse aorta (% reduction *vs* vehicle: 39±9) and also reduced the lipid content of plaques, without affecting hyperglycemia and serum lipid profile. Nrf2 activator attenuated atherosclerotic plaque inflammation in diabetic mice, by reducing total macrophage content (23±6%), M1/M2 phenotype balance (44±9%), foam cell size (34±4%) and chemokine gene expression (*Ccl2*, 76±6%; *Ccl5*, 72 ±6%). Atheroprotection was accompanied by systemic and local antioxidant effects, characterized by lower levels of oxidative stress markers (8-hydroxydeoxyguanine and superoxide anion) and higher levels of systemic total antioxidant capacity and antioxidant genes (heme oxygenase-1, 346 ±47%; superoxide dismutase, 307±43%; catalase, 246±29% *vs* vehicle). Interestingly, tBHQ treatment upregulated autophagy-related gene (*Atg5, Beclin1, Atg7, Lc3* and *p62*) and protein (LC3-II, 184±10%; p62, 193 ±15%) expression in aorta and liver of diabetic mice. A parallel *in vitro* study confirmed that tBHQ induced autophagy in vascular smooth muscle cells under both starving and normal serum culture conditions.
Conclusion: Nrf2 induction is a promising therapeutic approach needed to tackle diabetes-driven vascular damage, according to its protective effects on inflammation, oxidative stress and autophagy.

Carnosinase inhibition by thiol-containing compounds

T. Weigand[1], C.P. Schmitt[2], P. Nawroth[3], G. Vistoli[4], V. Peters[1];
[1]Division of Metabolic Diseases, University of Heidelberg, [2]Division of Paediatric Nephrology, University of Heidelberg, [3]Division of Endocrinology, University of Heidelberg, Heidelberg, Germany, [4]Department of Pharmaceutical Sciences, Università degli Studi di Milano, Milan, Italy.

Background and aims: Carnosinase 1 (CN1) activity is up-regulated under diabetic conditions by post-translational modifications. Supplementation of diabetic mice with carnosine mitigates diabetic complications. The cysteine residue at position 102, but not at position 229, regulates CN1 activity. We now tested whether thiol-containing compounds interact with CN1 cysteine residue at position 102 by cysteinylation and modify CN1 activity and therefore cytoprotective carnosine levels.
Materials and methods: The dynamic behavior of CN1 before and after addition of cysteine was examined by characterizing enzyme kinetics of the recombinant and renal enzyme and by using molecular dynamic (MD) simulations.
Results: Recombinant CN1 (rCN1) efficiency for carnosine degradation (5.2±0.2 μmol/mg/h/mM) was reduced by addition of thiol-containing compounds, such as reduced glutathione (3.2±0.4 μmol/mg/h/mM; p=0.05), cysteine (1.6±0.2 μmol/mg/h/mM; p=0.05) and N-acetylcysteine (2.0±0.3 μmol/mg/h/mM; p=0.05) whereas L-glutamic acid, glycine and GSSG (oxidized glutathione) had no effect on recombinant CN1 activity. Increased renal CN1 activity in diabetic (db/db) mice was reduced and normalized by adding GSH to renal tissue samples in a concentration-dependent manner. Substitution of rCN1 cysteine residues at position 102 (Mut 1^{C102S}) and 229 (Mut 2^{C229S}) showed that only cysteine at position 102 is mandatory for regulation of CN1 activity by thiols. Whereas Mut 1^{C102S} was not influenced, the addition of thiols to rCN1 Mut 2^{C229S} lowered catalytic efficiency (3.4±0.5 μmol/mg/h/mM; p=0.05 compared to control), indicating that the inhibitory effect is due to S-cysteinylation of cysteine at position 102 but not at position 229. MD simulation confirmed a conformational rearrangement of the negatively charged residues surrounding the zinc ions by S-cysteinylation of cysteine 102 causing a partial shift of the carnosine ammonium head with the consequent distancing of the carbonyl group, resulting in a less effective pose of the substrate within the catalytic cavity and a decrease in CN1 activity.
Conclusion: We provide evidence for a novel mechanism of CN1 regulation. Kinetic parameters and MD simulations revealed that inhibition by thiol-containing compounds is due to allosteric interactions through S-cysteinylation. Inhibition of circulating and tissue CN1, resulting in higher carnosine levels, may represent a valuable therapeutic strategy for mitigation of complications associated with diseases such as diabetes mellitus.

Loss of glyoxalase 1 in various mammalian cells is associated with an increased resistance against environmental stressors

J. Morgenstern[1], B. Fuchs[1], D. Schumacher[2], S. Herzig[3,4], M. Freichel[2], P. Nawroth[1,4], T. Fleming[1,4];
[1]Internal Medicine 1, University of Heidelberg, [2]University of Heidelberg, Heidelberg, [3]German Institute for Diabetes and Cancer (IDC), Neuherberg, [4]German Center for Diabetes Research (DZD), Neuherberg, Germany.

Background and aims: In contrast to other enzymes involved in the detoxification of xenobiotics, the glyoxalase system consisting of glyoxalase 1 and 2 (GLO1 and 2) has an extremely limited substrate specificity. In fact it is mainly responsible for the detoxification of methylglyoxal (MG), a toxic dicarbonyl compound formed spontaneously during glycolysis. Given this background MG has gained a lot of attention within the context of dicarbonyl induced damage under hyperglycemic conditions such as diabetes. Therefore since decades the glyoxalase system was meant to be indispensable to maintain cellular viability in eukaryotic cells. We have established three mammalian cell lines with a total loss of GLO1 to proof this hypothesis. Major aim of this approach was to look at metabolic side effects in those three *in vitro* model systems regarding cellular viability and resistance against xenobiotics.

Materials and methods: GLO1 knock-out in murine cardiac endothelial, kidney mesangial and neuronal Schwann cells was established using the CRISPR-Cas9 technique. Intracellular levels of MG and MG-modifications were measured by MS. The LD_{50} for various xenobiotics and UV-radiation was determined using MTT assay. Enzyme kinetics and total GSH/GSSG content were analyzed spectrophotometrically. Protein concentration and mRNA content were assesed using western blot and qPCR. All data are expressed as mean values ± standard error and were analyzed for significance using unpaired t-test with *Welch`s* correction. Differences were considered to be significant at $p<0.05$.
Results: The loss of GLO 1 was neither linked to increased levels of MG nor MG-modified proteins. The mRNA and protein expression in three different $GLO1^{-/-}$ cell models revealed an upregulation of several subtypes of aldo-keto-reductase (AKR) and aldehyde dehydrogenase (ALDH). Kinetic profiles for the upregulated enzymes present in the cytosolic fractions of $GLO1^{-/-}$ cells revealed that those oxidoreductases were able to detoxify formaldehyde, 4-hydroxynonenal, malondialdehyde and acrolein with higher efficiency compared to wild-type (WT) cells. This was confirmed by increased LD_{50}-values for those xenobiotics, hydrogen peroxide and ultraviolet radiation in a toxicity assay. Additionally $GLO1^{-/-}$ cells showed significantly improved ratios of GSH to GSSG compared to appropriate WT cells.
Conclusion: The loss of GLO1 in three mammalian *in vitro* models was compensated effectively regarding the MG metabolism, even under high glucose growth conditions. The upregulation of various oxidoreductases (AKR and ALDH) in $GLO1^{-/-}$ was associated with increased resistance against harmful environmental stressors such as ultraviolet radiation and exposure to hydrogen peroxide or several xenobiotics. Furthermore, the improved ratio of GSH to GSSG in $GLO1^{-/-}$ reflects an optimization in the potential oxidative stress response. Consequently we claim the intriguing hypothesis that the loss of GLO1 has protective character due to the upregulation of various enzymes of the xenobiotic defense metabolism. Further *in vivo* studies are required to prove the concept if GLO1 is fundamentally necessary for life or just a remnant of evolution.

Perivascular adipose tissue and endothelial dysfunction in an aged model of obesity

A.R. Costa, A. Pereira, Â.M. Geraldo, R. Seiça, C.M. Sena;
Institute of Physiology, IBILI, Faculty of Medicine, University of Coimbra, Coimbra, Portugal.

Background and aims: Obesity is a growing problem worldwide. In this context, perivascular adipose tissue (PAT) has recently been recognized as a novel factor in vascular biology, with implications in the pathophysiology of cardiovascular disease. The main goal of this study was to investigate the effects of high-fat diet on PAT and study its impact on endothelial function of mesenteric arteries of obese animal models.
Materials and methods: Eight-month-old male Wistar (W) rats were randomly divided in two subgroups: group 1) W control group fed with standard diet (W12m); group 2) W rats fed with high fat diet during 4 months (WHF) and compared with six-month-old male W rats (W6m). Glucose, lipids, leptin, adiponectin and HbA_{1c} concentrations were measured on blood samples. Vascular contraction and functional endothelial-dependent and independent vasorelaxation was evaluated in isolated mesenteric ring preparations from the different groups. Oxidative stress, inflammatory biomarkers, and adipocytokines were also evaluated in arteries and PAT of the different groups of rats.
Results: High fat diet induced significantly increased body weight, glucose at 2h after a glucose load and systemic levels of free fatty acids, leptin and leptin/adiponectin ratio. It also significantly reduced the efficacy of NO-dependent and independent vasorelaxation (by 60 and 22%, respectively) in mesenteric arteries accompanied by 2-fold increment in vascular oxidative stress. In WHF group, PAT significantly increased the expression of the receptor for advanced glycation end products (RAGE), intercellular adhesion molecule-1 (ICAM-1), chemokines (as monocyte chemotactic protein-1/CCL2, RANTES/CCL5) and pro-inflammatory adipokines (as resistin, leptin and lipocalin-2) compared to W6m, probably important contributors of endothelial dysfunction.
Conclusion: Inflammation in PAT directly impacts vascular disease of the underlying artery, perhaps contributing to the endothelial dysfunction underlying atherosclerosis.

Position of oxidative stress and microcirculation parameters in artificial neuronal network for assessment of chance for type 2 diabetes development

V.M. Shyshko[1], T.V. Mokhort[1], V.S. Spiridonava[1], E.E. Kanstantinava[2], N.L. Tsapaeva[3], I.V. Buko[4];
[1]Endocrinology, Belarusian State Medical University, [2]Endocrinology, A.V. Luikov Heat and Mass Transfer Institute of the National Academy of Sciences of Belarus, [3]Cardiology and Inner Diseases, Belarusian State Medical University, [4]Minsk City Center of Hygiene and Epidemiology, Minsk, Belarus.

Background and aims: Prevalence of type 2 diabetes (T2D) is on the rise that explains search of approaches to diagnosis and prophylaxis of disease. Oxidative stress (OS) and microcirculation (MC) firstly exhibit changes during deviations of glycaemia. Study changes in conjunctival MC and OS parameters in patients with T2D to create new configuration of artificial neuronal network (ANN).
Materials and methods: We included 155 patients and 41 almost healthy person and divided into 4 groups: 1 - almost healthy, 2 - overweight and obesity I st. (56 patients), 3 - prediabetes (59 patients), 4- T2D (40 patients). Computer-assisted intravital conjunctival microscopy was used to evaluate 20 parameters of MC. Activities of superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GP), glutathione reductase (GR) and concentrations of oxidized glutathione (GSSG), reduced glutathione (GSH) and thiobarbituric acid reactive substances (TARS) and total antioxidant activity (tAOA) were assessed as markers of OS. All patients underwent biochemical tests for HbA1c, lipid profile, GFR was calculated and eyegrounds examination was conducted. New configuration of ANN was created and included 38 input values and 5 output values.
Results: MC changes in study groups were identical some way compared to control group and included increased count of arteriolo-venular anastomosis (AVA), enhanced meandric tortuosity of venules ($Mean_v$) ($p<0,05$). Additionally identical for prediabetes and T2D arteriolo-venular diameter ratio (AVD) was decreased and tela was lost (Net) compared to control group ($p<0,05$). In T2D to all listed above changes we revealed enhanced meandrous tortuosity of capillaries ($Mean_c$) and inequalities in vessels caliber (Cal) ($p<0,05$ compared to other groups). Markers of OS were changed on case-by-case basis in groups. tAOA was increased in patients with prediabetes (69,48 (59,09;85,93)% vs 62,24 (47,60;71,39)% in patients with T2D ($p<0,05$). Overweight and obesity were associated with increased GSSG concentrations (0,36 (0,31;0,39) mmol/l vs 0,33 (0,31;0,37) mmol/l). T2D was characterized by decreased activity of SOD (65,24 (30,55; 89,47) RVU/ml vs 86,43 (36,49;130,36 RVU/ml in controls ($p<0,05$) and decreased GSH concentration (2,08 (2,08;2,92 mmol/l vs (2,53 (2,29;3,15) mmol/l ($p<0,05$)). According to estimated changes in MC and OS parameters and including other risk factors for T2D and microangiopathy development we created new configuration of ANN that showed high values of included parameters. During education of ANN several deviations were revealed. Detailed analyze of this patients (deviations) disclosed changes in MC and OS specific to T2D.

Conclusion: We observed increasing changes in microcirculation from overweight and obesity to prediabetes and diabetes and different changes of OS parameters in study groups. ANN can optimize work with large count of parameters and reveal patients with increased risk for T2D development. This can be done by receiving results from already educated ANN.

Glycaemic variability is associated with oxidative damage independently from glycaemic control in type 1 diabetes

S. Dagdelen, A.B. Bahcecioglu, I. Lay, A. Samadi, U. Unluturk, M. Bayraktar;
Internal Medicine, Department of Endocrinology and Metabolism, Hacettepe University, School of Medicine, Ankara, Turkey.

Background and aims: Oxidative stress contributes in diabetic organ damage. Oxysterols as indicators of oxidative stress have been shown to play critical roles with cytotoxic and proinflammatory actions in the course of Diabetes Mellitus. Currently the impact of glycemic variability on oxidative stress whether dependently or independently on glycemic control is a controversial issue. We aimed to investigate an association between oxysterol levels and glycemic variability as well as glycemic control in type 1 diabetic patients.
Materials and methods: Thirty adult patients with Type 1 diabetes mellitus (T1DM), (28 K, 2 E, mean age 32.4 ± 10.1 years, median 13 years, HbA1c mean: 8.1 ± 1.2%) who were on insulin pump were included in the study. The mean amplitude of glucose excursion (MAGE) of the second day, as a sign of intraday glycemic variability, and the mean of daily differences (MODD), as a sign of interday glycemic variability (consecutive 3 days) calculated by using72-hour Continuous Glucose Monitoring System (cGMS) data. Serum samples for oxysterols (7-ketosterol, cholestane-3β, 5α, 6β-triol (cholestanetriol))measurements were taken from patients at 0, 24 and 72 hours of cGMS measurements. Quantification of oxysterols were accomplished using high sensitivity and specific LC-MS / MS (tandem-mass spectrometry) method.
Results: There was a significant correlation between MAGE of the second day (24-48. hour, mean: 112.3 ± 57.6 mg / dl) and 7-ketosterol and 7-ketosterol/total cholesterol levels of the subsequent day (72nd hour) (r:0,558, p:0.001; r:0.468; p:0.009). There was no significant correlation between MODD and oxysterol levels. There was no significant correlation between HbA1c and oxysterol levels.
Conclusion: This study with continous glucose monitoring system data of the patients with advanced T1DM on insulin pump, showed that intraday glycemic variability is associated with oxidative stress independently of glycemic control. Accordingly, while attempting to provide glycemic control in these patients, insulinization strategies avoiding glycemic variability should be preferred

What predicts early glycaemic control in people with type 2 diabetes?

A.P. McGovern[1], U. Hoang[1], W. Hinton[1], N. Munro[1], S. Calderara[2], S. de Lusignan[1], M. Whyte[1];
[1]Department of Clinical & Experimental Medicine, University of Surrey, Guildford, UK, [2]Eli Lilly and Company, Vernier-Geneva, Switzerland.

Background and aims: It has been demonstrated that early glycaemic control substantially reduces the risk of microvascular complications in type 2 diabetes (T2D) and may also impact on subsequent macrovascular risk. Despite the evidence of the relationship between optimal glucose control and reduction in cardiovascular risks, a significant proportion of those with T2D fail to achieve early good glycaemic control. It is not clear which patient characteristics are associated with failure to achieve early glycaemic improvement. We evaluated the association between a range of patient characteristics and early glycaemic change.
Materials and methods: We performed a retrospective cohort analysis using a primary care sentinel network in England (Royal College of General Practitioners Research and Surveillance Centre). We identified people with new onset (incident) T2D between 1st January 2006 and 31st July 2016 and both an HbA1c measurement at the time of diagnosis and one year after diagnosis. We performed a linear regression analysis to identify factors associated with the change in HbA1c value from diagnosis to one year. Factors included for analysis were; HbA1c at diagnosis, patient age, gender, ethnicity, socioeconomic status, smoking status, body mass index (BMI), comorbidities, and medication use within the first year. Socioeconomic status was measured using the official national measure; index of multiple deprivation (IMD). Associations are reported as beta coefficients (mmol/mol change in HbA1c per unit change in model factor) with associated 95% confidence intervals (CI) and p values.
Results: From 72,910 people with T2D we identified 13,873 people with incident T2D and HbA1c measurement at diagnosis and one year post diagnosis. The mean HbA1c was 62.4 (SD 23.3) mmol/mol at diagnosis, 51.9 (SD 13.5) mmol/mol at one year. The mean change in HbA1c was -12.9 (SD 22.3) mmol/mol. Greater reduction in HbA1c was seen in those with higher HbA1c at diagnosis (-0.84; 95% CI -0.80 to -0.88; p=0.000) and increasing age (-0.13; -0.02 to -0.23; p=0.020). Compared to those of White ethnicity people of Asian ethnicity had less reduction in HbA1c at one year (difference 5.59; 9.88 to 1.30; p=0.011). Gender, socioeconomic status, smoking status, BMI, and co-morbidities did not significantly affect the change in glycaemic control. Insulin use within the first year was associated with the greatest reduction in HbA1c (-4.97; -1.36 to -8.59; p=0.007). The model accounted for a moderate proportion of the variation seen in glycaemic change (multiple R-squared = 0.650).
Conclusion: A large variation in glycaemic improvement within the first year of diagnosis can be seen in practice. Those who are younger or of Asian ethnicity have a smaller reduction in HbA1c after adjusting for initial glycaemic control. Whilst we have not determined the reasons for these differences these data suggest these groups should be targeted for more intense monitoring and aggressive intervention. The most effective treatment for early glycaemic control was insulin.

The ratio of glycated albumin to HbA_{1c} as a haemoglobin glycation index with intra-familial correlations

S. Amemiya[1], M. Mochizuki[2], I. Musha[1], T. Kikuchi[1], H. Yokomichi[3], S. Sugihara[4], T. Hoshino[5], the Japanese Study Group of Insulin Therapy for Childhood and Adolescent Diabetes;
[1]Pediatrics, Saitama Medical University, Saitama, [2]Pediatrics, Yamanashi University, Kofu, [3]Health Science, Yamanashi University, Kofu, [4]Pediatrics, Tokyo Women's Medical University, Tokyo, [5]Institute of Biopathological Medicine, Kanagawa, Japan.

Background and aims: The mean value of glycated albumin (GA)/HbA_{1C} (A1C) ratio over time was reported to be individually consistent and highly inversely correlated with the glycation gap (g-g) as a hemoglobin glycation index (HGI) in pediatric type 1 diabetes patients (T1D). This study aimed to clarify that GA/A1C ratio was also a HGI in non-diabetic subjects and had intra-familial correlations.
Materials and methods: The subjects in this cohort from 2008 to 2012 were Japanese children and adolescents with TID (n=544) and their non-diabetic family (NDF) (n=433). Mean value of GA/A1C ratio using simultaneous measurement of GA and A1C more than five times was calculated in each diabetic patient and the value at enrollment was used in non-diabetic family. Since GA/A1C ratio showed different results due

to a constituent as each A1C using the National Glycohemogobin Standardization Program (NGSP) unit, the International Federation of Clinical Chemistry (IFCC) unit and the KO500 unit as the sustainable method in Japan Diabetes Society, the analyses using each A1C unit were as follows. Correlations between GA and A1C and between GA/A1C ratio and A1C itself were examined in T1D and NDF.

Results: NDF revealed a significant and negative correlation between GA/A1C ratio and A1C itself (r=-0.37, -0.63 or -0.57, using NGSP, IFCC and KO500 units, respectively, all $p<0.0001$), while the correlation between GA and each A1C unit was lower in NDF than in T1D. The mean (SD) of GA was 23.9 (4.05) % and 13.9(1.09) %, in T1D and NDF, where each A1C in T1D and NDF was 8.05(0.98) and 5.20(0.27) %, 6.46(1.07) and 3.35(0.25) mmol/mol and 5.36(0.84) and 2.94(0.20) %, in NGSP, IFCC and KO500 units, respectively. Thus each GA/A1C ratio in NDF exhibited a HGI within narrow glycemic ranges of one fourth in SD of GA and each A1C in T1D. The GA/A1C ratio was 2.96(0.25), 0.37(0.03) and 4.47(0.37) in T1D, and 2.67(0.22), 0.42(0.04)) and 4.76(0.45) in NDF, using A1C-NGSP, A1C-IFCC and A1C-KO500, respectively. Overlap rates of SD range of GA/A1C ratio in T1D by that in NDF were 40.6, 41.7 and 64.0%, using NGSP, IFCC and KO500 units respectively. The GA/A1C ratio in T1D was correlated with that in father (121 pairs, r=0.40, 0.45 and 0.48; all $p<0.0001$), mother (137 pairs, r=0.25, $p=0.0028$, r=0.32, $p=0.0001$ and 0.29, $p=0.0006$) or sibling (91 pairs, r=0.21, $p=0.0512$, r=0.32, $p=0.0022$ and r=0.29, $p=0.0046$), using NGSP, IFCC and KO500 units, respectively, indicating the intra-familial correlations.

Conclusion: We propose the GA/A1C ratio as a useful HGI both in T1D and non-diabetic subjects. The lower a GA/ A1C ratio, the higher a hemoglobin glycation (HGI) is. While the g-g may be used in a fixed population, the GA/A1C ratio will be applied to a modifier of glycemic target and a predictor of diabetic complications in addition with A1C and be comparable between on-going populations regarding diabetic types, races, non-diabetic family et.al. Although each A1C standardization can be useful in common practice, GA/A1C ratio using IFCC and KO500 units may be more accurate as a HGI than that using NGSP unit. The role of hereditary and biochemical factors on HGI remains to be elucidated.

PS 097 Biomarkers for cardiovascular mortality

1108

Symmetric and asymmetric dimethylarginine as risk markers of cardiovascular disease, mortality and deterioration in kidney function in patients with type 2 diabetes

T. Hansen[1], E. Zobel[1], B.J. von Scholten[1], H. Reinhard[1], F. Persson[1], T. Teerlink[2], H.-H. Parving[3], P.K. Jacobsen[4], P. Rossing[1,3];
[1]Steno Diabetes Center Copenhagen, Gentofte, Denmark, [2]Department of Clinical Chemistry, Amsterdam, Netherlands, [3]University of Copenhagen, Copenhagen, [4]Department of clinical medicine, University of Copenhagen, Copenhagen, Denmark.

Background and aims: To evaluate symmetric dimethylarginine (SDMA) and asymmetric dimethylarginine (ADMA) as risk markers of cardiovascular disease, all-cause mortality and deterioration in renal function in a well characterised type 2 diabetic population with microalbuminuria and without symptoms of coronary artery disease.

Materials and methods: 200 participants followed for 6.1 years. SDMA and ADMA were measured at baseline. Endpoints included 1) composite cardiovascular endpoint (n=40); 2) all-cause mortality (n=26); and 3) decline in eGFR of >30% (n=42). Cox models were unadjusted and adjusted for traditional risk factors (sex, age, systolic blood pressure, LDL-cholesterol, smoking, HbA_{1c}, creatinine and urinary albumin excretion rate). To assess if SDMA or ADMA improved risk prediction beyond traditional risk factors we calculated c-statistics and relative integrated discrimination improvement (rIDI).

Results: Higher SDMA was associated with increased risk of all three endpoints (unadjusted: $p\leq0.001$; adjusted: $p\leq0.02$). Higher ADMA was associated with all-cause mortality (unadjusted: p=0.002; adjusted: p=0.006), but not cardiovascular disease or decline in eGFR ($p\geq0.29$).The c-statistics was not significant for any of the endpoints for either SDMA or ADMA ($p\geq0.10$). The rIDI for SDMA was 15.0% (p=0.081) for the cardiovascular endpoint, 52.5% (p=0.025) for all-cause mortality and 48.8% (p=0.007) for decline in eGFR; for ADMA the rIDI was 49.1% (p=0.017) for all-cause mortality.

Conclusion: In persons with type 2 diabetes and microalbuminuria higher SDMA was associated with incident cardiovascular disease, all-cause mortality and deterioration in renal function. Higher ADMA was associated with all-cause mortality. SDMA and ADMA significantly improved risk prediction for all-cause mortality, and SDMA for deterioration in renal function beyond traditional risk factors.

Serum uromodulin predicts mortality independently from the presence of type 2 diabetes

J. Ebner[1], A. Leiherer[1], A. Muendlein[1], C.H. Saely[2], E.-M. Brandtner[1], A. Schuler[2], A. Mader[3], P. Schwerzler[3], P. Fraunberger[4], H. Drexel[5];
[1]Vorarlberg Institute for Vascular Investigation and Treatment, [2]Academic Teaching Hospital Feldkirch, Feldkirch, Austria, [3]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [4]Medical Central Laboratory, Feldkirch, Austria, [5]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: Uromodulin is produced exclusively by the kidneys and present in urine and blood. Low serum uromodulin has recently been demonstrated to be associated with chronic kidney disease and type 2 diabetes (T2DM). Whether serum uromodulin also predicts mortality is unknown and is addressed in the present study.

Materials and methods: We measured uromodulin in a series of 529 patients who underwent coronary angiography for the evaluation of

established or suspected stable CAD and prospectively recorded mortality during a follow-up of up to 8 years.

Results: Uromodulin significantly correlated with eGFR (r=0.242, p<0.001) and, inversely, with age (r=-0.208, p<0.001), fasting glucose (r=-0.161, p<0.001), C-reactive protein (CRP; r=-0.133, p=0.002) and proBNP (r=-0.164, p=0.002); it was significantly lower in patients with T2DM than in nondiabetic subjects (148±70 vs. 171±79; p =0.001). Prospectively, we recorded 95 deaths; mortality was significantly higher in patients with T2DM than in those who did not have diabetes (28.2 vs. 14.6 %; p <0.001). Serum uromodulin proved protective for overall mortality in univariate analysis (HR=0.56 [95%CI 0.43-0.72]; p<0.001), and also after multivariate adjustment for standard risk factors including diabetes, eGFR, proBNP and presence of CAD as well (adj. HR=0.57 [95%CI 0.37-0.89]; p=0.014).

Conclusion: We conclude that serum uromodulin predicts mortality independently from kidney function and the presence of T2DM.

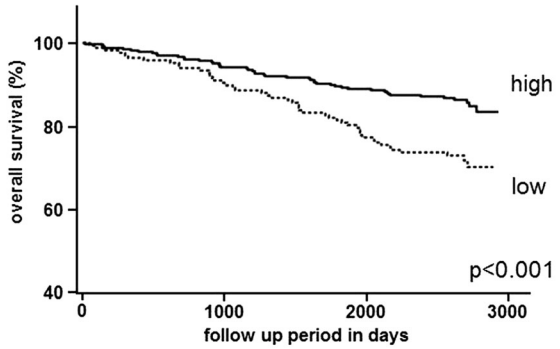

Figure 1: Survival with respect to uromodulin concentration.
The Kaplan Meier plot indicates the overall survival in the total study population of patients with low and high uromodulin concentration according to the low tertile cut-off (125.3 ng/ml). The low uromodulin group is represented by a dashed and the group with respectively higher uromodulin concentrations by a solid line. The log Rank p-values were <0.001.

Levels of soluble ST2 are associated to diabetes and cardiovascular mortality in patients from Tor Vergata Atherosclerosis Registry

M. Cardellini[1], M. Ballanti[1], I. Cardolini[1], F. Davato[1], R. Menghini[1], V. Casagrande[1], S. Rizza[1], A. Ippoliti[2], M. Federici[1];
[1]Department of Systems Medicine, University of Rome, [2]Department of Experimental Medicine and Surgery, University of Rome, Rome, Italy.

Background and aims: To identify novel biomarkers for cardiovascular diseases we studied a cohort of 399 patients with a chronic atherosclerotic disease and different degree of impaired glucose metabolism.

Materials and methods: 399 patients with atherosclerotic disease were enrolled in the Tor Vergata Atherosclerosis Registry (TVAR) from 2007 to 2014. All the patients had a major CV event or underwent a vascular procedure for significant vascular stenosis. We evaluated lipid profile, liver and kidney function, markers of inflammation and performed an Oral Glucose Tolerance Test in those patients with a negative history of type 2 diabetes (n=325). The follow up was performed every year by phone interview. The primary endpoint was major cardiovascular events (cardiovascular death, nonfatal stroke, nonfatal myocardial infarction, and peripheral vascular surgical procedures) and the secondary endpoint was death for any other disease.

Results: We divided the 399 patients in four groups depending on the glucose tolerance status**.** 118 were normal glucose tolerant (NGT), 138 were impaired glucose tolerant (IGT), 69 had a new diagnosis of type 2 diabetes (nT2D) and 74 were diabetic at enrollment (oT2D). The four groups did not differ for age, sex or BMI. Among the several metabolic and inflammatory variables, we interestingly found that the levels of soluble ST2 (sST2), the receptor for the inflammatory cytokine IL33, were significantly increased from NGT to oT2D (NGT 14420.3±8747.9 vs IGT 14303.1±6838.3 vs nT2D 15260.3±6639.0 vs oT2D 19707.9 ±8378.2, ANOVA p>0.00001). Circulating sST2 levels increased with age (R=0.229, p=0.00001) and reduced kidney function (GFR, R=-0.204, p=0.00001). We also found that levels of sST2 were significantly correlated with fasting plasma glucose (R=0.164, p=0.002), Hba1c (R=0.167, p=0.002), and HOMA index (R=0.159, p=0.004) after adjusting for age, sex and GFR. We didn't find any significant correlation between sST2 and lipid profile, inflammatory biomarkers or insulin secretion. We performed a follow up for all-cause and cardiovascular mortality for a mean of 61,08±34,80 months on 371 patients. During follow-up 66 deaths (20,7%) occurred, 27 of which were due to cardiovascular causes (8,5%). We divided the 371 patient in tertiles of sST2 levels and found that patients within the highest tertile of sT2 showed an increased rate of all-cause and cardiovascular mortality, as shown in figure 1 (all-cause mortality, log rank test, p<0.007 and CVD mortality log rank test, p=0.05).

Conclusion: Some previous evidences showed that the sST2/IL-33 pathway might be relevant for vascular disease and diabetes in animal models but its role in human is still under debate. In our cohort with chronic atherosclerosis and different degrees of detective glucose metabolism we found that sST2 is associated with diabetes and increased all-cause and cardiovascular mortality. Further mechanistic studies determining how sST2 is linked to atherosclerosis and diabetes pathways may clarify its role in cardiovascular diseases.

Higher plasma methylglyoxal levels are associated with incident cardiovascular disease in individuals with type 1 diabetes: a 12-year follow-up study

N.M.J. Hanssen[1,2], J.L.J. Scheijen[1,2], A. Jorsal[3], H.-H. Parving[4], L. Tarnow[3], P. Rossing[3], C.D.A. Stehouwer[1,2], C.G. Schalkwijk[1,2];
[1]Internal medicine, Maastricht University, [2]CARIM, School for Cardiovascular Diseases, Maastricht, Netherlands, [3]Steno Diabetes Center Copenhagen, [4]University of Copenhagen, Copenhagen, Denmark.

Background and aims: Methylglyoxal (MGO), a major precursor for advanced glycation endproducts (AGEs), is increased in diabetes. In diabetic rodents, inhibition of MGO prevents cardiovascular disease (CVD). Whether plasma MGO levels are associated with incident CVD in people with type 1 diabetes is unknown.

Materials and methods: We included 159 individuals with persistent normoalbuminuria and 162 individuals with diabetic nephropathy (DN) from the outpatient clinic at a diabetes center. We measured MGO at baseline with tandem mass spectrometry. We recorded fatal and non-fatal CVD over a median follow-up of 12.3 years (interquartile range 7.6-12.5). Data were analyzed with Cox regression, with adjustment for sex, age, HbA1c, DN, diabetes duration, smoking, systolic blood pressure, anti-hypertensive medication and BMI.

Results: During follow-up, 73 individuals suffered at least one CVD event (36 fatal and 53 non-fatal events). Higher MGO levels were associated with total- (HR: 1.47; 95%CI: 1.13-1.91), fatal- (HR: 1.42; 95%CI: 1.01-1.99) and nonfatal incident CVD (HR: 1.46; 95%CI: 1.08-1.98). A similar trend was observed for total mortality (HR: 1.24; 95%CI: 0.99-1.56).

Conclusion: This study shows, for the first time, that plasma MGO levels are associated with cardiovascular events in individuals with type 1 diabetes. MGO may thus explain the increased risk, at least in part, for CVD in type 1 diabetes.

Association of dehydroepiandrosterone with severity of type 2 diabetes: the Rotterdam study

N. Kastrati, M. Glisic, E. Asllanaj, S. Sedaghat, A. Ikram, J.S.E. Laven, O.H. Franco, T. Muka;
Erasmus Medical Center, Rotterdam, Netherlands.

Background and aims: Emerging evidence shows that high levels of dehydroepiandrosterone (DHEA) are associated with reduced risk of type 2 diabetes (T2D). It is not known whether DHEA is associated with diabetes severity. We examined whether higher levels of DHEA were associated with less complications of T2D, later initiation of insulin therapy and reduced risk of mortality.
Materials and methods: We included 1130 men and women with T2D from the Rotterdam Study, a prospective follow-up study. DHEA levels were measured at baseline. Complications of T2D included chronic kidney disease (CKD), hypertension (HTN), and stroke. Prevalent CKD was defined as estimated glomerular filtration rate <60 ml/min/1.73 m^2. Prevalent HTN was defined as systolic blood pressure ≥140 mmHg or diastolic blood pressure ≥90 mmHg or use of blood pressure lowering medication. Incident stroke events and insulin therapy initiation were obtained on the basis of medical records. Mortality data were obtained by notification from the municipal administration. Logistic regression (for CKD, HTA and insulin therapy initiation) and Cox proportional hazards models (for stroke and mortality) with adjustment for relevant confounders were used to calculate odds ratios (ORs) and hazard ratios (HRs), and their 95% confidence intervals (CIs).
Results: Higher levels of DHEA were associated with lower odds of having CKD (OR=0.66, 95%CI: 0.47-0.92) and HTA (OR=0.66, 95%CI: 0.49-0.90). During 19 years of follow-up, we identified 164 incident cases of insulin initiation, 110 cases of stroke and 540 deaths. Higher levels of DHEA were associated with later initiation of insulin therapy (OR=0.61, 95%CI: 0.41-0.93) and reduced risk of all-cause mortality (HR=0.81, 95%CI: 0.69-0.95), whereas no association was found between DHEA levels and risk of stroke (HR=0.83, 95%CI: 0.58-1.18). Further adjustment for glucose, insulin and downstream hormone levels such as total estradiol and testosterone did not affected any of these associations.
Conclusion: These findings suggest that high levels of DHEA are associated with fewer complications in diabetics. It is at present unclear whether medications or lifestyle factors that alter DHEA metabolism can be effectively used in prevention of diabetes complications.

Table 1 The association between dehydroepiandrosterone levels, diabetes complications, initiation of insulin therapy and risk of mortality*.

	Model 1 Relative risk(95%CI)*#[1]	Model 2 Relative risk(95%CI)*#[2]	Model 3 Relative risk(95%CI)*#[3]

GDF-15 and FGF-23 are associated with mortality in type 2 diabetic patients with microalbuminuria

M. Frimodt-Møller[1], B. von Scholten[1], H. Reinhard[1], T.W. Hansen[1], F. Persson[1], H.-H. Parving[2,3], P. Rossing[4,3];
[1]Steno Diabetes Center Copenhagen, [2]Rigshospitalet, Copenhagen, [3]University of Copenhagen, [4]Steno Diabetes Center Copenhagen, Copenhagen, Denmark.

Background and aims: We evaluated two biomarkers (growth differentiation factor 15 (GDF-15) and (FGF-23) reflecting different aspects of renal pathophysiology as determinants of decline in estimated glomerular filtration rate (eGFR), incident cardiovascular disease (CVD) and all-cause mortality in patients with type 2 diabetes (T2D) and microalbuminuria, but without clinical coronary artery disease.
Materials and methods: Prospective study including 200 patients. GDF-15 and FGF-23 were measured at baseline and were available in 191 patients. Adjusted Cox models included sex, age, LDL cholesterol, smoking, HbA_{1c}, creatinine, systolic blood pressure and urine albumin excretion rate (UAER). A decline in eGFR of >30%, which has recently been suggested as a valid renal outcome, at any time point during follow-up was the predefined endpoint of CKD progression. Hazard ratios (HR) are provided per 1 SD increment of log-transformed values of the urinary biomarkers.
Results: Patients were (± SD) 59 ± 9 years old, eGFR 91.1 ± 18.3 ml/min/1.73m^2 and UAER (IQR) 103 (39-230) mg/24-h. During a median 6.1 years follow-up, there were 40 incident CVD events and 26 deaths and a total of 42 patients reached the predefined CKD progression endpoint after 4.9 years (median). Higher GDF-15 was a determinant of decline in eGFR >30% in unadjusted (HR (95% CI) 1.7 (1.3-2.4); p=0.001) and adjusted (HR 1.7 (1.1-2.5); p=0.018) models, a predictor of CVD in the unadjusted model (HR 1.4 (1.0-1.9); p=0.034) but not in the adjusted model (HR 1.3 (0.9-1.8); p=0.25) and of all-cause mortality in unadjusted (HR 1.8 (1.3-2.6); p<0.001) and adjusted (HR 1.9 (1.2-2.9); p=0.003) models. Higher FGF-23 was not associated with decline in eGFR >30% or CVD, but was associated with all-cause mortality in unadjusted (HR 1.5 (1.1-2.0); p=0.010) and adjusted (HR 1.6 (1.1-2.2); p=0.011) models.
Conclusion: In patients with T2D and microalbuminuria, GDF-15 was independently associated with decline in kidney function and all-cause mortality, and higher FGF-23 was associated with all-cause mortality.
Disclosure: **M. Frimodt-Møller:** None.

Plasma matrix metalloproteinases are associated with incident cardiovascular disease and all-cause mortality in patients with type 1 diabetes: a 12-year follow-up study

S.A. Peeters[1], L. Engelen[2], J. Buijs[3], A. Jorsal[4], H.-H. Parving[5], L. Tarnow[6], P. Rossing[6], C. Schalkwijk[1], C.D.A. Stehouwer[1];
[1]Internal Medicine, Maastricht University Medical Centre, Maastricht, [2]Centraal Bureau voor de Statistiek, Heerlen, [3]Internal Medicine, Zuyderland, Heerlen, Netherlands, [4]Aarhus University Hospital, Aarhus, [5]Department of Medical Endocrinology, Rigshospitalet, Copenhagen, [6]Steno Diabetes Center, Gentofte, Denmark.

Background and aims: The pathophysiological mechanisms leading to cardiovascular disease (CVD) in type 1 diabetes have only been partly elucidated. Altered regulation of extracellular matrix remodeling by matrix metalloproteinases (MMPs) and tissue inhibitor of metalloproteinase (TIMP) may contribute to vascular complications in type 1 diabetes. Therefore, we investigated associations between plasma MMP-1, -2, -3, -9, -10 and TIMP-1, and cardiovascular events and all-cause mortality in type 1 diabetic patients.
Materials and methods: We prospectively followed 337 type 1 diabetic patients (mean age 41.4 years (9.6), 39% female), 170 with and 167 without diabetic nephropathy, with median follow-up of 12.3 years.

Survival analyses were applied to investigate differences in plasma MMP-1, -2, -3, -9, -10, and TIMP-1-levels in patients with and without a cardiovascular event and in those who died vs survivors. All analyses were adjusted for age, sex, duration of diabetes, HbA1c, nephropathy and for other conventional cardiovascular risk factors. In addition, we investigated the extent to which low-grade inflammation (LGI), endothelial dysfunction (ED) and renal dysfunction (eGFR and albuminuria) contributed to these associations.

Results: After adjustment for potential confounders, higher MMP-2 plasma levels were significantly associated with higher incidence of cardiovascular events [HR 1.49 (95%CI 1.11;1.99)], and higher plasma levels of MMP-1 [1.38 (1.07;1.78)], MMP-2 [1.60 (1.19;2.15)] and MMP-3 [1.39 (1.05;1.85)] were associated with all-cause mortality. All associations were independent of LGI and ED as estimated by plasma markers. Associations between MMP-2 and cardiovascular events and between MMP-3 and mortality were attenuated after further adjustment for eGFR and changes in eGFR.

Conclusion: In patients with type 1 diabetes followed for a median of 12.3 years, higher plasma MMP-2 levels are associated with incident CVD and higher plasma MMP-1, MMP-2, MMP-3 are associated with all-cause mortality. These associations are independent of cardiovascular risk factors, LGI and ED. However, baseline eGFR and decline in eGFR during follow-up attenuated the association between MMP-2 and CVD as well as the association between MMP-3 and all-cause mortality; eGFR may thus, in part, mediate these associations.

Visceral adipose tissue volume is associated with ^{18}F-FDG-PET assessed arterial inflammation in male patients with early type 2 diabetes

M.R. Reijrink[1], S.A. De Boer[1], D.S. Spoor[2], J.D. Lefrandt[1], H.J. Lambers Heerspink[3], R. Boellaard[2], M.J.W. Greuter[4], R.H.J. Slart[2], D.J. Mulder[1];
[1]Vascular Medicine, University of Groningen, University Medical Center Groningen, [2]Nuclear Medicine and Molecular Imaging, University of Groningen, University Medical Center Groningen, [3]Clinical Pharmacy and Pharmacology, University of Groningen, University Medical Center Groningen, [4]Radiology, University of Groningen, University Medical Center Groningen, Groningen, Netherlands.

Background and aims: Already early in the course of their disease, patients with type 2 diabetes (T2D) have a considerably increased cardiovascular risk, irrespective of glycemic control. Visceral adipose tissue (VAT) is thought to play an important role, by inducing insulin resistance (IR) and non-alcoholic fatty liver disease (NAFLD) and by being metabolically active and producing adipocytokines. Its contribution to early atherosclerosis development is not fully understood. We investigated the association between VAT volume and subclinical arterial inflammation in early T2D patients by using ^{18}F-fluordeoxyglucose (FDG) positron emission tomography (PET) with low dose computed tomography (CT) and performed a pilot to explore the value of FDG-uptake in VAT as a proxy for its metabolic activity.

Materials and methods: In 44 patients with T2D (age 63 [54-66] years, BMI 30.4 [28-36], HbA1c (%) [6.3±0.4]), without cardiovascular disease or glucose lowering medication an FDG-PET was performed. VAT and subcutaneous adipose tissue (SAT) volumes (cm^3) were quantified at L1-L5 with a semi-automatic method based on CT. Arterial inflammation was quantified by glucose corrected target-to-background ratio ($_{mean}$TBR) of FDG standardized uptake value $(SUV)_{max}$ of the aorta, carotid, iliac, and femoral arteries versus blood pool activity. HOMA-IR (index of IR), ALT (proxy of NAFLD), and adiponectin were measured in plasma. Finally, FDG-uptake in VAT was measured (VAT-SUV_{mean}).

Results: Fat distribution (VAT/SAT ratio) differed between males (n=27; [1.2 (0.94-1.7)]) and females (n=17; 0.6 [0.4-0.7] (p<0.0001)). VAT volume correlated with HOMA-IR (β=0.37, p=0.015), ALT (β=0.57, p<0.001), and adiponectin (β=-0.39, p=0.008). Since VAT volume and gender interacted in relation to $_{mean}$TBR (p=0.003), men and women were investigated separately. VAT volume, but not SAT volume correlated with $_{mean}$TBR in males (β=0.652 (p<0.001)) but not in females (β=-0.059 (p=0.821)). This association was independent of HOMA-IR, ALT, and adiponectin. Unexpectedly, VAT-SUV_{mean} correlated negatively with VAT volume in both sexes (males: β=-0.509, p=0.007, females: β=-0.598, p=0.011).

Conclusion: VAT volume is associated with FDG-PET assessed arterial inflammation in early T2D males, independent of markers for IR and NAFLD, and adiponectin. These findings underscore the role of VAT, in contrast to SAT, in early atherosclerosis development in T2D. The FDG uptake in VAT needs further study and validation.

Combined effect of high sensitive C-reactive protein and serum amyloid component P on mortality rate in patients with type 2 diabetes

C. Menzaghi[1], M.G. Scarale[2], L. Salvemini[1], M. Copetti[2], V. Trischitta[1];
[1]Research Unit of Diabetes and Endocrine Diseases, IRCCS, [2]Biostatistics Unit, IRCCS, San Giovanni Rotondo, Italy.

Background and aims: Though the role of some inflammatory acute phase proteins (APPs) on cardiovascular (CV) mortality in type 2 diabetes (T2D) is known, that of all APPs as considered as a whole has never been addressed. We aimed at investigating the combined effect of of high sensitive C-reactive protein (hs-CRP), fibrinogen, serum amyloid component P (SAP), haptoglobin and alfa-2 macroglobulin, on both all-cause and CV mortality rate.

Materials and methods: All five APPs were assayed using multiplex detection 5-plex kit from Bio-Rad (Hercules, CA) in 334 patients with T2D from the Gargano Heart Study-prospective design (follow-up=5.4 ±2.5 yrs; 73 all-cause and 51 CV-mortality events).

Results: In a model comprising all 5 log-transformed and standardized APPs, only hs-CRP and SAP, were associated with all-cause (HRs; 95%Cs=1.9; 1.5-2.5 and 0.8; 0.6-0.9, respectively) as well as CV (HRs; 95%CIs=1.4; 1.2-1.8 and 0.3; 0.1-0.7, respectively) mortality. Patients were then stratified according to relatively low and high hs-CRP and SAP levels (< or > the median value: 1.4 mg/l and 36.2 μg/ml, respectively), so to obtain four groups: low/high (1; i.e. presumably the most protected individuals), low/low (2), high/high (3), and high/low (4; i.e. presumably the most at risk individuals) hs-CRP/SAP levels. As compared to group 1, group 2, 3 and 4 had HRs; (95%CIs) of 2.6 (0.8-8.9), 4.8 (1.5-15.7) and 10.0 (3.0-33.4), for all-cause and 2.7 (0.6-11.9), 4.5 (1.0-19.2) and 12.2; (2.8-52.9), for CV mortality, respectively. Similar results

were observed after adjusting for age, sex, smoking habit, BMI, HbA1c, diabetes duration and all ongoing treatments.

Conclusion: In conclusion, in patients with T2D: i) hs-CRP and SAP show an independent effect on both all-cause and CV mortality; ii) when the two markers are combined together, a greatly increased predicting ability on both outcomes is observed. This suggests that the simultaneous use of hs-CRP and SAP may prove to be very much effective for clinical use in predicting mortality rate in T2D. Further studies in larger diabetic prospective cohorts, are needed to both confirm our finding and better address the intrinsic nature of the interwoven effect between hs-CRP and SAP.

High sensitivity C-reactive protein, LDL cholesterol and cardiovascular outcomes in patients with type 2 diabetes and acute coronary syndrome from EXAMINE

Y.-C. Hwang[1], D. Morrow[2], C. Cannon[3], Y. Liu[3], R. Bergenstal[4], S. Heller[5], C. Mehta[6], W. Cushman[7], G. Bakris[8], F. Zannad[9], W. White[10]; [1]Kyung Hee University Hospital at Gangdong, Seoul, Republic of Korea, [2]TIMI Study Group, Cardiovascular Division, Brigham and Women's Hospital, Boston, [3]Baim Cardiovascular Institute, Boston, [4]International Diabetes Center, Park-Nicollet Clinic, Minneapolis, USA, [5]University of Sheffield, Sheffield, UK, [6]Harvard School of Public Health, Boston, [7]University of Tennessee College of Medicine, Memphis, [8]University of Chicago Med, Chicago, USA, [9]Universite de Lorraine, Nancy, France, [10]University of Connecticut School of Medicine, Farmington, USA.

Background and aims: High-sensitivity C-reactive protein (hsCRP) level is known to be an independent predictor for future development of cardiovascular disease. The aim of this study was to assess the risk of major adverse cardiovascular events (MACE) of cardiovascular death, nonfatal myocardial infarction (MI) and stroke according to baseline hsCRP level in patients with type 2 diabetes and recent cardiovascular events enrolled in the EXAMINE trial.

Materials and methods: Study participants were stratified by baseline hsCRP values using established decision-limits (<1, 1-3, and >3 mg/l) for prediction of CV outcomes. Study participants were also divided into 4 groups according to both baseline hsCRP (≤3 mg/l, >3 mg/l) and achieved LDL cholesterol <70 mg/dl or ≥70 mg/dl. Multivariate Cox proportional hazards models were used to analyze the independent association between baseline hsCRP level and MACE as well as urgent revascularization due to unstable angina, hospitalization for heart failure, and death from any cause.

Results: At baseline, patients with higher hsCRP were more likely to have higher blood pressure, fasting glucose, glycated hemoglobin levels, and LDL cholesterol levels. During 30 months of follow-up, cumulative rates of MACE were 11.5% (119 events), 14.6% (209 events), and 18.4% (287 events) in patients with baseline hsCRP <1 mg/l, 1-3 mg/l, and >3 mg/l, respectively (P<0.001). Patients with baseline hsCRP >3 mg/l showed independent associations with future MACE, nonfatal MI, hospitalization for heart failure, and death from any cause compared to patients with baseline hsCRP <1 mg/l (Table). Additionally, the rates of MACE were 11.0% (128 events), 14.4% (100 events), 15.6% (194 events), and 21.3% (182 events) in patients with both low LDL cholesterol and hsCRP, low LDL cholesterol and high hsCRP, high LDL cholesterol and low hsCRP, and both high LDL cholesterol and hsCRP, respectively (P<0.001).

Conclusion: Levels of hsCRP were associated with secondary cardiovascular events in patients with type 2 diabetes and recent acute coronary syndrome and this association appears to be independent of and additive to the achieved LDL cholesterol.

Table. Hazard ratios* (95% confidence interval) for cardiovascular outcomes according to baseline hsCRP concentration in EXAMINE

Carotid preclinical atherosclerosis in Mediterranean individuals with type 1 diabetes: prevalence and association with the Steno T1 Risk Engine

A.J. Amor[1,2], E. Ortega[1,2], V. Perea[3], M. Giménez[1,4], I. Vinagre[1], E. Esmatjes[1,4], I. Conget[1,4];
[1]Endocrinology and Nutrition Department, Hospital Clínic de Barcelona, Barcelona, [2]CIBER de Fisiopatología de la Obesidad y Nutrición (CIBEROBN), Instituto de Salud Carlos III (ISCIII), Madrid, [3]Endocrinology and Nutrition Department, Hospital Universitari Mútua de Terrassa, Barcelona, [4]CIBER de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Instituto de Salud Carlos III (ISCIII), Madrid, Spain.

Background and aims: Specific cardiovascular risk (CVR) scores could help tailor cardioprotective treatment to patients with type 1 diabetes (T1D), and, also, to decrease their main cause of mortality: cardiovascular disease (CVD). We aimed to assess the relationship between CVR score "Steno T1 Risk Engine (Steno-Risk)" and preclinical carotid atherosclerosis in our Mediterranean T1D patients.
Materials and methods: T1D patients without CVD from a tertiary hospital were selected. Inclusion criteria were as follows: ≥40 years, diabetic nephropathy, or diabetes duration ≥10 years with at least one additional CVR factor. Intima-media thickness (IMT) and plaque presence (IMT ≥1.5 mm) were assessed by B-mode ultrasonography at the common carotid (CC), bulb, and internal carotid (IC). Abnormal IMT-CC was defined as IMT above age-and-sex specific 75th percentile. The Steno-Risk was used to estimate 10-years CVR (<10% low; 10-20% moderate; ≥20% high risk). This score includes: age, gender, diabetes duration, HbA1c, systolic blood pressure, LDLc, albuminuria, glomerular filtration rate, smoking habit and regular exercise (≥3.5 h/week).
Results: We included 90 patients (37% men, age 48.7±9.3 years, duration of diabetes 24.9±6.3 years). Prevalence of abnormal IMT-CC and carotid plaque were 54% and 42%, respectively, with no sex differences. The Steno-Risk was directly associated with mean IMT-CC (r=0.357; p=0.001) and mean IMT-Bulb (r=0.228; p=0.033). Patients' characteristics according to CVR are shown in the table. There was a higher prevalence of microvascular complications in individuals with high vs. low risk: nephropathy, 29 vs. 0%; retinopathy, 46 vs. 7%, respectively (both p<0.05). Abnormal IMT-CC (26.7, 56.9, 66.7%; p=0.022) and carotid plaque presence (26.7, 39.2 and 58.3%; p=0.043) increased with increasing risk (for low, moderate and high risk, respectively). IC plaque presence (6.7, 25.5 and 37.5%) and presence of ≥3 plaques (6.7, 7.8 and 20.8%, for low, moderate and high risk, respectively) were also positively associated with Steno-Risk (both p<0.05).
Conclusion: We found a high prevalence of preclinical atherosclerosis in our primary prevention sample of Mediterranean T1D patients with no sex differences. The Steno-Risk score was significantly associated with preclinical carotid atherosclerosis. Optimization of cardiovascular prevention management in T1D warrants additional studies including the use of specific scales of CVR, early detection strategies of preclinical atherosclerosis and cardiovascular clinical outcomes.

Type 2 diabetes, chronic kidney disease, and mortality in patients with established cardiovascular disease

C.H. Saely[1], A. Vonbank[1], C. Lins[2], D. Zanolin[2], A. Leiherer[2], A. Schuler[1], P. Rein[1], A. Muendlein[2], A. Mader[3], P. Schwerzler[3], H. Drexel[4];
[1]Academic Teaching Hospital Feldkirch, [2]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, Austria, [3]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [4]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: Both type 2 diabetes (T2DM) and chronic kidney disease (CKD) are associated with a high risk of cardiovascular disease (CVD) and premature death. We aimed at investigating the single and joint effects of T2DM and of CKD on all-cause mortality in high-risk patients with established CVD.
Materials and methods: We prospectively investigated 2108 patients with established CVD (1789 with angiographically proven coronary artery disease and 319 with sonographically proven peripheral artery disease) over 7.0±2.7 years.
Results: Deaths occurred more frequently in T2DM patients (n=652) than in non-diabetic subjects (38.2% vs. 19.6%; p <0.001) and in patients with CKD (eGFR <60ml/min/1.73m²; n=357) than in those with an eGFR ≥60ml/min/1.73m² (48.8% vs. 19.8%; p <0.001). When both, T2DM and CKD were considered, 1248 subjects had neither T2DM nor CKD, 503 had T2DM but not CKD, 208 did not have diabetes but had CKD, and 149 had both diabetes and CKD. When compared with mortality among patients with neither T2DM nor CKD (16.1%), mortality was significantly higher in patients with T2DM who did not have CKD (30.5%; p<0.001) as well as in non-diabetic patients with CKD (40.1%; p<0.001) and was highest in patients with both, T2DM and CKD (62.4%; p<0.001), in whom mortality was higher than in those with T2DM but no CKD (p<0.001) or those without T2DM but with CKD (p=0.045); mortality was higher in non-diabetic CKD patients than in diabetic patients who did not have CKD (p=0.013).
Conclusion: We conclude that CKD in patients with established CVD confers an even higher mortality risk than T2DM. Mortality is extremely high in CVD patients with the combination of CKD and Diabetes.

The gut microbiom and cardiovascular complications in patients with type 2 diabetes

E. Siegel[1], I. Platten[2], M. Kraft[2], J. Lorenzo-Bermejo[3], C. Hasslacher[2];
[1]Gastroenterologie und Diabetologie, St. Josefskrankenhaus Heidelberg, [2]Clinical Study Departement, St. Josefskrankenhaus Heidelberg, [3]Institute of Medical Biometry and Informatics, Heidelberg University Hospital, Heidelberg, Germany.

Background and aims: The composition of the gut microbiom seems to reflect not only the development of bowel disease but also the course of systemic diseases like obesity and diabetes. We investigated the relationship between the composition of the gut microbiom and the prevalence of cardiovascular complications (CVC) in patients with type 2 diabetes.
Materials and methods: Demographic characteristics, routine lab results, prevalence of CVC and composition of the gut microbiom assessed by 16S rRNA sequencing of fecal samples were collected from 60 patients with type-2-diabetes. After exclusion of bacterial types with a low abundance (median proportion of 0%), the relationship between bacterial type abundance and CVC rate was investigated by logistic regression.
Results: 28 patients presented with CVC (coronary heart disease 57 %, stroke 14 %, peripheral artery occlusive disease 29 %). Differences regarding demographic factors and lab results between patients with and without CVC were only observed for gender (females with CVC: 25%, without CVC: 59 %). Microbiota differences at phylum and class-level did not reach 5% statistical significance. At order-level the average proportion of Coriobacteriales was higher for patients with versus without CVC (0.29% vs 0.13%; p= 0.002). The odds ratio of CVC for patients in the highest quartile of Coriobacteriales abundance (>0.30%) was 9.6 (95%CI 1.86 to 49.5) compared to patients in the lowest quartile (abundance < 0.08%). Logistic regression analysis revealed a 200-fold increased risk of CVC for every 0.01% increase in Coriobacteriales abundance (p=0.01). This association was also present in lower classification levels (species Collinsella aerofaciens). Compared with patients without CVC, patients with CVC showed a 25% lower abundance of butyrate producing bacteria (1.35 ± 1.40% vs 1.69 ± 1.60%; p=0.34) and a 51% higher abundance of TMAO producing bacteria (0.59 ± 0.42% vs 0.39 ± 0.28%; p=0.03).
Conclusion: Coriobacteriales spp. abundance was associated for the first time with the risk for CVC in type 2 diabetes patients. Furthermore, patients with CVC showed a higher amount of TMAO producing bacteria than patients without CVC.

Administration of VCP, a new p38 MAPK inhibitor, promoted recovery in diabetic stroke

Y. Cai, S. Ju;
Jiangsu Key Laboratory of Molecular Imaging and Functional Imaging, Southeast University, Nanjing, China.

Background and aims: Type 2 Diabetes is associated with a doubling risk for ischemic stroke and have less favorable clinical outcomes. Several studies in animal models had shown that the activation of p38 MAPK increased in ischemic brain tissue.On the other hand, MAPK pathways are upregulated with insulin resistance and hyperglycemia induced MAPK phosphorylation. P38 MAPKs is linked to increased production of inflammatory mediators such as proinflammatory cytokines and matrix metalloproteinases. Activation of P38 MAPKs in T2DM will worsen the brain damage after stroke . In this study, we administrated diabetic stroke mice with a new p38 MAPK inhibitor-VCP, which is a highly selective inhibitor of the p38-α and p38-βMAPK isoforms and is more potent in vitro than standard p38 kinase inhibitor RWJ67657.
Materials and methods: All animal experiments were approved by the Institutional Animal Care Committee of Medical School of Southeast University. T2 diabetes mellitus was induced in C57BL/6(8-week-old) mice by administration of high-fat diet in combination with intraperitoneal injection of streptozotocin. Wild-type and diabetes mice were induced in ischemic stroke through a photochemical reaction. The animals were scanned on day 14 post ischemia using diffusion tensor imaging (DTI).
Results: The infarct volumes are shown as hyperintensity on T2-weighted images. Diabetic stroke mice treated with VCP presented smaller infarct volume compared with other groups on day 14 (wildtype group: 6.65%±1.33%,diabetes saline group: 20.2%±6.6%,diabetes VCP group: 14.4%±2.3%, $p<0.05$). In addition, diabetic stroke mice treated with VCP showed significant reductions in neurological functional deficits compared with control mice according to the modified neurological severity score (wildtype group:2.75±0.43; diabetes saline group: 4.33 ±0.47, diabetes VCP group:1.33±0.47, $p<0.05$). In vivo DTI analysis revealed that VCP treatment significantly increased fractional anisotropy (FA) in the lesion of infarction on day 14 compared with the other groups. The fiber counts in the lesion of the mice treated with VCP were significantly increased (Figure.1).Immunofluorescent staining showed that the expression of MMP-9 were down regulated in group treated by VCP.
Conclusion: Administration of VCP,a new p38MAPK inhibitor, in T2DM mice significantly improves recovery from diabetic stroke, which might have been caused by enhancing WM axonal and decreasing MMP-9 expression.

Coronary artery disease or history of stroke triples the odds of having diabetes

E. Szymanska-Garbacz[1], P. Bijoś[2], M. Jabłkowski[1], L. Czupryniak[3];
[1]Infectious & Liver Diseases Dept, Medical University of Lodz, Lodz, [2]TEVA Pharmaceuticals Polska Sp. z o.o., Warsaw, [3]Diabetology and Internal Diseases Dept, Warsaw Medical University, Warsaw, Poland.

Background and aims: Current estimates show that at least a third of people with diabetes are unaware of their disease. Unfortunately, still too often diabetes is found as late as at the occurring of acute myocardial infarction or stroke. We hypothesized that in general population the history of coronary artery disease (CAD) or stroke are significant risk factors for diagnosing diabetes.
Materials and methods: In 2014-2015 we conducted a primary care physician (PCP)-based nationwide screening programme aiming at identifying individuals with undiagnosed diabetes or prediabetes. 561 PCPs enrolled 21,726 subjects. No earlier diagnosis of diabetes or prediabetes and the presence of at least one risk factor (age>45 yrs, family history of diabetes, sedentary lifestyle, smoking, presence of fatty liver disease, hypertension, hyperlipidemia, CAD, peripheral artery disease, obstructive sleep apnoea syndrome, polycystic ovary syndrome, history of stroke, gestational diabetes or having a child of birth weight >4 kg, BMI>25 kg/m^2 or waist circumference >80 cm [women] or 94 cm [men]) were inclusion criteria. All individuals underwent fasting plasma

glucose (FPG) measurement, and if it exceeded 125 mg/dl, second FPG measurement was conducted. The subjects with first FPG measurement 100-125 mg/dl had an oral 75 g glucose tolerance test (OGTT) performed.
Results: Diabetes was diagnosed in 4,221 (19.4%) subjects, and having had a stroke or CAD tripled the risk for having diabetes, and their effect was greater than that of abdominal obesity, fatty liver disease or lifestyle or family history of diabetes (Table 1).
Conclusion: In conclusion, non diabetes subjects with coronary artery disease or history of stroke are at high risk of having diabetes and should be actively screened towards it.

Table 1. Odds ratio for having diabetes.

	Odds Ratio	95% Confidence Interval
History of stroke	3.310	2.948-3.716
CAD	3.158	2.934-3.398
Abdominal obesity	2.828	2.615-3.059
Fatty liver disease	2.655	2.461-2.864
BMI>25 kg/m2	2.626	2.425-2.844
Sedentary lifestyle	1.882	1.744-2.032
Family history of diabetes	1.780	1.661-1.908

Evaluation of different neurological scores and scales to predict fatal stroke in hospitalised stroke patients with type 2 diabetes

A. Angelidi, A. Papazafiropoulou, E.M. Tzouganatou, E. Eustratiadi, P. Lampropoulos, I. Georgopoulos, G. Kranidiotis, A. Melidonis;
First Department of Internal Medicine and Diabetes Center, General Hospital "Tzaneio", Piraeus, Greece.

Background and aims: Stroke is one of the most common causes of death worldwide and the most frequent cause of permanent disability. Diabetes mellitus type 2 (T2DM) is a well-known traditional stroke risk factor. Various scales and scores have been established for the neurological evaluation and prognosis regarding the outcome of stroke patients. The purpose of this study is a comparative assessment of various neurological scores and scales to predict a fatal outcome in stroke hospitalized patients with or without T2DM.
Materials and methods: The study included a total of 96 hospitalized stroke patients (40 men, 46 with T2DM), during the period January to December 2016. Anthropometric, clinical, and laboratory data were estimated for each participant. Furthermore, NIHSS (NIH Stroke scale), RRE-90 (Recurrence Risk Estimator), ESRS (Essen Stroke Risk Score), SPI-II (Stroke Prognosis Instrument II), and GCS (Glasgow Coma scale) were also calculated. Discrimination capability was assessed based on the area under the receiver operating characteristic curve (Area Under the Curve, AUC), sensitivity and specificity, positive (PPV) and negative (NPV) predictive values were calculated.
Results: Fatal endpoint was found in 6.5% of all hospitalized patients (5.3% and19.2% in the group of individuals without and with T2DM respectively). In patients with T2DM, receiver operating characteristic analysis revealed that for NIHSS scale a cutoff of ≥10 showed sensitivity: 80%, specificity: 71%, AUC: 0,767 an for RRE score a cutoff of ≥1,5 showed sensitivity 20%, specificity: 80%, AUC: 0.55. ESRS score for a cutoff of ≥4,5 showed sensitivity: 80%, specificity: 58%, AUC: 0,674. SPI-II score for a cutoff of ≥7,5 showed sensitivity: 80%, specificity: 47.4% AUC: 0,60, while the GCS scale for a cutoff of ≥10 showed sensitivity: 80%, specificity: 14.3%, AUC: 0,276. Respectively for stroke patients without T2DM, NIHSS scale for a cutoff of ≥11 showed sensitivity 100%, specificity: 80,6%, AUC: 0,889, while RRE score for a cutoff of ≥1,5 showed sensitivity: 50%, specificity: 52.9% , AUC: 0.397. In addition, ESRS score for a cutoff of ≥3,5 showed sensitivity 20%, specificity: 58,8%, AUC: 0,206, SPI-II score for a cutoff of ≥7,5 showed sensitivity 20%, specificity: 93 9%, AUC: 0,121, and GCS scale for a cutoff of ≥10 showed sensitivity: 50%, specificity: 8,3%, AUC: 0,111.
Conclusion: The results of the present study showed that NIHSS scale displays the best sensitivity and specificity as a predictor of fatal outcome in patients hospitalized with stroke regardless of the presence or not of T2DM. Moreover, SPI-II and ESRS scores showed equally good sensitivity and specificity as predictors of fatal outcome in stroke patients with T2DM.

1124

Comorbidity prevalence among patients with established cardiovascular disease and type 2 diabetes

H. Hannachi, K. Iglay, S.S. Engel, X. Li, D. O'Connell, L.M. Moore, S. Rajpathak;
Merck & Co., Inc., Kenilworth, USA.

Background and aims: The presence of comorbidities in type 2 diabetes (T2D) can impact a physician's management approach, including selection of antihyperglycemic agents. While the prevalence of comorbidities has been reported widely, limited information is available on the prevalence among patients with cardiovascular disease (CVD) and differences from those without CVD. Therefore, the current study sought to determine the prevalence of comorbidities in these populations.
Materials and methods: A retrospective study was conducted using the Quintiles Electronic Medical Record database. Patients ≥18 years diagnosed with T2D (or prescribed an oral T2D medication) who had ≥1 encounter from October 2014 to September 2015 and ≥1 year of medical history available were included.
Results: Of the 1,514,966 eligible patients, 54% were female, median age was 65 years, and median A1c was 6.7%. 25% of patients had CVD, with coronary artery disease being the most commonly diagnosed form. Median A1c was similar for those with and without CVD (6.8% and 6.7%). The prevalences of comorbidities by CVD type are shown in the table below. The most common conditions for those with and without CVD included hypertension (98% and 91%), overweight/obesity (81% in both groups), hyperlipidemia (95% and 79%), chronic kidney disease (39% and 19%), and heart failure (20% and 4%). Use of ICD-9 codes for comorbidity assessment might have resulted in underreporting.
Conclusion: Patients with T2D and CVD have higher rates of common comorbidities compared to those without CVD.

Comorbidity	No CVD (n=1,136,438)	Any CVD (n=378,528)	CAD only (n=229,532)	PAD only (n=43,853)	Cerebrovascular disease only (n=33,643)
Hypoglycemia	1.4%	2.1%	1.7%	2.7%	2.5%
Chronic Kidney Disease	18.9%	38.6%	35.3%	40.9%	37.0%
Neuropathy	8.6%	13.7%	10.8%	21.8%	15.0%
Congestive Heart Failure	4.3%	20.3%	20.5%	12.0%	11.8%
Genital Mycotic Infection	2.6%	1.7%	1.4%	2.6%	2.5%
Overweight/Obese	80.5%	80.5%	82.6%	78.1%	75.7%
Urinary Tract Infection	1.8%	1.8%	1.5%	2.5%	2.7%
Pancreatitis	0.2%	0.2%	0.2%	0.4%	0.3%
Liver Disease	3.8%	3.0%	2.8%	4.0%	3.2%
Retinopathy	0.7%	0.7%	0.5%	1.0%	0.8%
Hypertension	91.1%	98.3%	98.5%	97.1%	96.9%
Hyperlipidemia	78.5%	94.8%	95.8%	89.7%	89.7%

Footnote: CVD=cardiovascular disease; CAD=Coronary artery disease; PAD=peripheral artery disease. CKD was defined based on ICD-9 diagnosis or eGFR <60 mL/min/1.73m². If not already estimated in the database, eGFR was calculated using the MDRD Study equation. Neuropathy, heart failure, genital mycotic infections, UTIs, pancreatitis, liver disease and retinopathy were defined using ICD-9 diagnoses. Overweight/obesity was defined by either the presence of an ICD-9-CM code or a most recent body mass index (BMI) measure ≥25 kg/m². Hypoglycemia was assessed using a modified algorithm by Ginde et al. Hypertension was defined using ICD-9 diagnoses or SBP ≥140 or DBP ≥90 mmHg using the most recent blood pressure measurement prior to the index date or use of medications to treat hypertension. Hyperlipidemia was defined using ICD-9 diagnoses, by an LDL-c ≥100 mg/dL or use of medications for lowering cholesterol.

1125

Impact of past and current smoking on the risk of future cardiovascular events in angiographied coronary patients with type 2 diabetes

R. Gansch[1], C.H. Saely[2], C. Lins[3], D. Zanolin[3], A. Leiherer[3], A. Vonbank[2], A. Schuler[2], A. Muendlein[3], P. Rein[2], A. Mader[1], P. Schwerzler[1], H. Drexel[4];

[1]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [2]Academic Teaching Hospital Feldkirch, Feldkirch, Austria, [3]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, Austria, [4]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: Smoking is a major risk factor for heart disease. When combined with other risk factors (such as unhealthy blood cholesterol levels, high blood pressure, and overweight or obesity) smoking further raises the risk of heart disease. The impact of smoking on cardiovascular event risk in angiographied coronary patients is unclear and is addressed in the present study.
Materials and methods: We enrolled 1804 consecutive patients undergoing coronary angiography for the evaluation of established or suspected stable coronary disease (CAD). Patients who had smoked within 30 days prior to angiography were considered current smokers. Prospectively, cardiovascular events were recorded over a mean follow-up time of 6.3 ±3.7 years.
Results: At baseline, both in patients with T2DM (n=522; 28.9% of the study population) and in nondiabetic subjects the prevalence of a past (44.1 and 39.5%; p=0.035), and, albeit less so, of current smoking (18.0 and 17.7%; p = 0.247) was high. Among patients with T2DM the prevalence of significant CAD with lumen narrowing ≥50% was 61.0% in those who had never smoked vs. 70.9%, p=0.032 and 70.8%, p=0.101 in past and current smokers, respectively. Among nondiabetic patients the corresponding prevalence rates of significant CAD were 45.9% vs. 63.8%, p<0.001 and 53.7%, p=0.046, respectively. Prospectively, current smoking independently predicted cardiovascular events after multivariate adjustment including baseline CAD in patients with diabetes (HR 1.93 [1.20-3.08]; p=0.006) as well as in nondiabetic patients (HR 1.50 [1.07-2.09]; p=0.019), whereas past smoking neither in patients with T2DM nor in nondiabetic subjects was associated with cardiovascular events (HRs 1.07 [0.74-1.55]; p=0.715 and HR 1.11 [0.87-1.41]; p=0.415). An interaction term diabetes x current smoking was not significant (p=0.350), indicating that current smoking was equally predictive of cardiovascular events in patients with T2DM and in nondiabetic subjects.
Conclusion: We conclude that current but not past smoking strongly increases cardiovascular event risk in angiographied coronary patients with diabetes independently from the baseline CAD state.
Disclosure: **R. Gansch:** None.

PS 099 Cardiovascular complications: prevalence and treatment initiation

1126

Global prevalence of type 2 diabetes complications in 14,391 patients initiating second-line therapy: the DISCOVER study

M.V. Shestakova[1,2], K. Khunti[3], N. Arya[4], J. Cid-Ruzafa[5], P. Fenici[6], M.B. Gomes[7], N. Hammar[8,9], A. Nicolucci[10], S. Pocock[11], W. Rathmann[12], H. Watada[13], I. Shimomura[14], F. Tang[15], M. Kosiborod[15,16], DISCOVER; [1]Endocrinology Research Center, Moscow, [2]I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation, [3]University of Leicester, Leicester, UK, [4]AstraZeneca, Gaithersburg, USA, [5]Evidera, Barcelona, Spain, [6]AstraZeneca, Cambridge, UK, [7]Rio de Janeiro State University, Rio de Janeiro, Brazil, [8]AstraZeneca Gothenburg, Mölndal, [9]Institute of Environmental Medicine, Karolinska Institute, Stockholm, Sweden, [10]Center for Outcomes Research and Clinical Epidemiology, Pescara, Italy, [11]London School of Hygiene and Tropical Medicine, London, UK, [12]Institute for Biometrics and Epidemiology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich Heine University, Düsseldorf, Germany, [13]Graduate School of Medicine, Juntendo University, Tokyo, [14]Graduate School of Medicine, Osaka University, Osaka, Japan, [15]Saint Luke's Mid America Heart Institute, Kansas City, [16]University of Missouri, Kansas City, USA.

Background and aims: The global prevalence of diabetes-related complications is currently not well described. DISCOVER is a global, prospective, observational study involving 14 391 patients from 37 countries with type 2 diabetes initiating second-line glucose-lowering therapy.
Materials and methods: Patients were recruited from primary and specialist healthcare settings. Data were collected using a standardized case report form. Macrovascular complications were defined as a composite of coronary artery disease, heart failure, stroke and peripheral artery disease. Microvascular complications were defined as a composite of retinopathy, nephropathy and neuropathy. Prevalence estimates were standardized for age and sex using a hierarchical logistic model.
Results: Median time since diagnosis was 4.1 years (interquartile range: 2.0-7.9 years). The overall adjusted prevalence of macrovascular complications was 13.0%, ranging from 4.1% to 46.6% across countries (Figure). The overall adjusted prevalence of microvascular complications was 17.7%, ranging from 5.5% to 41.1% across countries.
Conclusion: The global burden of macrovascular and microvascular complications is substantial, even among patients initiating second-line treatment who are presumably still at low risk. Particularly high rates were seen in Eastern European, Middle Eastern and African countries.

Figure. Age- and sex-adjusted prevalence of macrovascular complications at baseline.

1127

Mortality and life expectancy according to cardiovascular comorbidity among 41,161 adults with type 2 diabetes: a Korean national sample cohort study, 2002 to 2013

Y. Kang, Y. Cho, S. Lee, J.-Y. Park, W. Lee, Y.-J. Kim, C. Jung;
Asan Medical Center, Seoul, Republic of Korea.

Background and aims: Although type 2 diabetes is a strong risk factor for cardiovascular disease and mortality, information on its association with mortality and life expectancy according to cardiovascular comorbidities is limited, especially in Asia. Thus, this study aimed to assess mortality and reductions in life expectancy associated with cardiometabolic multimorbidity.
Materials and methods: A total of 569,831 participants aged more than 30 years from Korean National Health Insurance Service-National Sample Cohort (NHIS-NSC) were enrolled between 2002 and 2006 and were followed for the median of 12.0 years. They were categorized into 5 mutually exclusive groups according to the baseline disease status: none (reference group); diabetes only; diabetes and stroke; diabetes and myocardial infarction (MI); and diabetes, stroke and MI. Mortality rates and hazard ratios (HRs), reductions of life expectancy, and age-specific contributions to life expectancy were calculated by constructing life tables.
Results: The mortality rates per 1000 person-years were 6.85, 19.86, 67.17, 66.34, and 115.52 in the reference, diabetes only; diabetes and stroke; diabetes and MI; and diabetes, stroke, and MI groups, respectively. The corresponding HRs for all-cause mortality were 1.58 (95% CI 1.54-1.62), 3.53 (95% CI 3.21-3.89), 3.37 (95% CI 2.90-3.92), and 5.25 (95% CI 3.36-8.21), compared with the reference group. The estimated reductions in life expectancy were greater at younger ages, and markedly increased with more cardiometabolic comorbidities.
Conclusion: Young type-2 diabetic Asians, especially those with cardiovascular comorbidity lived less than their non-diabetic equivalents. Thus, these individuals require special attention to prevent further reductions in life expectancy.
Disclosure: **Y. Kang:** None.

1128

Prevalence of cardiovascular disease and evaluation of standard of care in type 2 diabetes: a nationwide study in primary care

J. Rungby[1], M. Schou[2], P. Warrer[1], L. Ytte[1], G. Andersen[3];
[1]Department of Endocrinology IC, Bispebjerg University Hospital, [2]Herlev University Hospital, [3]Boehringer-Ingelheim, Copenhagen, Denmark.

Background and aims: Cardiovascular disease (CVD) complicates type 2 diabetes (T2D). Empagliflozin and liraglutide have demonstrated improved survival in patients with T2D and CVD. We assessed prevalence and standard of care (SoC) of patients with T2D and established CVD managed in primary care.
Materials and methods: 129 general practitioners, from both rural and urban areas, responsible for 348373 patients, identified T2D patients from the clinic's electronic patient record system (EPRS) based on ICPC-2 coding system. Patients with concomitant CVD were subsequently identified and characterized.
Results: 17113 patients (4,9%) had T2D. T2D with established CVD was found in 3665 patients (21,4%). A maximum of 20 patients form each gp (2003 patients were futher analyzed for concommittant CVD: Mean age was 72 yrs; 34,6% were women, see table 1. SoC was good; HbA1c was 52,3 mmol/mol, BP 131,4/75,7 mmHg and LDL-cholesterol 2,0 mmol/l. Mean eGFR was 68,2 ml/min.; 32,2% had micro or macroalbuminuria. Almost 80% were in antiglycemic drug treatment predominantly with metformin in mono or combination therapy (63,4%), insulin was used in 19,5%. 21,8% were treated non-pharmacological. 64,9 % had an ACEI/ARB, 78,3% a statin and 96,1% were in antithrombotic therapy, of these 53% with acetylsalicylic acid; 66,9% were in diuretic treatment.
Conclusion: In a nationwide database study in primary care the prevalence of CVD in T2D patients were high (21,4%). SoC was in accordance with local guidelines. Identifying this high-risk group of T2D patients and optimizing treatment might add further CV benefits as suggested in recent cardiovascular outcomes trials. Identification of eligible patients is possible with existing EPRS.

[1]The Diabetes Unit, Hadassah Hebrew University Hospital Medical Center, Jerusalem, Israel, [2]TIMI Study Group, Brigham and Women's Hospital, Harvard Medical School, Boston, USA, [3]The Diabetes Unit, Hadassah Hebrew University Medical Center, Jerusalem, Israel, [4]Tokai University Hospital, Isehara, Japan, [5]TIMI Study Group, Division of Cardiovascular Medicine, Brigham and Women's, Boston, [6]TIMI Study Group, Brigham and Women's Hospital, Harvard Medical School, Boston, USA, [7]University of Toronto, Toronto, Canada, [8]University of Texas Southwestern Medical Center, Dallas, USA, [9]University of Liverpool, Liverpool, UK, [10]AstraZeneca R&D, Gothenburg, Sweden, [11]Brigham and Women's Hospital/TIMI Study Group, Boston, USA.

Background and aims: Dapagliflozin (DAPA) is a SGLT-2 inhibitor approved for use in patients with type 2 diabetes (T2D), having met pre-marketing safety requirements. Cardiovascular (CV) outcomes trials permit well-powered assessment of the CV safety and efficacy of new anti-hyperglycemic agents. We hereby describe the design and patients baseline characteristics at the DAPA Effect on CV Events (DECLARE-TIMI 58) trial.
Materials and methods: The DECLARE-TIMI 58 is a multinational phase 4, randomized, placebo-controlled trial in patients with T2D and established CV disease (ECVD) or with multiple risk factors (MRF) for CV disease (define as: men: age ≥55 women: ≥60 and at least 1 of: dyslipidemia, hypertension, or smoking). The objective of the trial is to determine the effect of DAPA on CV outcomes relative to placebo when added to current background therapy. The first step is to show that DAPA does not increase the risk for the composite of CV death, MI, or ischemic stroke (MACE). The second step is to test superiority of DAPA in reducing the co-primary efficacy endpoints of MACE and the composite of CV death or hospitalization due to heart failure.

Results: The study randomized 17,276 patients with T2D including 6,978 patients with ECVD and 10,228 patients with MRF (table). The trial will continue until 1,390 patients experience the adjudicated composite endpoint of MACE.

Conclusion: DECLARE-TIMI 58 trial is expected to provide conclusive data on the effect of DAPA relative to standard of care on CV outcomes in T2D patients at high risk for CV events.

Cardiovascular hospitalisation among type 2 diabetes patients by stages of eGFR and albuminuria

G.A. Nichols[1], A. Derauz-Luyet[2], S.J. Hauske[3], K.G. Brodovicz[4];
[1]Kaiser Permanente Center for Health Research, Portland, USA, [2]Boehringer Ingelheim GmhB, Ingelheim-am-Rhein, [3]Boehringer Ingelheim GmhB & Co. KG, Ingelheim-am-Rhein, Germany, [4]Boehringer Ingelheim Pharmaceuticals, Ridgefield, USA.

Background and aims: Up to 40% of type 2 diabetes (T2D) patients have chronic kidney disease (CKD) as defined by low estimated glomerular filtration rate (eGFR) (eGFR < 60 mL/min/1.73 m^2) and/or presence of albuminuria. Both low eGFR and albuminuria are known to independently increase cardiovascular (CV) risk but longitudinal studies that include both measures of CKD are scarce. We aimed to compare the 11-year incidence of CV hospitalizations in T2D patients with and without low eGFR and/or with and without albuminuria.

Materials and methods: We used the electronic medical records of an integrated delivery system in the USA to identify 17,054 patients with diagnosed T2D for whom we could calculate eGFR (CKD-EPI formula) from the first available serum creatinine value from 2006-2012 (baseline), confirmed by a second eGFR three months later if the first was < 60 mL/min/1.73 m^2. We required patients to have a UACR within +/- 6 months of the creatinine test. We used KDIGO stages of eGFR (G1: ≥90mL/min/m2; G2: 60-89; G3a: 45-59; G3b: 30-44; G4: 15-19; G5: <15 or ESRD) and albuminuria (A1: <30 mg/g; A2: 30-300; A3: >300) to define 18 possible categories of kidney function. The outcome of interest was incidence per 1,000 person-years (p-y) of first CV hospitalization (primary diagnosis of ischemic heart disease, stroke, or heart failure) estimated over 11 years of follow-up (through 2016). Incidence rates were adjusted for age, sex, duration of diabetes, prior history of CV disease, and use of an angiotensin-converting-enzyme inhibitor or an angiotensin II receptor blocker using generalized linear models with Poisson errors and person-time as an offset to account for differential follow-up.

Results: Nearly two-thirds of patients (n=10,915; 64%) had normal kidney function (stages G1or G2 and A1), 14% had eGFR < 60 mL/min/m^2 (Stage G3A or higher), 28% had albuminuria (stage A2 or A3), and 6% both eGFR < 60 mL/min/m^2 and albuminuria There were 1,696 events over 86,738 person-years of follow-up. Adjusted CV hospitalization rates were lowest among patients with normal kidney function (4.7/1000 p-y, 95% CI 4.0-5.5) and highest among patients at stages G5 and A3 (76.8, 34.4-171.4). Incidence was higher at each eGFR stage as albuminuria stage increased. For example, incidence was over 50% higher at stage G1/A2 (7.4, 6.1-8.1), and over twice as high at stage G1/A3 (10.8, 7.1-16.5). Incidence was also higher at each albuminuria stage as eGFR stage increased. For example, stage G3a/A1 incidence was 23.0 (19.2-27.6) and 41.7 (25.8-67.4) at stage G4/A1.

Conclusion: Low eGFR and albuminuria each independently increase CV hospitalization risk. The combination of higher stages eGFR and albuminuria is particularly potent.

Short-term treatment with linagliptin reduces plasma levels of nitrate in parallel with the reduction in FDG-PET-assessed arterial inflammation in early type 2 diabetes

J. Boersema[1], S.A. de Boer[1], A.M. van Roon[1], H. Hop[1], R.H.J. Slart[2,3], B.O. Fernandez[4], J.-L. Hillebrands[5], M. Feelisch[4], H.J.L. Heerspink[6], H. van Goor[5], D.J. Mulder[1];
[1]Dept. of Internal Medicine, div. of Vascular Medicine, University Medical Center Groningen, Groningen, [2]Dept. of Nuclear Medicine and Molecular Imaging, University Medical Center Groningen, Groningen, [3]Dept. of Biomedical Photoacustic Imaging (BMPI), University of Twente, Enschede, Netherlands, [4]Clinical and Experimental Sciences, Faculty of Medicine, University of Southampton, Southampton, UK, [5]Dept. of Pathology, University Medical Center Groningen, Groningen,

[6]Dept. of Clinical Pharmacy and Pharmacology, University Medical Center Groningen, Groningen, Netherlands.

Background and aims: We showed that the dipeptidyl peptidase-4 (DPP-4) inhibitor linagliptin reduces vascular stiffness (pulse wave velocity (PWV)) and arterial inflammation (arterial ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET) uptake) in early type 2 diabetes (T2D) patients in a randomized controlled trial (RELEASE study). The underlying mechanisms are incompletely understood. One potential pathway may be via improvement in redox tone. We compared plasma levels of reactive nitrogen oxide species (nitrite, nitrate, and nitrosylation products (RXNO)) and free thiols (FT, redox balance) between T2D patients and controls, assessed the effect of linagliptin monotherapy, and whether changes were paralleled by changes in vascular stiffness and arterial inflammation.
Materials and methods: 45 treatment naive T2D patients (median age 63 (IQR 54-66) years, 61% male, mean HbA1c 6.3±0.4 (%)) without cardiovascular disease were randomized (1:1) to linagliptin 5 mg or placebo for 26 weeks in a double-blind fashion. PWV, FT (corrected for total protein), nitrite, nitrate, and RXNO were assessed at baseline, and after 4 and 26 weeks of treatment and arterial inflammation at baseline and after 26 weeks. Arterial inflammation was quantified by FDG uptake as the pre-scan glucose corrected maximum standardized uptake value corrected for background (TBR) of the large vessels (meanTBR). For comparison, nitrite, nitrate, RXNO, and FT were also measured in young healthy controls (median age 24 (IQR 21-25) years, 80% female).
Results: RXNO levels (23.4 (12.1) vs 15.8 (5.9) nM; p=0.007) were significantly increased in patients vs controls, while nitrite (0.22 (0.15) vs 0.14 (0.08) μM; p=0.098) and nitrate (35.1(16.5) vs 27.6(12.6) μM ; p=0.18) were not significantly different. No differences in FT were observed (5.72(0.41) vs 5.82(0.44) vs μM/g protein; p=0.51). Nitrate (-3.27(15.0) vs 18.0(26.1); p=0.003) decreased from baseline to week 4 in linagliptin vs controls and a trend was observed for RXNO (-1.79(18.9) vs 8.8(18.7); p=0.078). No significant changes were observed from week 4 to 26 for both. No effects of linagliptin were seen on nitrite and FT levels. Only the change in nitrate (r=0.49;p=0.024) was positively associated with the decrease in meanTBR but not with PWV. Changes in reactive nitrogen oxide species were strongly interrelated.
Conclusion: Nitrosylation products are elevated and linagliptin reduces nitrate within 4 weeks of treatment in patients with early T2D. The decrease in nitrate is associated with reduction in FDG-PET assessed arterial inflammation. These data suggest that potential beneficial vascular effects of incretins and DPP4 inhibitors may be partly mediated by effects on the nitric oxide pathway.

Antiplatelet effect of aspirin during 24 hours in patients with type 2 diabetes without cardiovascular disease

L. Vernstroem[1], K.L. Funck[1], E. Laugesen[1], E.L. Grove[2], A.-M. Hvas[3], P.L. Poulsen[1];
[1]Department of Endocrinology and Internal Medicine, Aarhus University Hospital, [2]Department of Cardiology, Aarhus University Hospital, [3]Center of Hemophilia and Thrombosis, Department of Clinical Biochemistry, Aarhus University Hospital, Aarhus, Denmark.

Background and aims: Primary prevention of cardiovascular disease (CVD) with aspirin in patients with type 2 diabetes (T2DM) is controversial. Patients with T2DM and a history of CVD have a reduced antiplatelet effect of aspirin, which has been associated with an increased platelet turnover. However, the antiplatelet effect of aspirin in patients with T2DM without CVD has not been explored. The primary aim of this study was to investigate if platelet aggregation increases during the standard 24-hour aspirin dosing interval in patients with T2DM and in healthy controls after 1 week of low-dose aspirin treatment. Furthermore, we evaluated platelet turnover and the acute effects of aspirin on platelet aggregation.
Materials and methods: We performed an open-label parallel group intervention study. We included 21 patients with T2DM and 21 age and sex-matched controls. Platelet aggregation was measured by impedance aggregometry (Multiplate® Analyzer) using arachidonic acid and thrombin-receptor-activating-peptide as agonists. Markers of platelet turnover were measured by flow cytometry (Sysmex® XE-5000). Blood samples were obtained at baseline and 1 hour after administration of 75 mg of aspirin. Participants were then treated for 6 days with once-daily aspirin, and blood samples were repeated 1 hour and 24 hours after aspirin intake.
Results: After 6 days of treatment, platelet aggregation levels increased during the 24-hour aspirin dosing interval in both patients and controls (T2DM: + 85 ± 101 U (aggregation units × minute), p<0.001, controls: + 80 ± 105 U, p<0.001, figure). At baseline, patients with diabetes had increased platelet aggregation compared to controls (949 ± 159 U vs. 835 ± 194 U, p=0.03). Platelet aggregation was reduced after the first dose of aspirin (T2DM: 731 ± 256 U, controls: 634 ± 218 U). Additionally, after six days of treatment, aggregation levels were further reduced (T2DM: 172 ± 101 U, p<0.001, controls: 215 ± 86 U, p<0.001). Patients with T2DM had a higher number of immature platelets compared to controls (8.0 ± 4.8 10^9/L vs. 5.9 ± 2.3 10^9/L), indicating an increased platelet turnover, although this finding was not statistically significant (p=0.09).
Conclusion: Aspirin-treated patients with T2DM without a history of CVD had increased platelet aggregation at the end of the standard 24-hour dosing interval, however this increase did not differ from the increase observed in healthy controls. Aspirin-naïve T2DM patients had increased platelet aggregation compared to healthy controls, confirming alterations in platelet aggregation in patients with T2DM. Our study indicates that patients with T2DM may achieve additional benefit from twice daily dosing of aspirin. Large-scale clinical outcome trials are needed to determine this.

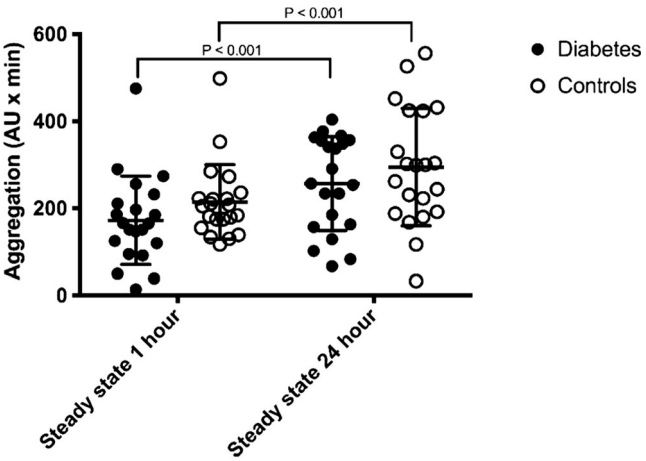

Figure: Steady state: Platelet aggregation 1 and 24 hours after intake of aspirin 75 mg using arachidonic acid as agonist in patients with type 2 diabetes and controls.

Are the cardiovascular risk reductions seen with empagliflozin in the EMPA-REG OUTCOME trial explained by conventional cardiovascular risk factors?

R.L. Coleman[1], A.M. Gray[2], U.C. Broedl[3], D. Fitchett[4], J.T. George[5], H.-J. Woerle[3], B. Zinman[6,7], R.R. Holman[1];
[1]Diabetes Trials Unit, University of Oxford, [2]Health Economics Research Centre, University of Oxford, Oxford, UK, [3]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany, [4]St Michael's Hospital, Division of Cardiology, University of Toronto, Toronto, Canada, [5]Boehringer Ingelheim Ltd., Bracknell, UK, [6]Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, [7]Division of Endocrinology, University of Toronto, Toronto, Canada.

Background and aims: To estimate the degree to which cardiovascular risk reductions demonstrated with empagliflozin administration in the EMPA-REG OUTCOME trial might be explained by changes observed in conventional cardiovascular factors during the study.
Materials and methods: A T2D-specific computer simulation model was used to simulate three year cardiovascular event rates utilizing annual patient-level data from 7,020 EMPA-REG OUTCOME participants that included atrial fibrillation, smoking, albuminuria, HDL-cholesterol, LDL-cholesterol, systolic blood pressure, HbA_{1c}, heart rate, white cell count, haemoglobin and estimated glomerular filtration rate, as well as history of ischaemic heart disease, heart failure, amputation, blindness, renal failure, stroke, myocardial infarction or ulcer. Multiple simulations were performed for each participant to minimize first and second order uncertainty and to optimise the precision of the confidence intervals surrounding the cardiovascular risk point estimates. Estimated absolute event rates for empagliflozin and placebo assigned participants were used to calculate modelled cardiovascular relative risk reductions (RRRs).
Results: Compared to the observed RRRs, our simulated results suggest that empagliflozin could reduce absolute placebo rates for all-cause mortality by 4% (~13% of 32% RRR observed), cardiovascular death by 3% (~8% of 37% RRR observed), hospitalization for heart failure by 5% (~15% of 35% RRR observed), fatal and nonfatal myocardial infarction by 2% (compared with the non-significant 13% RRR observed), and fatal and nonfatal stroke by 6% (compared with the non-significant 18% relative risk increase observed).
Conclusion: Empagliflozin-associated changes in conventional cardiovascular risk factor values recorded in the EMPA-REG OUTCOME trial appear to explain only a small proportion of the actual cardiovascular risk reductions observed for key endpoints. Alternative risk-reduction mechanisms need to be explored to determine whether the observed changes in risk can be explained by other factors, or as a drug-specific effect.

Figure: Observed risk reductions and proportions attributable by simulation to conventional cardiovascular risk factors

Prognostic value of fasting plasma glucose, two hour postload glucose and HbA_{1c} in patients with coronary artery disease

B. Shahim[1], D. De Bacquer[2], G. De Backer[3], V. Gyberg[1], K. Kotseva[4], L. Mellbin[1], O. Schnell,[5], J. Tuomilehto[6], D. Wood[4], L. Rydén[1];
[1]Cardiology, Medicin, Stockholm, Sweden, [2]Department of Public Health, Ghent, [3]Department of Public Health, Ghent, Belgium, [4]Cardiovascular Medicine, National Heart and Lung Institute, Imperial College of London, London, UK, [5]Forschergruppe Diabetes e.V., Munich, Germany, [6]Disease Risk Unit, National Institute for Health and Welfare, Helsinki, Finland.

Background and aims: Three test are recommended for identifying dysglycaemia: fasting glucose (FPG), 2h-postload glucose(2h-PG) from an oral glucose tolerance test (OGTT) and glycated haemoglobin A1c (HbA1c). This study explores the prognostic value of these screening tests in patients with coronary artery disease (CAD).
Materials and methods: 4,004 CAD patients without a history of diabetes (age 18-80 years) were screened for dysglycaemia by means of FPG, 2h-PG and HbA1c. The prognostic value of these tests was studied after two years of follow up. The primary endpoint included cardiovascular mortality, non-fatal myocardial infarction, stroke or hospitalisation for heart failure and a secondary endpoint incident diabetes.
Results: Complete information including all three glycaemic parameters was available in 3,775 (94.3%) patients of who 246 (6.5%) experienced the primary endpoint. Neither FPG nor HbA1c predicted the primary outcome while the 2h-PG, dichotomised as <7.8 vs. ≥7.8 mmol/L, was a significant predictor (HR 1.38, 95% CI 1.07-1.78; p=0.01). During follow-up 78 (3.0%) of the 2,609 patients without diabetes at baseline developed diabetes. A FPG between 6.1-6.9 mmol/L did not predict incident diabetes while both HbA1c 5.7-6.5% and 2h-PG 7.8-11.0 mmol/L were significant independent predictors.
Conclusion: The 2h-PG, in contrast to FPG and HbA1c, provides significant prognostic information regarding cardiovascular events in patients with CAD. Furthermore, elevated 2h-PG and HbA1c are significant prognostic indicators of an increased risk of incident diabetes.

The haemoglobin glycation index and risk for diabetes-related complications in the ADVANCE trial

S.C.J. van Steen[1], M. Woodward[2], J. Chalmers[2], Q. Li[2], M. Marre[3], M.E. Cooper[4], P. Hamet[5], G. Mancia[6], S. Colagiuri[7], B. Williams[8], D.E. Grobbee[9], J.H. DeVries[1];
[1]Endocrinology, Academic Medical Center, Amsterdam, Netherlands, [2]The George Institute for Global Health, Sydney, Australia, [3]Hôpital Bichat-Claude Bernard and Université Paris, Paris, France, [4]Baker IDI

Heart and Diabetes Institute, Melbourne, Australia, [5]Centre Hospitalier de l'Université de Montréal, Montreal, Canada, [6]University of Milan-Bicocca and Instituto Auxologico Italiano, Milan, Italy, [7]Boden Institute, Sydney, Australia, [8]National Institute of Health Research UCL Hospitals Biomedical Research Centre, London, UK, [9]Julius Center for Health Sciences and Primary Care, Utrecht, Netherlands.

Background and aims: Previous studies have suggested that the hemoglobin glycation index (HGI) can be used as a predictor of diabetes-related complications in patients with type 1 or type 2 diabetes. We investigated whether HGI was better in predicting diabetes-related complications than HbA_{1c} in patients with type 2 diabetes, using data from the ADVANCE trial.

Materials and methods: We studied patients included in the ADVANCE trial with available baseline HbA_{1c} and fasting plasma glucose (FPG) (n=11,083). HGI is the difference between observed HbA_{1c} and HbA_{1c} predicted from a simple linear regression of HbA_{1c} on FPG. Using Cox regression, we investigated the association between HGI, both continuous and categorized, and adverse outcomes, considering treatment allocation (intensive or standard glucose control) and compared HGI and HbA_{1c} as a predictor of complications.

Results: Irrespective of treatment allocation, every standard deviation increase in HGI was associated with a significant risk increase of 14-17% for macrovascular and microvascular disease and mortality. However, adjusted for an identical set of standard covariates, HbA_{1c} was a stronger predictor for each of these outcomes than HGI. Intensive glucose control lowered mortality risk in high HGI patients only (HR 0.74, 95% CI 0.61-0.91, P=0.003), while there was no difference in the effect of intensive treatment on mortality in high HbA_{1c} patients.

Conclusion: HGI does predict risk for complications in ADVANCE patients, irrespective of treatment allocation, but no better than HbA_{1c}. Given the uncertain relevance beyond HbA_{1c}, clinical use of HGI in type 2 diabetes cannot be recommended.

Disclosure: **S.C.J. van Steen:** None.

1136

Glycaemic variability, but not HbA_{1c}, is an independent factor for the severity of coronary disease in patients with poorly controlled type 2 diabetes

B. Vergès, M. Benalia, C. Guenancia, G. Porot, M. Zeller, F. Bichat, J.-M. Petit, Y. Cottin;
CHU Dijon, Dijon, France.

Background and aims: Some studies have shown an association between glycemic variability, assessed by the mean amplitude of Glycemic Excursions (MAGE) and the severity of coronary disease in patients with type 2 diabetes and have shown that this association was superior to that for HbA1c. However, we do not know whether this association is also observed in metabolically severe patients with type 2 diabetes in whom constant hyperglycemia may mask the effect of glycemic variability. This prompted us to analyze prospectively the relationship between MAGE and the severity of coronary disease in patients with type 2 diabetes hospitalized for an acute Myocardial Infarction (MI) in whom Continuous Intravenous Insulin Infusion (CIVII) was needed because of blood glucose at entry above 180 mg/dl.

Materials and methods: All consecutive diabetic patients admitted to our University Hospital for acute MI between January 2014 and March 2016 and who received CIVII were included. The mean amplitude of glycemic excursions (MAGE) was calculated within 2 days after the acute MI. The severity of the coronary disease was assessed by the angiographic SYNTAX score. The population was divided into tertiles according to MAGE, and bivariate and multivariate analyses were performed.

Results: Among the 431 patients with type 2 diabetes hospitalized for acute MI, 196 met the inclusion criteria. The mean age of the population was 71.3 ± 12.1 yrs with a mean duration of diabetes of 11.4 ± 10.2 yrs and 29% were treated with insulin prior the acute MI. Mean HbA1c was 7.5±1.6 % and mean MAGE was 0.72±0.41. In multivariate analysis, four parameters were significantly and independently associated with the highest tertile of MAGE: female sex (OR(95%CI): 5.67 (2.29-14.02) p<0.001), Hb1Ac (OR(95%CI): 1.77 (1.33-2.34) p<0.001), Systolic blood pressure (OR(95%CI): 0.99 (0.97-1), p= 0.049) and SYNTAX score (OR(95%CI): 1.05 (1.01-1.08), p=0.007). The SYNTAX score was significantly higher in patients in the highest MAGE tertile compared to those in the lowest tertile (19.8±13.7 vs. 14.9±11.5, p=0.01). In univariate analysis, the SYNTAX score was also associated positively with age (p=0.005), history of coronary heart disease (CHD) or stroke (p=0.005), triglycerides (p=0.05) and negatively with glomerular filtration rate (p=0.028). In multivariate analysis, age (OR(95%CI): 1.05 (1.02-1.09) p=0.001), history of stroke (OR(95%CI): 6.25 (1.65-23.5) p=0.007) and the highest tertile of MAGE (OR(95%CI): 2.60 (1.24-5.41) p=0.011) were independently associated with the SYNTAX score, whereas Hb1Ac was not.

Conclusion: Our study shows that, in patients with metabolically severe type 2 diabetes, glycemic variability is an independent factor associated with the severity of coronary disease when HbA1c is not. These data underline the association between glycemic variability and the severity of coronary disease even in patients with poorly controlled type 2 diabetes.

Disclosure: **B. Vergès:** None.

Real world evidence for legacy effect of early glycaemic control in type 2 diabetes on risk of macrovascular disease

M. Whyte, U. Hoang, W. Hinton, A.P. McGovern, N. Munro, S. de Lusignan;
Department of Clinical & Experimental Medicine, University of Surrey, Guildford, UK.

Background and aims: Tight glycemic control right from the diagnosis of type 2 diabetes (T2D) may be effective in reducing long term incidence of cardiovascular disease. Clinical trials can have insufficient duration of follow-up to observe this effect. We evaluated whether the trajectory of HbA1c achieved within 12 months after diagnosis of T2D is independently associated with lowering the risk of new myocardial infarction (MI) or cerebrovascular accident (CVA) within 10 years.

Materials and methods: We performed a cohort analysis using a primary care data from the Royal College of General Practitioners Research and Surveillance Centre. The network of primary care practices covers 1.7% of population of England. The cohort of patients with a first diagnosis of T2D between 2006-16 were identified from the dataset. We examined risk for MI or CVA at anytime over 10 years of follow-up using logistic regression. Odds ratios (and 95% confidence intervals) for these macrovascular outcomes were calculated for nine separate glycaemic trajectories based on the following HbA1c thresholds at diagnosis and 1 year. Category A: HbA1c 48 - 57mmol/mol, category B: 58-74mmol/mol, category C: ≥75mmol/mol. Covariates including: gender, age, smoking (active; ever), blood pressure, BMI, ethnicity, chronic kidney disease (stage 3 to 5), atrial fibrillation, rheumatoid arthritis, LDL-cholesterol, insulin use, sulphonylurea, pioglitazone, rosiglitazone, metformin were included in the logistic model.

Results: 72,910 people with T2DM identified of whom 1962 had HbA1c data plus 10 years follow-up. Trajectories of improved control over 1-year were associated with less risk of later MI than those who stayed in upper categories of HbA1c (Table 1). Male gender 1.916 (1.177, 3.193; P<0.05), CKD 2.189 (1.285, 3.714; P<0.01), insulin use 2.247 (1.320, 3.819; P<0.01) were associated with greater risk of MI. Conversely, none of these independent variables were significantly associated with stroke.

Conclusion: In those with the highest HbA1c at diagnosis of T2D, achieving improvement in glycaemic control within 1-year reduced the likelihood of later myocardial infarction. Conversely, the level of glucose

control either at diagnosis or at 1-year had no impact on likelihood to have a CVA. Hypothetically the association of insulin use and later MI may relate to hypoglycaemia and MI risk. Further work is needed to determine whether trajectories of control after 12-months significantly impacts upon the risk of MI and at what timepoint the risk with insulin use emerges.

		10-year Odds Ratio for event	
		MI	CVA
HbA1c at diagnosis		0.980 (0.957, 1.001)	1.003 (0.982, 1.023)
HbA1c transition	Category A-> Category B	1.624 (0.505, 4.449)	0.983 (0.353, 2.342)
	Category A-> Category C	2.563 (0.127, 17.116)	4.49^{10-7} (0, 451)
	Category B-> Category A	2.691* (1.206, 6.008)	0.704 (0.324, 1.454)
	Category B-> Category B	3.481** (1.417, 8.418)	0.564 (0.180, 1.475)
	Category B-> Category C	5.499* (1.326, 19.048)	1.990 (0.522, 6.122)
	Category C-> Category A	2.459 (0.715, 8.395)	0.493 (0.148, 1.580)
	Category C-> Category B	3.318 (0.892, 12.064)	0.722 (0.200, 2.473)
	Category C-> Category C	6.975** (1.792, 26.837)	0.746 (0.170, 2.918)

Treatment with statins is independently associated with increased glycated haemoglobin levels in patients with type 1 diabetes

G. Penno, M. Garofolo, E. Russo, D. Lucchesi, L. Giusti, G. Daniele, F. Campi, R. Miccoli, S. Del Prato;
Endocrinology and Metabolism, University of Pisa, Pisa, Italy.

Background and aims: Statin treatment has been associated with increased risk of incident type 2 diabetes (T2DM) and with impaired glycemic control in T2DM. So far, to the best of our knowledge, only one study reported an association between use of statins and glycated haemoglobin (HbA1c) levels in individuals with type 1 diabetes mellitus (T1DM).
Materials and methods: In this cross-sectional study, the association of statin treatment with HbA1c levels has been examined by uni- and multivariable models in 774 quite young and well treated T1DM belonging to a single centre (men/women 53/47%, 40.2±11.7 year-old with a mean duration of diabetes of 19.3±12.2 years and a mean HbA1c of 7.8±1.2%).
Results: Out of 774 individuals with T1DM, one hundred (12.9%) were on statin treatment. As expected, T1DM on statins were older, had longer diabetes duration, higher BMI, waist-to-hip ratio (WHR) and systolic blood pressure, higher total- and LDL-cholesterol and also higher triglycerides and non HDL-cholesterol, worse kidney function but similar urinary albumin to creatinine ratio (A/C ratio). Statins users were more likely on treatment with blood pressure-lowering drugs or RAS-blockers with no differences in gender distribution, family history of cardiovascular disease (CVD), A/C ratio strata. Advanced retinopathy (27.1% *vs.* 13.9%), eGFR stages ≥2b (17.0% *vs.* 5.2%) and any CVD (30.0% *vs.* 5.3%) were more frequent in statin users (p<0.0001 for all) than in non-users. Insulin dose (IU by kg/body weight) and HbA1c levels were similar in both groups. Upon stratification by HbA1c quartiles (thresholds 7.1%, 7.7% and 8.4%), rates of statin users increased from Q1 (8.9%) to Q2 and Q3 (15.9% and 17.7%, respectively) to drop again in Q4 (8.7%; Pearson Chi-square 11.252, 3df, p=0.010). After speculating that statins are unlikely to significantly contribute to the worst HbA1c levels (Q4), logistic regression with backward stepwise variables selection was applied to evaluate independent contributors to Q2&Q3 HbA1c levels (n. 399 T1DM) with the Q1 HbA1c strata as the reference group (n. 192 T1DM). By unadjusted regression, statin treatment doubled the risk of having Q2&Q3 HbA1c levels (Odds ratios (OR) = 2.077; 95%CI 1.183-3.647, p=0.011). By multiple regression, triglycerides (OR = 1.040 x 10 mg/dl, 95%CI 1.000-1.080, p=0.077) and eGFR stages ≥2b (OR = 0.670, 95%CI 0.469-0.959, p=0.029) other than statin treatment (OR 1.954, 95%CI 1.090-3.505, p=0.025) were independently related to HbA1c Q2&Q3 quartiles with no effects of gender, age, duration of diabetes, BMI and WHR, total cholesterol, A/C ratio (or A/C ratio strata), treatment with BP-lowering agents or RAS blockers, smoking habits or coexistence of any CVD.
Conclusion: In type 1 diabetes, use of statins is independently associated to impaired glycemic control. In particular, the probability to be at target for HbA1c is lower in individuals with type 1 diabetes on statin treatment (17%) than in T1DM not on statins (26%). Likely, in type 1 diabetes, insulin regimens should be revised at the time of starting treatment with statins.

Visit-to-visit variability of blood pressure is independently associated with macrovascular and microvascular complications in patients with type 2 diabetes

M.G. Radaelli[1], F. Martucci[1], S. Perra[1], G. Manzoni[1], A. Oltolini[1], S. Pasi[1], S. Accornero[1], G. Castoldi[2], G. Lattuada[1], G. Grassi[2], G. Mancia[2,1], G. Perseghin[2,1];
[1]Dept Medicine and Rehabilitation, Policlinico di Monza, [2]Università degli Studi Milano Bicocca, Monza, Italy.

Background and aims: Recent evidence suggest that CVD risk is related on the consistency of blood pressure control between on-treatment visits. Visit-to-visit variability of systolic blood pressure is a biomarker of arterial stiffness, autonomic dysfunction, endothelial damage and systemic inflammation but it may also reflect poor patients' adherence to the pharmacologic therapy.
Materials and methods: We analyzed the relationships between macrovascular and microvascular complications of diabetes in 818 patients attending at least four times our secondary care diabetes clinic between 2013-15 with the coefficient of variation of the visit-to-visit measurements of the sitting systolic and diastolic blood pressure. We segregated these patients in tertiles of the coefficient of variation of systolic (cut-off: 7.7% and 11.8%) and diastolic (cut-off: 8.2% and 12.9%) blood pressure.
Results: Patients with the high visit-to-visit variability of systolic blood pressure were older (p<0.04), but no difference in the duration of diabetes (p=0.90), systolic (139±16, 139±16 and 139±15 mm Hg; p=0.87), diastolic (79±8, 78±9 and 77±9 mm Hg; p=0.35) blood pressure and heart rate (78±11, 79±10 and 77±10; p=0.19) were detected. Glycemic control was not different between tertiles of coefficient of variation (HbA1c 7.47 ±2.76%, 7.49±1.90% and 7.57±2.36%; p=0.97), meanwhile estimated GFR was lower in the tertile with high visit-to-visit coefficient of variation of blood pressure (p<0.03). Diabetic retinopathy and microalbuminuria, as a composite end-point, did not show a strong difference between tertiles (50%, 44% and 56%; p=0.09). In contrast, established CVD was more prevalent in patients with higher coefficient of variation of systolic blood pressure (39%, 48%, 52%; p<0.01). Treatments with statin (p=0.16), ACE-inhibitors (p=0.83) and ARB (p=0.98) were not different among tertiles but use of diuretics and Ca-antagonist was more frequent (p<0.05) in patients with higher variability. When the 10 year UKPDS Risk Engine was used as dependent variable, coefficient of variation of systolic and diastolic blood pressure were associated with the risks of coronary heart disease, fatal coronary artery

disease, and the risks of stroke and fatal stroke also when adjusted for drug therapy.

Conclusion: The results of this analysis support the hypothesis that in patient with type 2 diabetes a lack of stable control of ambulatory blood pressure is related to established and increased risk of macrovascular and, only to a lesser extent, microvascular complications.

Disclosure: **M.G. Radaelli:** None.

Modelling incremental benefits on macro- and micro-vascular complications rates when targeting lower systolic blood pressure levels in type 2 diabetes

S.A. Mostafa[1], R.L. Coleman[1], O.F. Agbaje[1], A. Gray[2], R.R. Holman[1], M.A. Bethel[1];
[1]Diabetes Trials Unit, [2]Health Economics Research Centre, Nuffield Department of Population Health, Oxford, UK.

Background and aims: Randomised controlled trials of systolic blood pressure (SBP) lowering demonstrate reductions in long-term complications to a level of 140mmHg in type 2 diabetes mellitus (T2DM) and 120mmHg in people without diabetes. Guidelines recommend individualisation of SBP targets; however, few data are available on the potential benefits that different targets might achieve. We have estimated 10-year risks for T2DM complications when targeting SBP levels between 160mmHg and 120mmHg to quantify the likely incremental benefits.

Materials and methods: We used a T2DM-specific computer simulation model (UKPDS Outcomes-Model version 2.0) to estimate 10-year event rates for T2DM complications: myocardial infarction (MI), stroke, blindness, amputation, and all-cause mortality using T2DM participant data from the Trial Evaluating Cardiovascular Outcomes with Sitagliptin Study. Complete baseline risk factor variables for age, sex, ethnicity, HbA1c, HDL, LDL, weight, smoking status, presence of albuminuria, atrial fibrillation and history of micro- and macrovascular events, were available for 5717 patients. Risk factor values were held constant over 10 years with 5 different simulations that allocated SBP levels to 160, 150, 140, 130 or 120mmHg. Cumulative relative risk reductions (cRRR) at each 10mmHg decrement were compared from 160mmHg using Kruskal-Wallis tests with $p<0.05$ as significant.

Results: Participants were mean (SD) age 66 (7.9) years, HbA1c 7.3 (0.6) %, LDL-cholesterol 2.3 (0.9) mmol/l, HDL-cholesterol 1.12 mmol/l (0.3), median (IQR) T2DM duration 9.8 years (5.1 to 15.6), with 28.3% women, 66.6% White ethnicity and 52.7% with history of smoking. For each 10mmHg SBP decrement from 160 to 120mmHg cRRRs differed significantly for all simulated outcomes; p for trend <0.001 (Table). When targeting a SBP of 140mmHg (current guideline target) compared to a baseline of 160mmHg cRRR estimates were 4.5%, 24.8%, 10.9%, 14.7% and 2.8% for MI, stroke, blindness, amputation and all-cause mortality respectively. When targeting a SBP of 120mmHg compared to 160mmHg the cRRR estimates for the same respective events were 10.0%, 44.9%, 20.9%, 27.4% and 5.2%.

Conclusion: These simulated complication rates could help inform the degree to which complications might be reduced by targeting particular SBP values in T2DM. Targeting a SBP of 140mmHg from 160mmHg, as recommended by guidelines, led to significant reductions in complication rates. Furthermore, there were continuous reductions in all modelled outcomes for complications including below 140mmHg.

10-year estimated absolute risks and 95% confidence intervals for individual macro- and micro-vascular events and mortality at different imposed SBP levels and corresponding relative risk reductions from an SBP of 160mmHg

SBP (mmHg)	160	150	140	130	120	p-value for trend

High brown fat activity as a marker of low subclinical atherosclerosis at 5-year follow-up in nondiabetic adults

J.R.H. Raiko[1], J. Orava[1], O. Raitakari[2], N. Savisto[3], K.A. Virtanen[1];
[1]Turku PET Centre, Turku University Hospital, [2]Centre of Applied and Preventive Cardiovascular Medicine, University of Turku, [3]Turku PET Centre, University of Turku, Turku, Finland.

Background and aims: Brown adipose tissue (BAT) activity correlates negatively with obesity and insulin resistance and BAT has been suggested to act as a protective factor against atherogenesis in animal models. We aimed to examine markers of subclinical atherosclerosis in a group of individuals who had 5 years earlier participated in positron-emission tomography (PET) studies with measurements of BAT activity.

Materials and methods: Study cohort (M/F=5/26, baseline age 41.4 ±7.9, baseline BMI 26.8±6.3kg/m^2) underwent PET imaging at baseline with [^{18}F]FDG (glucose uptake, GU) and [^{15}O]H_2O (perfusion) to measure BAT activity during cold exposure. At 5-year follow-up, ultrasound was performed to measure carotid intima-media thickness (IMT) in the common carotid (cIMT), carotid bulbus and internal carotid artery. Carotid distensibility (CDist) acts as marker of arterial elasticity and flow-mediated dilation (FMD) estimated endothelial function. Median values were used as cut-points for high cold-induced BAT activity (BAT GU>2.20 μmol/100g/min and perfusion>8.3 ml/100g/min).

Results: At follow-up, maximum IMT was 758±137 μm, Cdist was 93±48 μm/100 mmHg and maximum FMD was 6.0±6.2%. In high BAT activity group, bulbus IMT was lower (645±156 vs. 797±139 μm, P=0.017) and CDist higher (110±51 vs. 69±30 μm/100 mmHg, P=0.015) compared to low BAT activity groups. Baseline BAT perfusion associated with maximum cIMT at follow-up (β=-0.36, P=0.04) independently of 10-year Framingham cardiovascular disease risk score at baseline.

Conclusion: BAT activity at baseline correlated inversely with measurements of subclinical atherosclerosis at 5-year follow-up in asymptomatic

adults. Thus, cold-activated BAT glucose metabolism and perfusion may act as markers of low subclinical atherosclerosis in humans.

Serum levels of angiogenic growth factors in subjects with type 2 diabetes with and without peripheral artery disease

D.M. Bulumbaeva, V.V. Klimontov, N.B. Orlov, V.I. Konenkov;
Scientific Institute of Clinical and Experimental Lymphology, Novosibirsk, Russian Federation.

Background and aims: A growing body of evidence indicates abnormalities of angiogenesis in hyperglycemic conditions. However, the features of humoral regulations of angiogenesis in diabetic macrovascular complications remain to be clarified. The aim of our study was to assess the panel of circulating regulators of angiogenesis in type 2 diabetic subjects in relation to peripheral artery disease (PAD).
Materials and methods: We observed 196 patients with type 2 diabetes, 43 M/153 F, 43-70 years of age. The presence of PAD was verified by duplex ultrasound. The levels of vascular endothelial growth factor A, C and D (VEGF-A, VEGF-C, VEGF-D), placental growth factor (PLGF), angiopoietin-2, epidermal growth factor (EGF), heparin-bound EGF-like growth factor (HB-EGF), endoglin, soluble Fas ligand (sFASL), insulin-like growth factor-binding protein-1 (IGF-BP1), transforming growth factor α (TGF-α), and urokinase plasminogen activator (uPA) in blood serum were assessed by Multiplex assay and compared to control (25 healthy subjects matched by age and sex).
Results: The ultrasound sings of PAD were detected in 97 observed diabetic subjects, including 11 subjects with critical limb ischemia (CLI). Patients with PAD, as compared to those without, had increased serum levels of VEGF-A (p=0.004), VEGF-D (p=0.003), PLGF (p=0.0002), endoglin (p=0.03), sFASL (p=0.01), HB-EGF (p=0.01), TGF-α (p=0.0009) and uPA (p=0.02). The concentrations of EGF and angiopoetin-2 tended to be increased (p=0.1 and p=0.06 respectively). The levels of other regulators demonstrated no significant differences between diabetic groups. Among patients with PAD, the presence of CLI was associated with higher levels of VEGF-A (p=0.02) and endoglin (p=0.047). When compared to control, diabetic patients with non-affected low limb arteries demonstrated decreased concentrations of VEGF-A (p=0.04), VEGF-C (p=0.02), endoglin (p=0.03), PLGF (p=0.03), and uPA (p=0.01). Meantime, no differences were observed between diabetic subjects with PAD and healthy individuals. The concentrations of angiogenic factors were not related to age, body mass index, diabetes duration and glycaemic control.
Conclusion: The obtained results demonstrate the failure of humoral regulation of adaptive angiogenic response in type 2 diabetic subjects with PAD.

Fatty acid binding protein-4 predicts MACE events in PAD patients only in those without diabetes

C. Hoebaus, C.T. Herz, R. Koppensteiner, G.-H. Schernthaner;
Internal Medicine II, Medical University Vienna, Vienna, Austria.

Background and aims: The adipokine fatty acid binding protein-4 (FABP4) is primarily produced by adipocytes and macrophages. FABP4 increases in type 2 diabetes mellitus (T2DM) and is associated with diabetic nephropathy. It promotes atherosclerosis development in the animal model and is associated with coronary artery disease plaque severity. This study evaluates a possible influence of FABP4 on cardiovascular outcome in patients suffering from peripheral artery disease (PAD) in relation to glucose metabolism.
Materials and methods: This study included 327 PAD patients (109 female, 218 male, Fontaine stage I-II, 124 T2DM). Patients were followed for the occurrence of cardiovascular events (myocardial infarction, stroke and death) for five years. Baseline fasting FABP4 was assessed using bead-based multiplex assay with a sensitivity of 95.7 pg/mL. Mann-Whitney U test, univariate and multivariable regression modeling were applied as appropriate.
Results: FABP4 serum levels were significantly lower in patients without diabetes (15.3 (9.1, 21.5) ng/mL) compared to PAD patients with T2DM (17.2 (10.9, 25.6) ng/mL, p=0.01). FABP4 was significantly linked to fasting insulin (R=0.202, p=0.002) and fasting C-peptide (R=0.405, p<0.001). Additionally, FABP4 was significantly connected to 2h-oGTT insulin (R=0.190, p=0.001), 2h-oGTT C-peptide (R=0.266, p<0.001), and 2h-oGTT glucose (R=0.120, p=0.033) of the oral glucose tolerance test. Serum FABP4 levels showed a significant association with the classical MACE endpoint (death, non-lethal myocardial infarction, non-lethal stroke) (p=0.038). In subgroup analysis revealed a more pronounced association of MACE and FABP4 in those without diabetes (p=0.002) resulting in a HR of 1.7 (95% CI: 1.22-2.42) per intra-quartile range increase. This association not significantly modified by adjustment for patient age, gender, LDL-cholesterol, systolic blood pressure, body mass index, c-reactive protein, kidney function (MDRD eGFR), and fasting insulin levels (HR 1.83 (95% CI 1.08-3.10, p=0.026). In the T2DM subgroup no significant link between FABP4 and MACE was found (p=0.873).
Conclusion: This is the first report on the impact of elevation of circulating FABP4 levels on cardiovascular events in peripheral artery disease. However, this association of FABP4 and MACE is only present in the absence of T2DM irrespective of other established risk factors.

PS 101 Cardiovascular intervention in mice and men

1144

Empagliflozin reduces LV mass and improves diastolic function in an experimental model of heart failure with preserved ejection fraction

K. Connelly, Y. Zhang, K. Thai, G. Kabir, J.-F. Desjardins, R. Gilbert;
Medicine/Cardiology, Keenan Research Centre in the Li Ka Shing Knowledge Institute, St. Michael's Hospital and University, Toronto, Canada.

Background and aims: Hypertension and volume overload are key factors that contribute to the diabetic patient's propensity to develop heart failure with preserved ejection fraction (HFpEF) wherein the expansion of extracellular fluid volume not only precipitates the congestive manifestations of heart failure, dyspnoea and oedema, but also leads to adverse cardiac remodelling that further exacerbate the extent of cardiac dysfunction. We hypothesised that by inducing a mild osmotic diuresis and thereby reducing volume overload, SGLT2 inhibition with empagliflozin would attenuate the adverse functional and structural manifestations in an experimental model of HFpEF, the uni-nephrectomised deoxycorticosterone-salt (DOCA Salt) rat model.

Materials and methods: Experiments were conducted in male Sprague-Dawley rats according to standard protocol. Rats underwent unilateral nephrectomy (UNX) followed one week later by the administration of DOCA with 1% saline as drinking water ad libitum. Animals were randomised to receive either empagliflozin or vehicle with administration to coincide with the DOCA implants and followed for a further 4 weeks. Cardiac function was assessed by echocardiography and conductance catheterisation just prior to termination.

Results: When compared to control UNX animals, DOCA salt rats developed hypertension, signs of volume overload and HFpEF as manifested by significant ($p<0.05$) (i) increased systolic blood pressure; (ii) increased heart weight; (iii) reduced haematocrit, a marker of volume overload; (iv) increased lung weight, an index of pulmonary interstitial ± alveolar oedema; and (v) prolonged Tau and reduced dp/dt min, markers of dysfunction in the early, energy-dependent phase of diastole. See Table 1. Without affecting blood pressure, empagliflozin significantly ($p<0.05$) reduced heart weight, increased haematocrit, lessened lung weight and attenuated the abnormalities in Tau and dp/dt min when compared with untreated DOCA rats. In addition, empagliflozin also increased ejection fraction.

Conclusion: DOCA salt UNX animals are a model of heart failure with preserved ejection fraction demonstrating evidence of diastolic dysfunction with pulmonary congestion. Empagliflozin therapy improved LV mass and reduced diastolic dysfunction, key markers of HFpEF. The role of SGLT2 inhibition as a strategy for treating HFpEF merits further investigation.

Effects of saturated, mono- and poly-unsaturated fatty acids and effects of the GLP-1 analogue exendin-4 on survival of human cardiospheres and cardiac progenitor cells

R. D'Oria[1], M.A. Incalza[1], C. Caccioppoli[1], V. Andrulli Buccheri[1], V. Margari[2], D. Paparella[3], A. Natalicchio[1], S. Perrini[1], F. Giorgino[1], L. Laviola[1];
[1]Endocrinology & Metabolic Diseases, University of Bari, [2]Cardiac Surgery, Santa Maria Hospital, [3]Cardiac Surgery, University of Bari, Bari, Italy.

Background and aims: Mono- and polyunsaturated fatty acids exert beneficial effects on the cardiovascular system, whereas saturated fatty acids are associated with cardiovascular damage. The vitality of human cardiac progenitor cells (hCPC) and human cardiospheres (hCS) is essential for healthy myocardial tissue homeostasis. GLP-1 and its analogues exert prosurvival effects in cardiac cells. Thus, we investigated the effects of saturated, mono- and poly-unsaturated fatty acids and the protective effects of the GLP-1 analog exendin-4 on the viability of hCPC and hCS.

Materials and methods: hCPC and hCS were isolated from human right auricle biopsies and exposed to different concentrations of palmitate, oleate or eicosapentaenoic acid (EPA) up to 24 h. Apoptosis was assessed by caspase-3 cleavage and ELISA. Autophagy was evidenced by autophagosome labeling and immunoblotting of LC3-II and beclin1. Ceramide accumulation was evidenced by immunofluorescence. The expression of ceramide synthase-5 (CerS5), a key enzyme in *de novo* synthesis of ceramide, was studied by quantitative RT-PCR and immunoblotting.

Results: Palmitate, but not oleate or EPA, induced apoptosis of hCPC. Exposure to palmitate was also associated with impaired hCS isolation and increased hCPC autophagy, as well as it augmented CerS5 expression and ceramide accumulation in hCPC. However, both CerS5 inhibition with fumonisin-B1 and CerS5 knockdown with a specific siRNA reduced palmitate-induced apoptosis and autophagy. Noteworthy, pretreatment with exendin-4 preserved hCS isolation and reduced the palmitate-induced CerS5 expression, ceramide biosynthesis and hCPC apoptosis and autophagy. Co-incubation with the GLP-1 receptor (GLP-1R)

antagonist exendin(9-39), or inhibition of GLP-1R signaling with the PKA inhibitor H89 or by siRNA-mediated knockdown of the GLP-1R fully abolished the ability of exendin-4 to prevent apoptosis and autophagy.
Conclusion: Palmitate promotes apoptosis in hCPC, whereas oleate and EPA appear to have no impact on hCPC viability. Exendin-4 prevents the palmitate-induced abnormalities of hCPC and hCS by counteracting ceramide generation. Hence, GLP-1 and its analogues may limit the lipotoxic damage in the human heart by preserving the viability of myocardial progenitors.

Anti-atherogenic effects of liraglutide independent of the AMPK pathway in diabetic apolipoprotein E-null mice

M. Koshibu, Y. Mori, H. Kushima, K. Kohashi, M. Hiromura, M. Terasaki, T. Fukui, T. Hirano;
Showa University School of Medicine, Tokyo, Japan.

Background and aims: Accumulating evidence supports the anti-atherogenic effect of glucagon like peptide (GLP)-1 in addition to its glucose lowering effect. Among various mechanisms proposed, AMP-activated protein kinase (AMPK) has been demonstrated as a central molecule mediating this effect of GLP-1. However, whether GLP-1 could suppress atherosclerosis independent of the AMPK pathway remains unclear.
Materials and methods: Male apolipoprotein E-null mice (BalBc-background) were intra-peritoneally injected with 100 mg kg^{-1} d^{-1} of streptozotocin for 5 consecutive days at 15 w/o, following which, they were again injected with streptozotocin at 50 mg kg^{-1} d^{-1} at 17 w/o. At 20 w/o, mice with blood glucose levels over 11 mmol/L were used for experiments. The diabetic mice were switched to a western diet (0.15% cholesterol and 30% fat), and were subcutaneously implanted with two osmotic pumps for agent delivery: one for saline or liraglutide 17 or 107 nmol kg^{-1} d^{-1} (low and high dose, respectively) and the other for saline or an AMPK inhibitor dorsomorphine hydrochloride (25 mg kg^{-1} d^{-1}). Thioglycolate-induced peritoneal macrophages and vessel samples were collected after 4 weeks.
Results: The diabetic mice showed severe hyperglycaemia (fasting blood glucose, 15±2 mmol/L; HbA1c, 8.9±0.4%) and dyslipidaemia (total cholesterol, 12.7±0.2 mmol/L). Although HbA1c levels tended to be lower in liraglutide-treated mice, there was no significant difference in physiological and biochemical parameters between the groups. Both doses of liraglutide reduced atherosclerotic plaque burden (oil red O staining) and intra-plaque macrophage accumulation (MOMA-2 staining) at the aortic sinus by approximately 50%. In addition, plaque area on the aortic surface was lower in liraglutide-treated mice than those in saline-treated mice. Treatment with the AMPK inhibitor enhanced atherosclerosis compared to that observed with saline treatment, without affecting physiological and biochemical parameters. In the mice co-treated with the AMPK inhibitor, anti-atherogenic effects of low-dose liraglutide were completely abolished, while those of high-dose liraglutide were preserved. In the right brachiocephalic artery, an atherosclerotic lesion-prone site, both doses of liraglutide reduced the expression of interleukin-6 and monocyte chemotactic protein-1 as assessed by real time PCR. High-dose liraglutide suppressed the expression of these molecules in the presence of the AMPK inhibitor, while low-dose liraglutide failed to do so. In the induced peritoneal macrophages, high-dose liraglutide also suppressed the expression of pro-inflammatory cytokines in the presence of the AMPK inhibitor.
Conclusion: We demonstrated that both AMPK-dependent and independent mechanisms are involved in the anti-atherogenic effects of liraglutide, and that a higher dose of liraglutide is required to exert anti-inflammatory effects independent of AMPK.

GLP-1 secretion after myocardial infarction is amplified by linagliptin and leads to improved left ventricular function and mitochondrial respiratory capacity

M. Lehrke[1], S. Diebold[1], J. Möllmann[1], F. Kahles[1], A. Nickel[2], C. Maack[2], N. Marx[1];
[1]UK-Aachen, Aachen, [2]Saarland University Medical Center, Homburg, Germany.

Background and aims: The incretin hormone GLP-1 holds cardioprotective efficacy and was recently found to be increased by inflammatory stimuli. This study was performed to characterize the secretion of GLP-1 in response to myocardial infarction in mice and investigate its functional relevance.
Materials and methods: Myocardial infarction (MI) was induced by permanent LAD ligation in 6 week old, male C57BL/6J mice, the dipeptidylpeptidase-4 (DPP-4) inhibitor linagliptin (3 mg/kg p.o., bid) was given for 3 days before to LAD ligation, GLP-1 and exendin-9 (both 100 nM/kg i.p.) were given for 1 day before LAD ligation, experiments were performed in wild type and GLP-1 Receptor KO mice.
Results: Myocardial infarction (MI) led to a significant increase of circulating GLP-1 concentrations (from 7.9 pM to a maximum of 20.8 pM after 6 hours; n=6; $p<0.05$ in comparison to baseline and sham control). Prevention of GLP-1 degradation by pretreatment with linagliptin increased left ventricular contractility (10101± 1690 dp/dt by Millar catheter) relative to control (7830 ± 1445 dp/dt; $p<0.05$ n=8) 6h post MI, while antagonism of the GLP-1 receptor (exendin-9; 100 nM/kg i.p., 1 day pretreatment) worsened contractility (6469 ± 944 dp/dt; $p< 0.05$ n=7). Further, linagliptin failed to improve left ventricular function in GLP-1 receptor KO mice demonstrating a GLP-1 receptor-dependent effect. Mechanistically we found linagliptin or GLP-1 pretreatment to similarly increase myocardial AMPK-activation in non-infarcted tissue (1.6 fold induction by linagliptin; $p< 0.01$ n=6; 1.5 fold induction by GLP-1; $p<0.04$ n=4;), which was associated with improved respiratory capacity of isolated mitochondria from non-infarcted myocardial tissue (2 fold induction by GLP-1; $p<0.04$ n=6; 1.7 fold induction by DPP-4 inhibition; $p< 0.04$ n=7) detected by Clark electrode.
Conclusion: Myocardial infarction is a GLP-1 secreting stimulus, which improves left ventricular function in a GLP-1 receptor dependent manner. This is amplified by linagliptin dependent DPP-4 inhibition leading to AMPK-activation and improved mitochondrial respiration of cardiomyocytes in non-infarcted tissue.

Effect of liraglutide on physical performance in type 2 diabetes (LIPER2): a randomised, double-blind, controlled trial

A.M. Wägner[1,2], G. Miranda-Calderín[3], M. Alberiche-Ruano[1], M.J. López-Madrazo[1], A. Ugarte-Lopetegui[3], H. Marrero-Santiago[4], L. Suárez-Castellano[4], C. Aleman[3], N. Castillo-García[3], C. Martínez-Mancebo[5], A. Díez-del-Pino[6], F.J. Nóvoa-Mogollón[1];
[1]Endocrinology, Complejo Hospitalario Universitario Insular Materno-Infantil, [2]Instituto Universitario de Investigaciones Biomédicas y Sanitarias (IUIBS), Universidad de Las Palmas de Gran Canaria, [3]Rehabilitation and Physical Medicine, Complejo Hospitalario Universitario Insular Materno-Infantil, [4]Cardiology, Complejo Hospitalario Universitario Insular Materno-Infantil, [5]CS Maspalomas, Gerencia de Atención Primaria. Servicio Canario de la Salud, [6]Hospital Pharmacy, Complejo Hospitalario Universitario Insular Materno-Infantil, Las Palmas de Gran Canaria, Spain.

Background and aims: Preclinical studies and small clinical trials suggest that glucagon-like peptide 1 (GLP1) may have a positive effect on ventricular function. A clinical trial showed reduced cardiovascular

events in patients with type 2 diabetes treated with the GLP1 analogue liraglutide. The aim of this study was to assess the effect of liraglutide on measures of cardiac function and physical performance in patients with type 2 diabetes.

Materials and methods: LIPER 2 is a phase IV, randomized, double-blind, placebo-controlled, parallel-design trial. Patients with type 2 diabetes and an HbA1c of 7-10% on oral agents (except DPP4 inhibitors) and/or intermediate/long-acting insulin were randomised (computer-generated sequence, ratio 1:1) to receive liraglutide 1.8mg/d vs placebo for 6 months. The primary end-point was the maximal oxygen consumption (VO2 max) during a cycle ergometry. Other end-points included distance covered during a 6-min walk test, left ventricular ejection fraction and other measures of ventricular systolic and diastolic functions assessed by echocardiography (following international guidelines), heart rate, blood pressure, pro-brain natriuretic peptide, C-reactive protein, HbA1c, lipids, apolipoprotein B, body weight and waist girth. Safety end-points were also monitored. Intention to treat analysis was performed (all randomised patients included). Last observation carry forward was performed for missing data.

Results: Twenty four patients (15 women), aged 52 (11.7) years, with 8.7 (5.8) years' diabetes duration, BMI 34.98 (6.2) Kg/m^2, HbA1c 8.2 (0.68)% were randomised to liraglutide (12) or placebo. There were no differences in VO_2máx (17.98 (4.8) vs 15.90 (4.96) ml/Kg/min, p>0.1), VE/VCO2 slope (30.18 (4.8) vs 32 (4.49)), left ventricular ejection fraction, measures of diastolic function such as E/E', or in the 6 min walk test (530.7 (86) vs 503.9 (84) metres) at 6 months. There was a trend towards lower maximal systolic blood pressure during the ergometry (171.7 (24.4) vs 192.5 (25.6) mmHg, p=0.052), as well as lower HbA1c (6.7 vs 7.7% p=0.005) at the end of the study in the liraglutide group. There were no severe adverse events. All the patients receiving liraglutide (1 drop-out) and 25% of those receiving placebo reported gastro-intestinal symptoms. Amylase and lipase were higher in the treated group.

Conclusion: In this small study, liraglutide improved glycaemic control in type 2 diabetes, but did not show significant effects on physical performance or myocardial function. Gastrointestinal symptoms were very common.

Effect of cilostazol, a phosphodiesterase III inhibitor, on coronary artery stenosis and plaque characteristics in patients with type 2 diabetes

D.-H. Lee[1], E. Chun2[2], S. Choi[1], H. Jang[1], S. Lim[1];
[1]Internal Medicine, Seoul National University Bundang Hospital, [2]Radiology, Seoul National University Bundang Hospital, Seongnam-City, Republic of Korea.

Background and aims: Cilostazol is an antiplatelet agent that inhibits phosphodiesterase III, increases cAMP concentrations and consequently inhibits platelet aggregation. Cilostazol also has beneficial effect on vascular smooth muscle cell, endothelial cell and lipid metabolism. Therefore, it may be effective in treatment of macrovascular complication in diabetes. We performed a prospective interventional study to evaluate the effect of cilostazol compared with aspirin in Korean diabetic patients with subclinical coronary atherosclerosis.

Materials and methods: One hundred diabetic patients (64 men, ages 60.9 ± 9.1 years) who had mild to moderate atheroma evaluated with coronary multidetector-row CT (MDCT) were randomly assigned to either cilostazol 200 mg/day (CTZ group) or aspirin 100 mg/day (ASA group) (n = 50 each) for 12 months. Coronary artery calcium score (CACS) and coronary artery stenosis and plaque volume were investigated. Primary outcome was change of coronary artery disease assessed by coronary MDCT. Secondary outcomes included change in risk factors of atherosclerosis such as glucose and lipid metabolism and inflammatory parameter.

Results: The CACS was increased in both groups (316.6 ± 525.9 to 372.2 ± 575.2 in CTZ group, p <0.05 and 328.0 ± 481.7 to 388.5 ± 515.2, p <0.05 in ASA group). In CTZ group, there was significant decrease in maximal coronary stenosis (48.1 ± 17.9 to 38.8 ± 24.6%, p = 0.010), however, there was a small insignificant decrease in ASA group (41.7 ± 14.3 to 39.5 ± 13.3%, p = 0.118). The total plaque volume decreased from 75.2 ± 53.1 to 64.8 ± 52.2 mm^3 in CTZ group and slightly decreased from 74.9 ± 56.5 to 72.4 ± 55.3 mm^3 in the ASA group (p = 0.020 and p = 0.867, respectively). Furthermore, in CTZ group, non-calcified plaque volume decreased significantly (17.6 ± 9.5 to 11.5 ± 3.6 mm^3, p = 0.037) and calcified plaque volume also decreased but statistically insignificant (59.7 ± 48.8 to 52.9 ± 47.2 mm^3, p = 0.074). However, in ASA group, there were insignificant differences both in non-calcified and calcified plaque volumes (p >0.05 for all). Triglycerides and HDL-cholesterol improved significantly in CTZ group (135.5 ± 68.3 to 114.6 ± 46.5 mg/dL, p = 0.017 in triglycerides and 47.8 ± 10.1 to 51.2 ± 10.4 mg/dL, p = 0.011 in HDL-cholesterol).

Conclusion: The present study demonstrated that cilostazol treatment decreased coronary artery plaque, particularly in noncalcified portion and improved lipid profile. Cilostazol is a potential treatment option for preventing the progression of coronary atherosclerosis in patients with diabetes.

Higher one-year mortality in patients with diabetes and ST-segment elevation myocardial infarction undergoing primary percutaneous coronary intervention

P. Lundman[1,2], S. Karayiannides[1,3], O. Froebert[4], S. James[5], B. Lagerqvist[5], A. Norhammar[6];
[1]Department of Clinical Sciences, Karolinska Institutet, Stockholm, [2]Department of Cardiology, Danderyd University Hospital, Stockholm, [3]Department of Internal Medicine, Danderyd University Hospital, Stockholm, [4]Department of Cardiology, Faculty of Health, Orebro University, Orebro, [5]Department of Medical Sciences, Cardiology and Uppsala Clinical Research center, Uppsala University, Uppsala, [6]Cardiology Unit, Department of Medicine, Karolinska University Hospital, Karolinska Institutet, Stockholm, Sweden.

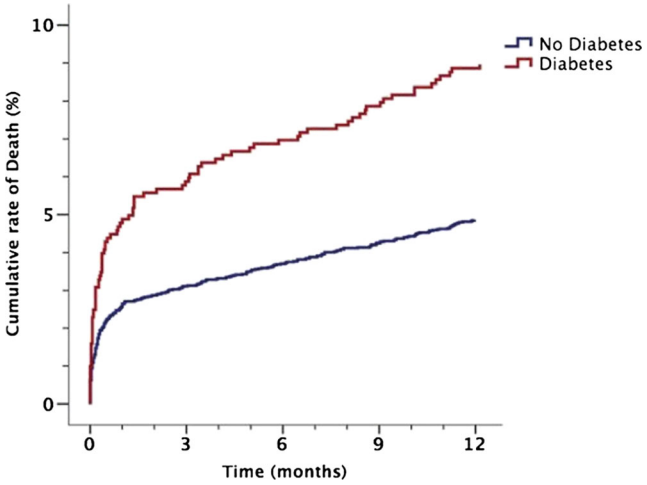
Background and aims: Patients with diabetes mellitus have a worse prognosis after acute coronary syndromes than patients without diabetes. Outcomes in patients with diabetes after ST-segment elevation myocardial infarction (STEMI) in the era of modern interventional treatment and antiplatelet therapy are less well studied. The aim is to characterise outcomes and complications in a contemporary population with diabetes and STEMI undergoing primary percutaneous coronary intervention (PCI).

Materials and methods: In the registry-based randomised Thrombus Aspiration in ST-Elevation myocardial infarction in Scandinavia (TASTE) trial, 7244 patients with STEMI were randomised to undergo manual thrombus aspiration followed by PCI or to undergo PCI alone. Thrombus aspiration did not affect mortality at one year in the 1005 patients (13.9%) with diabetes [Hazard ratio (HR) 1.04; CI 0.69-1.58, p=0.839]. Therefore, all patients with diabetes, irrespective of randomisation in TASTE, were studied as one cohort. All patients were followed for incidence of all-cause mortality, myocardial infarction or stent thrombosis until one year after index event. HRs were calculated using a Cox proportional hazard regression model adjusted for comorbidities.

Results: Patients with diabetes were older (mean age 67.6 vs 66.0 years, p<0.001), more often had a previous myocardial infarction (19.9 vs 10.3%, p<0.001) and undergone previous PCI (17.3 vs 8.4%, p<0.001).

Thrombus grade did not differ between patients with and without diabetes (Grade 0 to Grade 5, p=0.909) and neither did the type of affected coronary vessel. Pharmacological cardiovascular treatment did not differ between groups, but the use of drug eluting stents was higher in patients with diabetes (59.0 vs 48.4%, p<0.001). After adjustment for comorbidities, diabetes independently increased the risk for mortality (HR 1.57; CI 1.23-2.00, p<0.001), but was not an independent risk factor for future myocardial infarction or stent thrombosis.

Conclusion: Diabetes remained an adverse prognostic risk factor in this contemporary setting, resulting in increased one-year mortality in a large cohort of patients with STEMI treated with PCI. This was not influenced by thrombus aspiration and not explained by a higher thrombus burden or differences in cardiovascular medical therapy compared to patients without diabetes.



Clinical Trial Registration Number: NCT01093404

Visit-to-visit blood pressure variability and cardiovascular outcomes in patients with type 2 diabetes following acute coronary syndromes in the EXAMINE trial

W.B. White[1], W. Cushman[2], G. Bakris[3], R. Bergenstal[4], S. Heller[5], C. Mehta[6], S. Nissen[7], F. Zannad[8], Y. Liu[9], C. Cannon[9];
[1]Cardiology Center, University of Connecticut, School of Medicine, Canton, [2]University of Tennessee College of Medicine, Memphis, [3]University of Chicago Medicine, Chicago, [4]International Diabetes Center, Minneapolis, USA, [5]University of Sheffield, Sheffield, UK, [6]Harvard School of Public Health, Boston, [7]Cleveland Clinic Foundation, Cleveland, USA, [8]University of Nancy, Nancy, France, [9]Baim Clinical Research Institute, Boston, USA.

Background and aims: Primary cardiovascular (CV) prevention studies have shown that high visit-to-visit systolic BP variability (VVV) may be associated with an increased risk of CV events. However, little is known about VVV of the BP and secondary CV outcomes in a very high CV risk population.

Materials and methods: We evaluated CV event rates in EXAMINE, a CV outcomes safety trial in 5380 patients with type 2 diabetes following acute coronary syndromes (ACS) randomized to the DPP-4 inhibitor alogliptin or placebo, according to VVV of the SBP calculated during the first 6 months post-randomization. The risks of major adverse CV events (MACE) and CV death or heart failure (HF) in all randomized patients were analyzed using a Cox proportional hazards model with adjustment for baseline covariates in quartiles of systolic BP VVV from 6 months to the end of the post-randomization period. The lowest (1st) quartile of VVV was the reference group. Events were prospectively adjudicated by an independent committee blinded to treatment assignment.

Results: Mean systolic BPs were higher in quartile 4 (133 mmHg) but quartiles 1, 2 and 3 were the same (128 mmHg). Baseline history of HF was higher in quartile 1 (34%) than in the quartiles 2, 3, and 4 (24-26%). Other clinical and demographic characteristics at baseline were comparable in the quartile groups of VVV of the BP. The rates of MACE were higher in quartiles 2 through 4 of VVV vs. quartile 1; comparable findings were found for CV death or HF compared to quartile 1 [Table]. Results for the event components of all-cause mortality, cardiovascular death, hospitalized heart failure, non-fatal myocardial infarction, stroke also had similar patterns to MACE.

Conclusion: In patients with type 2 diabetes and a recent ACS, systolic BP VVV was associated with worsened CV outcomes. Potential mechanisms of increased VVV of the BP include arterial stiffness, endothelial dysfunction/subclinical inflammation, and poor adherence to antihypertensive therapy. Studies designed to better understand the reasons for high VVV of BP may provide clinically useful information for reducing CV events in high CV risk patients.

SBP VVV group	Number of patients	Incident rate for MACE (%)	Adjusted MACE HR (95% CI) for quartiles of systolic BP VVV*	Incident rate for CV death or heart failure (%)	Adjusted CV death or HF HR (95% CI) for quartiles of systolic BP VVV*
Quartile 1	1200	7.4	**Reference**	4.7	**Reference**
Quartile 2	1191	12.0	1.60 [1.15, 2.23]	8.9	1.70 [1.12, 2.59]
Quartile 3	1222	15.7	1.43 [1.02, 1.99]	9.6	1.45 [0.95, 2.22]
Quartile 4	1203	16.8	1.85 [1.35, 2.55]	13.4	1.99 [1.33, 2.97]

Total cardiovascular events analysis of the EXAMINE trial of patients with type 2 diabetes and recent acute coronary syndrome

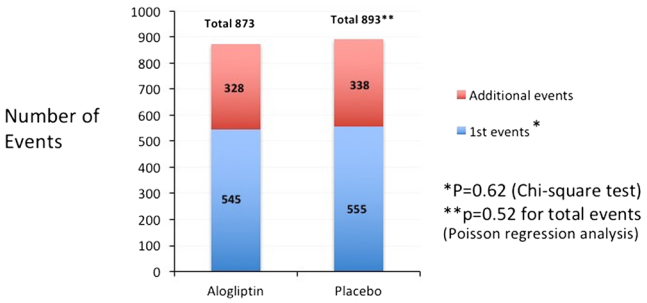
C.P. Cannon[1], M.A. Cavender[2], Y. Liu[3], J.M. Massaro[4], R.M. Bergenstal[5], C.R. Mehta[6], F. Zannad[7], W.B. White[8];
[1]Harvard Clinical Research Institute, Boston, [2]University of North Carolina, Chapel Hill, [3]Brigham and Women's Hospital and Harvard Medical School, Boston, [4]Boston Univ Sch of Public Health, Boston, [5]International Diabetes Center at Park Nicollet, St. Louis Park, [6]Harvard School of Public Health, Boston, USA, [7]Inserm, Université de Lorraine and CHU, Vandœuvre-lès-Nancy, France, [8]University of Connecticut Health Center, Canton, USA.

Background and aims: The Examination of Cardiovascular Outcomes with Alogliptin versus Standard of Care (EXAMINE) trial showed that alogliptin, an inhibitor of dipeptidyl peptidase 4, did not increase the rates of major adverse cardiovascular events versus placebo in patients with Type 2 Diabetes (T2DM) and recent acute coronary syndrome (ACS). Published analyses reported time to first event. We now report first, recurrent and total major adverse cardiovascular events (MACE) and components to provide a comprehensive picture of total cardiovascular outcomes.

Materials and methods: Patients with T2DM with a diagnosis of ACS within the previous 15 to 90 days were randomly assigned to alogliptin vs placebo and followed for a median of 18 months. We evaluated the composite

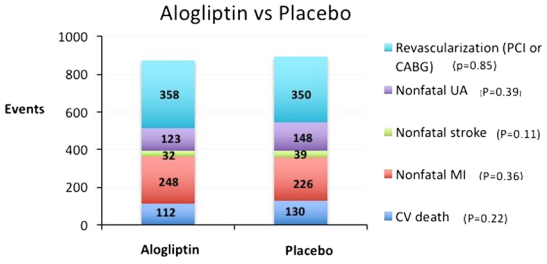
endpoint of CV death, nonfatal MI, nonfatal stroke, unstable angina or revascularization. We analyzed first, recurrent and total events during follow-up.
Results: There were 1100 first events and 666 additional events (328 in alogliptin and 338 in placebo). There was no significant difference in the number of first (Kruskal-Wallis test, p=0.54) or total events (Poisson regression, p=0.52) in the alogliptin vs placebo groups (Figure 1A). There were also no significant differences between treatments with respect to distribution of types.(Figure 1B).
Conclusion: Among a group of patients with T2DM and recent ACS, treatment with alogliptin did not increase the risk of 1st or total events as compared with placebo. These data support the cardiovascular safety of continued alogliptin therapy in a population with DM and CAD at high risk for recurrent MACE.

Figure 1A:
Number of First, Additional and Total events,
Alogliptin vs Placebo



There was no significant difference in the composite outcome between the two groups by the Finkelstein-Schoenfeld analysis (p=0.55)

Figure 1B
Total Number of Primary Endpoint Events by Type,
Alogliptin vs Placebo



There were no differences in types of events between the Alogliptin and Placebo groups
(p values per Poisson regression analysis)

Exogenous H_2S improves heart function in streptozotocin-induced type 1 diabetes

N. Dorofeyeva, G. Vorobyov, V. Sagach;
Department of Blood Circulation, A. A. Bogomoletz Institute of Physiology, NAS of Ukraine, Kiev, Ukraine.

Background and aims: Hydrogen sulfide (H2S) is a gas transmitters, that has important role in the regulation of cardiovascular function.We have recently shown that exogenous H2S improves diastolic heart function in hypertension and aging. Diabetes is also accompanied by heart and endothelium dysfunction. The aim of work is to investigate the effect of hydrogen sulfide on heart function in streptozotocin-induced diabetic rats.
Materials and methods: Rats were divided into control and diabetic groups. Type-1 Diabetes mellitus was induced with a single intraperitoneally injection of streptozotocin (60 mg/kg). After 2 month animals with a random blood glucose level >15 mmol/l were considered to be diabetic and were included in the study. The functional cardiohemodynamic indicators registered via microcatheter and Pressure-Volume System. The donor of the hydrogen sulfide NaHS (15,8 mg/kg) was administered intraperitoneally.
Results: It was shown that exogenous donor of the hydrogen sulfide (NaHS) improves pumping function of diabetic heart. Stroke volume increases by 43,1% (p<0,05), cardiac output increases by 25,4% (p<0,05). Ejection Fraction increses by 48,6% (p<0,05). We found,that after NaHS end-systolic pressure decreases by 17,2% and index of contractility was decresed. The end-diastolic myocardial stiffness decreased by 20,1% (P<0,05) in streptozotocin - induced diabetic rats. After NaHS the arterial stiffness was decreased by 24%, that indicates an improvement the ventriculo-arterial coupling.
Conclusion: Thus, NaHS improves pumping heart function, end-diastolic myocardial stiffness and arterial stiffness reduced and end-systolic pressure decresed in streptozotocin - induced diabetic rats.

Plasma copeptin, a surrogate of vasopressin, and risk for cardiovascular morbidity and mortality in people with type 2 diabetes

G. Velho[1], S. Ragot[2,3], R. El Boustany[1], P.-J. Saulnier[2,3], M. Fraty[2,3], K. Mohammedi[1,4], F. Fumeron[1,5], N. Bouby[1], L. Bankir[1], M. Marre[4,5], S. Hadjadj[2,3], R. Roussel[1,5];
[1]UMRS 1138, Centre de Recherche des Cordeliers, INSERM, Paris, [2]CIC 1402, INSERM, Poitiers, France, [3]Service d'Endocrinologie, CHU de Poitiers, Poitiers, [4]Service de Diabétologie - DHU FIRE, Assistance Publique Hôpitaux de Paris - Hôpital Bichat, Paris, [5]UFR de Médecine, Université Paris Diderot, Sorbonne Paris Cité, Paris, France.

Background and aims: Diabetic nephropathy is associated with increased risk of cardiovascular morbidity and mortality in people with diabetes. Experimental evidence supports a causal role for vasopressin (or antidiuretic hormone) in the development of chronic kidney disease and diabetic nephropathy through V2 receptor activation. Plasma copeptin, the COOH-terminal portion of pre-provasopressin and a surrogate marker of vasopressin, was shown to be positively associated with the development and progression of diabetic nephropathy, and with end stage renal disease in type 1 and type 2 diabetes. Here we assessed the association of plasma copeptin with the risk of cardiovascular events during follow-up in two prospective cohorts of French type 2 diabetic patients, and we examined if this association could be accounted for by deleterious effects of vasopressin on the kidney.

Materials and methods: We studied 3101 and 1461 unrelated type 2 diabetic patients from 2 French cohorts: DIABHYCAR and SURDIAGENE (microalbuminuria in 76% and 37%, and macroalbuminuria in 24% and 17% of participants at baseline, respectively). We considered the incidence during follow-up (median: 5 years) of a combined end point composed of CHD (myocardial infarction or coronary revascularisation), hospitalisation for congestive heart failure, and cardiovascular death. Copeptin concentration was measured in baseline plasma-EDTA samples by an automated immunoluminometric assay.
Results: The cumulative incidence of cardiovascular events was 18.7% (n=579) in DIABHYCAR and 30.5% (n=446) in SURDIAGENE. The incidence rate was 4.5 and 5.7 per 100 person-years, respectively. The cumulative incidence of cardiovascular events during follow-up by sex-specific tertiles of baseline plasma copeptin was 15.7% (T1), 18.7% (T2) and 21.7% (T3) in DIABHYCAR (p=0.002), and 20.7% (T1), 28.4% (T2) and 42.5% (T3) in SURDIAGENE (p<0.0001). Cox proportional hazards survival regression analyses confirmed the association of copeptin with cardiovascular events in both cohorts: adjusted HR with 95% CI for T3 vs. T1 was 1.39 (1.13 - 1.71), p=0.002 (DIABHYCAR), and 2.44 (1.91 - 3.13), p<0.0001 (SURDIAGENE), adjusted for sex, age, BMI, duration of diabetes, systolic and diastolic blood pressure, HbA1c, total cholesterol, and previous history of myocardial infarction at baseline. Associations remained significant when further adjusted for the estimated GFR and urinary albumin concentration (UAC) at baseline: adjusted HR 1.28 (1.03 - 1.58), p=0.03 (DIABHYCAR), and 1.66 (1.27 - 2.19), p=0.0003 (SURDIAGENE). No interaction was observed between plasma copeptin and eGFR (p=0.36) or UAC (p=0.53) categories on the risk of cardiovascular events in analyses of pooled cohorts.
Conclusion: Plasma copeptin is positively associated with severe cardiovascular events in people with type 2 diabetes. This association cannot be solely accounted for by the association of copeptin with kidney-related traits.

Hypoglycaemia increases platelet reactivity and promotes formation of proatherogenic platelet-leucocyte aggregates

A. Iqbal[1], M. Thomas[1], P. Novodvorsky[2], A. Bernjak[2], L. Birch[1], D. Lambert[1], L. Kay[1], F. Wright[1], L. Prince[1], S. Francis[1], R. Storey[1], I. Sabroe[1], S. Heller[2];
[1]Department of Infection, Immunity and Cardiovascular Disease, University of Sheffield, [2]Department of Oncology and Metabolism, University of Sheffield, Sheffield, UK.

Background and aims: Hypoglycaemia is emerging as a trigger for cardiovascular (CV) events observed in intensive glycaemic control of type 2 diabetes. Potential mechanisms include inflammation-induced thrombosis. High levels of circulating monocyte and neutrophil platelet aggregates (MPA & NPA) strongly increase CV risk. We hypothesised that hypoglycaemia increases platelet reactivity and MPA & NPA levels.
Materials and methods: Sixteen healthy volunteers underwent a hyperinsulinaemic hypoglycaemic (2.5 mmol/L) or euglycaemic (6.0 mmol/L) clamp. Blood was sampled at baseline and 60 minutes. Platelet aggregation induced by ADP 6.45 μM was measured using Multiplate impedance aggregometry. MPA and NPA were phenotyped and enumerated using multi-colour flow cytometry.
Results: Platelet aggregation increased following hypoglycaemia vs euglycaemia (AUC mean ± SEM: 74 ± 7 vs 53 ± 4; P<0.05). Total MPA (median [IQR] cells/μL: 106 [41-135] vs 51 [27-71]; P<0.05) and NPA (626 [471-820] vs 237 [71-786]; P<0.05) increased following hypoglycaemia vs euglycaemia. Hypoglycaemia increased intermediate monocyte specific MPA [11 cells/μL [5-15] vs 3 [2-9]; P<0.01) and non-classical monocyte MPA (P<0.01, Fig 1) with no significant change in classical monocyte MPA.
Conclusion: Hypoglycaemia increases platelet reactivity, MPA and NPA levels and leads to increased interaction between pro-inflammatory monocyte subsets and platelets. These novel data reveal mechanisms that may contribute to CV risk associated with diabetes and its therapy.

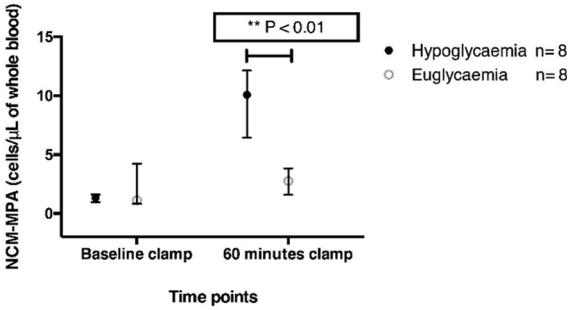

Figure 1: Effect of hypoglycaemia on the absolute number of circulating non-classical monocyte specific monocyte platelet aggregates (NCM-MPA). Data are presented as median with interquartile range.

Cardiovascular disease risk prediction in type 1 diabetes

B. Farran[1], S. McGurnaghan[1], L. Blackbourn[1], P.M. McKeigue[2], H.M. Colhoun[1,3], SDRN Epidemiology Group;
[1]The Institute of Genetics and Molecular Medicine, University of Edinburgh, [2]Old Medical School, Teviot Place, University of Edinburgh, Edinburgh, [3]Department of Public Health, NHS Fife, Kirkcaldy, UK.

Background and aims: The prevalence of type 1 diabetes (T1DM) continues to increase rapidly all over the world. T1DM is associated with an increased risk of cardiovascular disease (CVD). However, there are few comprehensive cohorts of subjects with T1DM and these often have small sample sizes, making it difficult to calculate event rates and build risk prediction models. We use recent data (2004-2014), on patients with T1DM, from a Scottish National dataset to calculate standardised incident CVD event rates and to build risk prediction tools.
Materials and methods: The study included 26680 adults from the Scottish population. Patient entry is defined as the latest of: 1/1/2004, date of diabetes diagnosis, date they turn 18 years of age, or date first evaluable for CVD events. Exit is defined as earliest of: 31/12/2014, death, last evaluable for events, or the date of first event. Follow-up time was split into one year intervals, where current age was time updated. Poisson regression was performed with backward selection, multivariable fractional polynomials and random forests to select the best model. Discrimination is measured using AUROC and calibration with Hosemer-Lemeshow tests.
Results: Incidence rates of CVD are falling with time, especially in the higher age bands. The overall incidence rates for males and females (standardised to the European Standard Population 2013) were 3858 and 3074 per 100,000 person years respectively. After removing patients with a prior CVD, 2449 people experienced a CVD event during follow-up, of which 1469 were male. Patients that develop CVD were older at diagnosis (and entry into the study), more likely to be ever-smokers, had higher systolic BP (SBP) and triglycerides, lower eGFR, and were more likely to be on anti-hypertensive treatment and statin therapy. A Poisson model fit using backwards elimination retained HbA_{1c}, weight, total cholesterol, SIMD, eGFR, HDL, diabetes duration, diagnosis year, current age, smoking status, gender, antihypertensive treatment, statin therapy, age^2 and age^3. This model yielded an AUC of 0.805. A forward selection model yielded an AUC of 0.804 with fewer variables. Random Forest

analysis dropped weight, height, SBP, gender, age at diabetes diagnosis, and diastolic BP as not being significant contributors to the outcome, giving an AUC of 0.802. Multivariable Fractional Polynomials gave the highest AUC at 0.809. Finally, we fit a model with age and gender interactions with all variables, and used a LASSO penalty to make the model more tractable. This gave an AUC of 0.806.

Conclusion: We show incidence rates using contemporary data on the national Scottish Type 1 diabetes population. We built models with good calibration and discrimination that can be used to calculate the individual risk estimates for patients, and this can be used for enabling clinical decisions such as initiating/stopping drug therapy.

Comparison of measures of aortic stiffness in asymptomatic patients with type 2 diabetes and association with outcomes

P.P. Swoboda, B. Erhayiem, R. Kan, A.K. McDiarmid, P. Garg, K.K. Witte, M.T. Kearney, R. Ajjan, J.P. Greenwood, S. Plein;
University of Leeds, Leeds, UK.

Background and aims: With aging there is progressive stiffening of the aorta that appears to be accelerated by risk factors including hypertension and diabetes. Cardiovascular magnetic resonance (CMR) can be used to reproducibly measure aortic stiffness without exposure to contrast agent or ionising radiation. The aim of this study was to establish if aortic stiffness measured by CMR is associated with adverse outcomes in asymptomatic patients with type 2 diabetes and to establish if it can be improved on treatment with renin-angiotensin-aldosterone (RAAS) inhibition.

Materials and methods: 94 asymptomatic patients with type 2 diabetes and no history of cardiac, renal or established microvascular disease underwent assessment of cardiovascular risk and CMR assessment of ascending aortic distensibilty (AAD), descending aortic distensibilty (DAD) and aortic pulse wave velocity (PWV). 25 of these patients with recent onset microalbuminuria were treated with RAAS inhibition and imaging repeated after one year. All 94 patients were followed up for 2.4 years for major adverse cardiovascular disease (CVD) events including silent myocardial infarction detected on late gadolinium enhancement CMR.

Results: 19 (20%) patients had at least one CVD event on follow up including silent MI on baseline scan 15 (16%), stroke 3 (3%), cardiovascular death 2 (2%), ST elevation MI 2 (2%), silent MI on follow up scan 1 (1%), percutaneous coronary intervention 2 (2%), heart failure 1 (1%) arrhythmia 1 (1%). On logistic regression only AAD had a significant association with CVD events; hazard ratio (HR) 0.49, 95% confidence interval 0.25-0.95, P=0.01, Table. The associations of DAD and PWV did not reach significance (P=0.19 and 0.45 respectively). AAD, DAD and PWV all had a significant association with age and 24 hour systolic blood pressure but only AAD had a significant association with glycaemic control, measured as HbA1c (Beta -0.016, P=0.04). The association between HbA1c and AAD persisted even after correction for age and hypertension. On treatment with RAAS inhibition, AAD, but not DAD or PWV, showed significant improvement from 1.51±1.15 to 1.97±1.07 10^{-3}mmHg^{-1}, P=0.007.

Conclusion: Ascending aortic distensibility measured by CMR is independently associated with poor glycaemic control and adverse cardiovascular events and appears to be reversible on treatment with RAAS inhibition. AAD is a promising surrogate marker for future longer term outcome studies. Table Logistic regression of the association between aortic stiffness and clinical factors with CVD events.

	Hazard Ratio	95% CI	P Value
AAD	**0.49**	**(0.25; 0.95)**	**0.01**

Short-term progression of coronary artery calcification in type 1 diabetes compared to matched controls

H.Ø. Hjortkjær[1], T. Jensen[2], K.F. Kofoed[1], H. Corinth[2], U.M. Mogensen[1], L. Køber[1], B.G. Nordestgaard[3], J. Hilsted[2];
[1]Department of Cardiology, Rigshospitalet, Copenhagen University Hospital, København Ø, [2]Department of Endocrinology, Rigshospitalet, Copenhagen University Hospital, København Ø, [3]Department of Clinical Biochemistry, Herlev Hospital, Herlev, Denmark.

Background and aims: Type 1 diabetes is associated with increased cardiovascular (CV) morbidity and mortality by mechanisms not fully understood. Coronary artery calcium (CAC) is associated with CV disease and progression of CAC is an independent predictor of mortality. The aim of this study was to examine whether short-term progression of CAC is increased in patients with type 1 diabetes compared with matched controls.

Materials and methods: Fifty-three normoalbuminuric patients with long-term (>10 years) type 1 diabetes were matched in a 1:2 ratio with 106 controls from the general population according to age, gender, and baseline CAC score and was examined through cardiac computed tomography scans at a mean (±SD) of 25 (3) months and 29 (5) months, respectively, for re-measurement of CAC score. Progression of CAC was determined according to the square root method, where progression was defined as a change ≥2.5 between the square root transformed values of follow-up and baseline CAC volume score.

Results: Forty of the 159 individuals had progression of CAC. Among patients with type 1 diabetes, 18 (34%) had progression of CAC compared to 22 (21%) of the controls (p=0.08). Due to adherence to treatment guidelines, patients with diabetes were more often on treatment with blood pressure-lowering medication and statins. In type 1 diabetes compared to controls blood pressure was mean (±SD) of 123/74 (13/7) mmHg vs. 142/88 (21/10) mmHg (p<0.001), LDL cholesterol was 2.4 (0.6) mmol/l vs. 3.3 (0.9) mmol/l (p<0.001), and BMI was 24.5 (3.0) kg/m^2 vs. 25.8 (3.7) kg/m^2 (p=0.03). There was no difference in smoking status. In multivariable logistic regression, adjusted for these risk factors of CV disease and risk factors of progression, including scan interval, type 1 diabetes was associated with an odds ratio of 4.0 (95 % CI 1.5 - 10.9, p<0.01) for progression of CAC. In patients with type 1 diabetes, HbA_{1C} was 63 (11) mmol/mol and diabetes duration was 33 (12) years.

Conclusion: To our knowledge, this is the first study to examine short-term progression of coronary artery calcium in patients with type 1 diabetes compared with matched controls from the general population. We found that even in well-treated, normoalbuminuric patients with type 1 diabetes, there was an odds ratio of 4.0 for short-term progression of CAC. This might explain some of the increased CV morbidity and mortality in patients with type 1 diabetes.

Long term prognostic value of coronary computed tomography angiography in asymptomatic elderly population including diabetic patients

S. Moon[1], Y. Kim[1], S. Lee[1], J. Bae[1], D. Lee[1], T. Oh[1], K. Kim[1], S. Choi[1], K. Park[2], H. Jang[1], S. Lim[1];
[1]Internal medicine, Seoul National University Bundang Hospital, [2]Internal Medicine, Seoul National University Hospital, Seoul, Republic of Korea.

Background and aims: There is still controversy about the long-term prognostic value of coronary computed tomography angiography (CCTA) for coronary heart disease (CHD) in asymptomatic individuals including diabetic patients. Also, CCTA's role among elderly population has not been established. We investigated the long-term prognostic value of CCTA in asymptomatic elderly patients with or without diabetes.

Materials and methods: A community based-cohort study of 470 asymptomatic elderly individuals (mean age 75.1 ± 7.3 years, 156 [33.2%] diabetic patients) who underwent CCTA and coronary calcium scoring (CACS) was conducted. Major adverse cardiac events (MACE) defined as composite of cardiovascular death, nonfatal myocardial infarction, unstable angina requiring hospitalization and late coronary revascularization were measured. CCTA findings were categorized by various means including the presence of proximal LAD or left main disease (pLAD/LM). CACS and conventional CHD risk factors related to Framingham risk score (Age, sex, systolic blood pressure, treatment of hypertension, diabetes, total cholesterol, HDL-cholesterol and current smoking status) were adjusted for analysis.

Results: There were 57 individuals (12.1%) with pLAD/LM findings for overall population and 18 (11.5%) for diabetic patients. During median follow up of 7.2 years (interquartile range: 6.8-7.3), MACE were occurred in 28 (6%) subjects among overall population and 10 (6.4%) among diabetic patients. Compared to individuals with negative pLAD/LM findings, positive group were significantly associated with MACE for overall population (4.4% [18 events] vs 17.5% [10 events]; hazard ratio (HR), 3.211 [95%CI 1.226-8.409], p = 0.018). Among diabetic patients, there were more significant association between pLAD/LM findings and MACE (2.9% [4 events] vs 33.3% [6 events]; HR, 14.050 [95%CI 1.406-140.388], p = 0.024).

Conclusion: Among asymptomatic elderly population, especially for diabetic patients, CCTA showed considerable prognostic value additive to conventional CAD risk factors and CACS over more than 6 years.

Risk of cardiac arrhythmias and electrophysiological responses during spontaneous hyperglycaemia in young people with type 1 diabetes

P. Novodvorsky[1], A. Bernjak[2], E. Chow[3], A. Iqbal[3], L. Sellors[1], S. Williams[1], R.A. Fawdry[1], R.M. Jacques[4], P.J. Sheridan[3], S.R. Heller[1];
[1]Academic Unit of Diabetes, Endocrinology and Metabolism, University of Sheffield and Sheffield Teaching Hospitals NHS Foundation Trust, [2]Academic Unit of Diabetes, Endocrinology and Metabolism and INSIGNEO Institute for In Silico Medicine, University of Sheffield, [3]Academic Units of Diabetes, Endocrinology and Metabolism and of Infection, Immunity and CVS disease, University of Sheffield and Sheffield Teaching Hospitals NHS Foundation Trust, [4]School of Health and Related Research, University of Sheffield, Sheffield, UK.

Background and aims: Little is known about the effects of hyperglycaemia on cardiac repolarisation and risk of cardiac arrhythmias. To our knowledge, frequencies of cardiac arrhythmias during hyperglycaemia have never been studied and data reporting the relation of hyperglycaemia and changes in QT_c-intervals are conflicting. Recently published animal and tissue culture studies suggest pro-arrhythmogenic effects of hyperglycaemia. We therefore examined the effects of spontaneous hyperglycaemia in young people with type 1 diabetes (T1D) on electrophysiological responses and risk of cardiac arrhythmias.

Materials and methods: Thirty-seven individuals with T1D (age <50 years, duration of diabetes >4 years) underwent 96 hours of simultaneous ambulatory ECG and blinded continuous interstitial glucose (IG) monitoring (CGM). Relative frequencies of arrhythmias were expressed as incident rate ratios (IRR). Heart rate, heart rate variability (HRV) (high frequency and normalised low frequency power) and cardiac repolarisation parameters (QT_c, T_pT_{end}) were established during hyperglycaemia (IG ≥ 15 mmol/l, duration ≥ 20 min) and compared to time-matched euglycaemia (IG 5 - 10 mmol/l) divided into night (23.00 - 7.00) and day.

Results: A total of 2395 hours of simultaneous ECG and CGM recordings were obtained. During hyperglycaemia (Fig.1), the risk of ventricular premature beats was higher at night (IRR 7.025, p=0.001), but lower during daytime (IRR 0.343, p=0.018) compared to euglycemia. Bradycardia was less frequent during both nocturnal and daytime hyperglycaemia (IRR 0.062, p<0.001 and IRR 0.010, p=0.001, respectively). No differences in heart rate, HRV and QT_c duration were detected during nocturnal or daytime hyperglycaemia in comparison to time-matched euglycaemia. T_pT_{end} interval was shortened during nocturnal hyperglycaemia (p=0.003).

Conclusion: We found increased risk of ventricular premature beats during nocturnal hyperglycaemia, but this risk was low during daytime hyperglycaemia. Bradycardia was less common during hyperglycaemia during both night and day. No significant differences in heart rate, HRV or QTc duration were detected during hyperglycaemia which suggests different pro-arrhythmogenic mechanisms compared to hypoglycaemia. These findings are novel but require further studies to etablish their clinical significance.

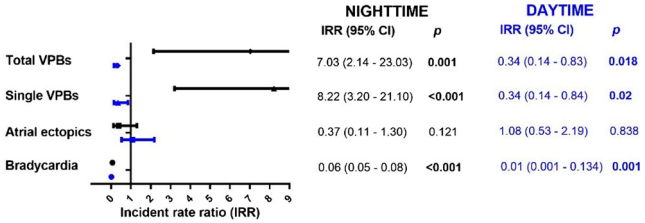

Figure 1. Relative frequencies of cardiac arrhthmias during hyperglycaemia (IG ≥ 15 mmol/l) at night and day in comparison to euglycaemia (IG 5 -10 mmol/l) expressed as incident rate ratios (IRR). VPBs - ventricular premature beats. Total VPBs - sum of single VPBs, couplets, triplets and short runs.

Prognostic differences in men and women with atrial fibrillation and diabetes: a nationwide report

S. Karayiannides[1,2], P. Lundman[1,3], L. Friberg[1], A. Norhammar[4,5];

[1]Department of Clinical Sciences, Karolinska Institutet, [2]Department of Internal Medicine, Danderyd University Hospital, [3]Department of Cardiology, Danderyd University Hospital, [4]Cardiology Unit, Department of Medicine K2, Karolinska Institutet, [5]Department of Clinical Physiology, Capio St Görans Hospital, Stockholm, Sweden.

Background and aims: To the best of our knowledge, the sex-specific prognosis in patients with atrial fibrillation and diabetes mellitus is less well studied in a contemporary population with an extensive national diabetes control program. The aim was to describe nationwide complication patterns in men and women with atrial fibrillation and diabetes.
Materials and methods: All men (n= 180 861) and women (n= 145 971) in Sweden with non-valvular atrial fibrillation during 2006 to 2012 were identified, and information on events, comorbidities and pharmacological therapy was extracted using nationwide mandatory registers. Patients were followed until 31 December 2013 and the mean follow-up time was 3.7 years (0.9 to 8 years). Hazard ratios (HR) were calculated using a Cox proportional hazard regression model adjusting stepwise for age, comorbidities and medication.
Results: Diabetes was present in 18.6% of men and 16.7% of women. The most frequent events in men with atrial fibrillation and diabetes compared to women were mortality (45.8% vs. 53.0%; p<0.001), heart failure (21.6% vs. 21.0%;p=0.062), ischaemic stroke (7.2 vs. 9.6%; p<0.001), myocardial infarction (7.1 vs. 7.6%; p=0.028) and any bleeding (6.6 vs. 5.9%; p=0.001) respectively. When adjusted for age, comorbidities and medication, female sex was associated with lower risk of mortality (HR; 95% confidence interval [CI], 0.77; 0.75-0.79), combined event (first of mortality, heart failure, ischaemic stroke or myocardial infarction; 0.82;0.80-0.84), but higher risk for ischaemic stroke (1.08;1.01-1.16). The standardized mortality ratio for men with atrial fibrillation and diabetes compared to the general population was 1.85 (CI; 1.78-1.92) and for women was 2.04 (CI; 1.96-2.13). Anticoagulants were used in 50.9% vs. 42.1% of men and women respectively.
Conclusion: Women with atrial fibrillation and diabetes have higher event rates for mortality, ischaemic stroke, myocardial infarction compared to men, lower rates for any bleeding and lower rates, that did not reach statistical significance, for heart failure. However, after adjustments, female sex was associated with lower risk of all types of cardiovascular complications, after diagnosis of atrial fibrillation, except for higher risk of ischaemic stroke in women.

S447X polymorphism of lipoprotein lipase and its association with the distribution of triglyceride values after an oral fat tolerance test in diabetes patients

P. Gavra[1], S. Iraklianou[1], G. Kolovou[2], A. Papazafeiropoulou[1], V. Kolovou[2], E. Fousteris[1], L. Rallidis[3], E. Boutati[4], G. Dimitriadis[4], A. Melidonis[1];
[1]Diabetes Center, Tzanio General Hospital, Piraeus, [2]Cardiology Department, Onassis Cardiac Surgery Center, Athens, [3]Cardiology Department, Attikon University Hospital, Athens, [4]2nd Internal Medicine Department, Attikon University Hospital, Athens, Greece.

Background and aims: Postprandial hypertriglyceridemia is an independent risk factor for coronary heart disease, as it is responsible for an atherogenic profile for at least eight hours .Postprandial hypertriglyceridemia is a multifactorial phenomenon as it is influenced by genetic and environmental factors. Lipoprotein Lipase (LPL) plays a key role in lipoprotein metabolism and influences the interaction between atherogenic lipoproteins and the receptors on the vascular wall. S447X is one of the most frequent polymorphisms of LPL in Caucasians. Its effect on LPL activity is controversial. The aim of the current study is to assess the effect of S447X polymorphism of LPL on triglyceride response after fat loading in patients with type 2 diabetes (DM2).
Materials and methods: The study population consisted of 51 males with DM2 (inclusion criteria BMI< 30 Kg/ m^2 and normal fasting plasma triglycerides [TG≤ 150 mg/dl]) who were treated with oral hypoglycemic agents with good glycemic control ($HbA_{1c} \leq 7\%$). Exclusion criteria were history of coronary heart disease and therapy with lipid lowering agents. The study group: (1) underwent an oral fat tolerance test (OFTT) with TG measured before and 2, 4, 6 and 8 hours after the test meal, and (2) was genotyped and S447X polymorphism of LPL was examined. Statistical analysis was performed with Mann-Whitney U test for comparison of numerical values between two groups (SS vs SX) . Areas under the curve (AUC) for serial measurements of TG at baseline and after OFTT were calculated using trapezoid rule. To assess the influence of of alleles S and X on TG levels we performed multiple regression analysis adjusting for age and BMI.
Results: The frequency of LPL S447X genotypes was 65,3% for SS and 34,7% for SX. The results of multiple regression analysis with TG -AUC as dependent variable showed that both alleles S and X were not related with TG-AUC in statistical significant level in total sample (S vs X , coefficient: -0.018, standard error: 154.640, p-value:0.907). In the group with positive OFTT (postprandial hypertriglyceridemia) there was a trend of association of S allele with the TG AUC (S vs X , coefficient : 0.338, standard error : 172,165, p value : 0.07)
Conclusion: S447X polymorphism of LPL is not associated with the distribution of TG values after OFTT in diabetic subjects. There was a trend of association of S allele with triglyceride distribution after fat loading only in the group with positive OFTT, but did not reach statistical significance.
Disclosure: **P. Gavra:** None.

Amadora, [4]iBET | Instituto de Biologia Experimental e Tecnológica, Oeiras, [5]Bayer Portugal, S.A, Carnaxide, Portugal.

Background and aims: In previous work, we reported the existence of anti-HDL (aHDL) antibodies and more particularly anti-apolipoprotein A-I (aApoA-I) antibodies (the main apolipoprotein contained in HDL) and anti-paraoxonase 1 (PON1, the main antioxidant enzyme in HDL) in patients with type 2 diabetes. Furthermore these antibodies may account for the HDL quantitative and/or qualitative fault as a protective factor. The identification of the antigen-binding site of the antibodies is essential for manipulate these pathways by defining new therapeutic targets. Herein we intend to determinate the main epitopes (molecule sections or peptides) recognized by the aApoA-I antibodies in patients with type 2 diabetes.
Materials and methods: Human ApoA-I was submitted to limited proteolysis using different endoproteases The proteolytic products were analyzed by SDS-PAGE and mass spectrometry. Different recombinant ApoA-I peptides:_C1 (residues D25-K231), C2 peptide (residues D25-K251), and ApoA-I full-length were produced in E. coli and purified by affinity and size exclusion chromatography. Since these three peptides only allow distinguish epitopes in the C-terminal region of Apo A-I a series of overlapping peptides were designed and constructed to span the entire sequence of Apo A-I. Immunoreactivity against these peptides was tested by ELISA in a cohort of 55 patients with type 2 diabetes.
Results: The expression and purification of ApoA-I peptides was achieved successfully. The preliminary data regarding the scan of immunoreactivities against these peptides suggest that patients with type 2 diabetes presented a significant decrease in immunoreactivity against the C1 peptide which suggests that the majority of the anti-ApoA-I antibodies present in these patients recognize an epitope in the C-terminal region of protein (Lys^{206}-Gln^{243}).
Conclusion: The identification of specific epitope(s) recognised by the anti-Apo A-I antibodies, may lead to a better understanding of their pathogenic role and potentially highlight novel targets for therapeutic intervention.

Increase in apolipoprotein A-II levels is associated with lower cardiovascular risk in the ACCORD Lipid Trial

M.L. Morieri[1,2], H.S. Shah[1], L. Lovato[3], J.C. Mychaleckyj[4], H.N. Ginsberg[5], A. Doria[6,7];
[1]Genetic & Epidemiology, Joslin Diabetes Center, Harvard Medical School, Boston, USA, [2]Department of Medical Science, University of Ferrara, Ferrara, Italy, [3]Wake Forest School of Medicine, Winston Salem, [4]Center for Public Health Genomics, University of Virginia, Charlottesville, [5]Irving Institute for Clinical and Translational Research, Columbia University, New York, [6]Genetic & Epidemiology, Joslin Diabetes Center, Boston, [7]Department of Medicine, Harvard Medical School, Boston, USA.

Background and aims: Despite the disappointing results of fibrates, CETP-inhibitors, and niacin cardiovascular disease (CVD) trials, recent genetic and epidemiological studies have reinvigorated the possible beneficial effect of improving lipid profile beyond LDL-cholesterol reduction. The aim of our study was to assess the relationship between temporal changes in lipids and apolipoproteins levels and CVD incidence in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) Lipid Trial.
Materials and methods: 5518 subjects with type 2 diabetes were randomized to fenofibrate + simvastatin or simvastatin alone. Hazard Ratios of MACE occurrence were estimated for 1-S.D. change from baseline to the average on-trial value of triglycerides, HDL-cholesterol, LDL-cholesterol, nonHDL-cholesterol, and 1-S.D. change from baseline to 12-months apolipoproteins (Apo A-I, Apo A-II, Apo B and Apo C-III) plasma levels. Covariates included gender, age, study treatment arms, CVD history, clinical center, and baseline levels of the lipid biomarker. Apolipoproteins levels at baseline and 12 months after randomization were available for 1683 of these subjects.
Results: Associations with lower CVD risk were observed for decreases in LDL-c (HR 0.86; 95% CI 0.76-0.98), nonHDL-c (HR 0.84; 95% CI 0.75-0.94), and triglycerides (HR 0.90; 95% CI 0.81-0.996), and an increase in HDL-c (HR 0.79; 95% CI 0.72-0.86). The LDL-c and nonHDL-c effects were larger in the simvastatin-alone than in the fenofibrate + simvastatin group (interaction P less than 0.05), whereas HDL-cholesterol and triglycerides had similar effects in the two groups. Among apolipoproteins, the increase in Apo A-II levels was associated with lower CVD (HR 0.82; 95% CI 0.73-0.93). This association, independent from changes in HDL-c and triglycerides levels, was statistically similar in the simvastatin-alone (HR 0.90; 95% CI 0.71-1.14) and fenofibrate + simvastatin group (HR 0.78; 95% CI 0.67-0.90, interaction P = 0.4).
Conclusion: These findings, while confirming known associations between lipid changes and CVD, point to an as yet unknown atheroprotective effect of increasing Apolipoprotein A-II levels in type 2 diabetes. Further studies are needed to test the causality of this association.

Atorvastatin increases FADS1, FADS2, and ELOVL5 gene expression via GGPP-dependent RHO kinase pathway in 3T3-L1 cells

I. Tatsuno[1], S. Tanaka[1], Y. Watanabe[1], N. Ishihara[1], S. Suzuki[2], T. Tanaka[2];
[1]Toho University Sakura Medical Center, Sakurra, [2]Chiba University Graduate School of Medicie, Chiba, Japan.

Background and aims: The health benefits of omega-3 long-chain polyunsaturated fatty acids (LCPUFAs), mainly consisting of eicosapentaenoic acid (EPA, 22:5 n-3) and docosahexaenoic acid (DHA, 22:6 n-3), have been extensively researched to demonstrate the significant relative cardiovascular risk reduction by intake of omega-3 LCPUFAs. Therefore, the balance between EPA or DHA and arachidonic acid (AA, 20:4 n-6), a 20-carbon, 4-double-bond LCPUFA of the omega-6 type, in the human body is likely to be important for regulating the production of mediators and subsequently vascular function. Indeed, serum EPA to AA ratio (EPA/AA) has been found to be a good biomarker for the risk of cardiovascular disease. Although the efficacy of statin for both primary and secondary prevention of cardiovascular disease has been established, it has been reported that increase in plasma AA concentration and decrease in plasma omega-3 fatty acid concentration and/or plasma omega-3/AA ratio have been observed in patients treated with statin, which might be involved in the residual risk after initiation of statin treatment, These data indicate that statin affects the endogenous synthesis of LCPUFAs, which is regulated by fatty acid desaturases (FADSs) and elongation of very long-chain fatty acids proteins (ELOVLs). We investigated the statin-induced regulation of these desaturases and elongases as well as cell viability using mouse 3T3-L1 cells.
Materials and methods: Mouse 3T3-L1 preadipocytes were purchased from Health Science Research Resources Bank (Osaka, Japan). Cell viability was assessed by measuring mitochondrial activity that reduces 2-(2-methoxy-4-nitrophenyl)-3-(4-nitrophenyl)-5-(2,4-disulfophenyl)-2H-tetrazolium monosodium salt (WST-8) to formazan, using the Cell Counting Kit-8 (Dojindo, Kumamoto, Japan). Gene expression was analyzed by quantitative real-time PCR.
Results: Atorvastatin increased Fads1, Fads2 and Elovl5 mRNA expression to 105.4±3.5, 109.5±7.9 and 106.0±4.1 % at 10 uM, and 168.1±1.5,

235.6±5.5 and 147.1±1.0 % at 30 uM, respectively, in a dose-dependent manner at 48 h. Mevalonate and geranylgeranyl-pyrophosphate (GGPP), but not cholesterol, fully reversed the atorvastatin-induced upregulation of gene expression. The Rho-associated protein kinase inhibitor Y-27632 inhibited the mevalonate- and GGPP-effected reversal of atorvastatin-induced upregulation of gene expression.

Conclusion: These findings demonstrate that statin may affect the endogenous synthesis of LCPUFAs by regulating Fads1, Fads2 and Elovl5 gene expression via the GGPP-dependent Rho kinase pathway.

High refill adherence to lipid-lowering therapy associated with lower risk for cardiovascular disease in type 1 diabetes

C. Hero[1], S.A. Karlsson[2], S. Franzén[3], A.-M. Svensson[3], M. Miftaraj[3], K. Andersson Sundell[2,4], B. Eliasson[1], K. Eeg-Olofsson[1];
[1]Department of Internal Medicine, Gothenburg, [2]Department of Public Health and Community Medicine, Gothenburg, [3]National Diabetes Register, Gothenburg, [4]Astra Zeneca AB, Medical Evidence and Observational Research, Mölndal, Sweden.

Background and aims: Cardiovascular disease (CVD) is the leading cause of shorter life expectancy in type 1 diabetes (T1D). The aim of this study was to assess risk of non-fatal and fatal CVD in relation to refill adherence to lipid-lowering therapy (LLT) in T1D patients.

Materials and methods: We included 6192 T1D patients, aged 18 years or older, from the Swedish National Diabetes who were also registered in the Swedish Prescription Drug Register initiating use of LLT between 1 July 2006 and 31 Dec 2010. Socioeconomic characteristics were collected from Statistics Sweden and comorbidities and outcome events from the National inpatient- and cause of death registers. First, patients were followed for 18 months estimating refill adherence to LLT and thereafter followed for CVD events, death or end of follow-up 31 Dec 2013. Adherence was estimated during the first 18 months of observation, by calculating Medication Possession ratio (MPR), i.e the proportion of days with medicines at hand during this period. Discontinuation was defined as being without medication at hand for more than or equal to 180 days. Cox regression analysis was performed to analyze MPR as predictor of non-fatal and fatal CVD, comparing the group with MPR above 80% to the group with MPR lower than or equal to 80%. We also analyzed the patients discontinuing LLT to the ones continuing. Analyses were adjusted for traditional risk factors, co-morbidities and socioeconomic status.

Results: In all, mean age was 45±12 years, diabetes duration 30±13 years, 58% were male, 13% were smokers, mean HbA1c was 66 ±14 mmol/mol, LDL 3.3±0.8 mmol/L and 24% had albuminuria. 93% were born in Sweden, 16% had insulin pump therapy, 43% were on antihypertensives and 9 % had a previous CVD. The mean MPR over 18 months was 72±28%. 52% had an MPR above 80%. Discontinuation of LLT was more common in patients without previous CVD and in those with no concurrent medication. Smokers were less adherent than non-smokers. There was a total of 767 non-fatal CVD and 58 fatal CVD events during mean follow-up of 5.3 years. Patients with an MPR above 80% had a 19% lower risk of non-fatal CVD compared to patients with MPR lower than or equal to 80%, HR 0.81 (95% CI 0.69-0.95) p=0.008. Patients discontinuing LLT had a 30% higher risk of non-fatal CVD, HR 1.30 (1.10-1.54) p = 0.002. In this study adherence did not affect risk of fatal CVD.

Conclusion: In T1D, high refill adherence to LLT was associated with lower risk for non-fatal CVD. Patients discontinuing LLT had a 30% higher risk of CVD. It is important to evaluate and emphasize adherence to prescribed LLT at clinical visits in order to reduce the risk of CVD in patients with T1D.

1167

Changes in lipid-lowering therapy following a cardiovascular event in patients with diabetes

T. Okerson[1], S.S. Cohen[2], J.M. Killian[3], S.A. Weston[3], K.L. Monda[1], A.M. Chamberlain[3];
[1]Amgen, Thousand Oaks, [2]EpidStat Institute, Ann Arbor, [3]Mayo Clinic, Rochester, USA.

Background and aims: Patients with diabetes mellitus (DM) are at increased risk of cardiovascular (CV) events, yet many do not receive sufficient guideline-recommended lipid lowering treatment (LLT). We evaluated LLT patterns before and after a CV event subsequent to a DM diagnosis.

Materials and methods: Residents of Olmsted County, Minnesota, USA with DM from 2005-2012 were identified from electronic medical records and divided into 2 groups: 1) those with incident DM and 2) those with incident CVD (MI, unstable angina, revascularization, or ischemic stroke/TIA) with concomitant DM. Patients were followed from the incident DM or CVD diagnosis for 18 months for a subsequent CV event. LLT was characterized before and after the CV event, or for those without an event, before and after the median follow-up time of patients with an event.

Results: 4503 patients had incident DM (mean age 57.2 years, 52.2% male) and 568 had incident CVD with concomitant DM (mean age 70.4 years, 50.5% male). The mean baseline (±90 days) low density lipoprotein cholesterol (LDL-C) was higher among patients with incident DM (2.87 ± 0.92 mmol/L) than incident CVD and concomitant DM (2.22 ± 0.80 mmol/L; p-value <0.01). At baseline, 878 (19.5%) of the incident DM patients were prescribed moderate intensity statins, with only 1456 (32.3%) prescribed any LLT. Among the incident DM patients, 82 experienced a CV event (rate per 100 person-years: 1.5 (1.2-1.8)). Median time to CV event was 208 days, with 35.4% and 1.2% prescribed moderate and high intensity statins, respectively, at the time of the event. Moderate and high intensity statin prescriptions increased to 47.4% and 10.3% sixty days post-event (Figure). Mean LDL-C decreased from 3.07 ± 1.08 at baseline to 2.20 ± 0.81 within 2-6 months post-CV event. Patients without a CV event had a similar LLT pattern until the median follow-up time, with no change thereafter. Among patients with CVD and DM, 60% were prescribed LLT at baseline, nearly double the proportion in the incident DM group. Subsequent CV events were observed in 111 patients (rate per 100 person-years: 18.8 (15.8-22.2); median time to CV event: 144 days). Among patients with CVD and DM who had a subsequent CV event, 41.4% and 23.4% were prescribed moderate and high intensity statins, respectively, at the time of the event, which increased to 47.1% and 21.6% 60 days post-event. Mean LDL-C decreased from 2.31 ± 0.75 at baseline to 1.96 ± 0.84 within 2-6 months post-CV event, which was similar to the post-CV event LDL-C in patients with DM alone (p=0.17). Fewer prescriptions for high intensity statins were observed among patients without a subsequent CV event.

Conclusion: Despite conclusive evidence of statin benefit in prevention of CV events, a large proportion of patients with DM were not on an appropriate intensity of statin or under the LDL-C goal, even after a CV event subsequent to their DM diagnosis. More aggressive efforts are necessary to reduce CV events in this high-risk group.

The early detection of lipodystrophy in insulin treated diabetic patients with the use of the thermal imaging camera

A. Maksymiuk-Klos, M. Bernas, E. Jagielińska-Kalinowska, P. Piątkiewicz;
Department of Internal Diseases, Diabetology and Endocrinology, Medical University of Warsaw, Warsaw, Poland.

Background and aims: The number of diabetic patients treated with insulin have substantially increased in recent years, partly due to steadily growing incidence of type 1 diabetes and partly because of a common practice of the early start of using insulin in the treatment of patients with type 2 diabetes. Long term use of insulin is associated with skin related local complications like subcutaneous fat tissue lesions (lipodystrophy). It occurs in diabetic patients with a prevalence of 20-50%. Lipohypertrophy is the most common cutaneous complication of insulin therapy, characterized by swelling of the fatty tissue around insulin injection sites. The aim of the study was to evaluate the incidence of lipodystrophy in diabetic patients treated with insulin and to verify the effectiveness of the thermal imaging camera to detect these pathological symptoms.
Materials and methods: The analysis was conducted on the data collected from patients hospitalized at Department of Internal Diseases, Diabetology and Endocrinology of our Medical University from November 2016 to March 2017. Patients with BMI ≥ 25 kg/m2 and over 6 months insulin therapy were included in the study. We assessed HbA1c, biochemical profile, body mass index (BMI). All patients had QuickDash and Mini Mental State Examination. Insulin administration was observed and estimated. Manual evaluation of adipose tissue and imaging with the thermal camera FLIR T 660 2.0 was performed.
Results: The study included 60 patients with type 1 and 2 diabetes. 53% was male and 47% female. The duration of insulin therapy in patients ranged from 1 to 26 years. The BMI was 25 to 39 kg/m2. Average HbA1c level was 8,02%. Almost every third diabetic patient did not receive insulin properly. It was associated with greater traumatism of the tissues and worse control of diabetes (HbA1c > 8%) (p< 0,05). Subcutaneous tissue lesions were detected in 15% of patients in palpation. Using thermal imaging camera, the changes (an example picture) were apparent in 51 % of the subjects (p<0,05).
Conclusion: Lipodystrophy is an important and frequent complication of insulin therapy but is often underestimated. Subcutaneous adverse effects of insulin injections can lead to poor glycemic control. We often forget about it and look for other causes of uncontrolled glycemia. The main risk factors of lipodystrophy are: using the same skin region for insulin injections, poor education and long duration of diabetes. The thermal imaging camera is a safe, inexpensive and non-invasive way to detect early changes in adipose tissue. It should be available in every Diabetology Department. Our study shows the need for repetitive training of diabetic patients for insulin therapy even if they have been taking insulin for a long time.

PS 104 Factors affecting endothelial function in vitro

1169

Prep1 deficiency improves vascular function by increasing endothelial nitric oxide production

I. Cimmino[1], S. Ricci[1], C. Del Giudice[2], A. Fiordelisi[2], V. Tornatore[1], O. Paciello[3], A. Costagliola[3], A. Liotti[1], S. Cabaro[1], M. Ciccarelli[4], G. Iaccarino[4], C. Miele[1], P. Formisano[1], F. Beguinot[1], F. Oriente[1];
[1]URT-GDD, National Council of Research - Department of Translational Medical Sciences, Federico II University of Naples, [2]Department of Advanced Biomedical Sciences, Federico II University of Naples, [3]Department of Veterinary Medicine and Animal Production, Federico II University of Naples, Naples, [4]Department of Medicine and Surgery, University of Salerno, Salerno, Italy.

Background and aims: Endothelial dysfunction is associated with several pathophysiological conditions, including cardiovascular disease, insulin-resistance and type 2 diabetes. The hallmark of endothelial dysfunction is the reduced Nitric Oxide (NO) bioavailability which leads to an increase of vasoconstriction and induces smooth muscle cell proliferation and migration. NO production is induced by endothelial nitric oxide synthase (eNOS), which, in turn, is regulated by several protein kinases on different specific sites. Moreover, phosphorylation on Threonine495 residue inhibits eNOS function while phosphorylation on Serine1177 residue activates NO production. We have previously identified Prep1 as a homeodomain transcription factor which plays an important role in the metabolic response. In particular, Prep1 hypomorphic heterozygous mice ($Prep1^{i/+}$) expressing low levels of protein, are protected from streptozotocin-induced diabetes and show improved insulin sensitivity both in muscle and in liver. In this study, we have evaluated the role of the transcription factor Prep1 in the regulation of vascular function.
Materials and methods: Blood Pressure of both systolic and diastolic measurements have been performed in WT and $Prep1^{i/+}$ mice using a pressure transducer catheter. NO production has been measured by a nitrate/nitrite colorimetric assay, while aortas have been characterized by histological analysis and Western blot. Mouse aortic endothelial cells (MAEC), transfected with Prep1 cDNA, were co-cultured with vascular smooth muscle cells (VSMC) and proliferation and migration were investigated by using the transwell permeable supports.
Results: $Prep1^{i/+}$mice feature a 30% and 20% decrease of systolic and diastolic blood pressure, respectively, and a 40% decrease of residual vasoconstriction after phenylephrine stimulation compared to WT littermates. Immunohistochemistry analysis from aorta sections indicate that Prep1 is more expressed in the endothelium than the other layers and is lower in $Prep1^{i/+}$ mice than the WT animals. $Prep1^{i/+}$ mice show a 20% increase of serum NO release, paralleled by a significant decrease of eNOSThr495 and a 25% increase of eNOSSer1177 phosphorylation, compared to the WT mice. Experiments performed in MAEC cells overexpressing Prep1 have, in part, confirmed the data obtained in vivo, as NO production is strongly reduced. In addition, a co-culture system of Prep1 overexpressing MAEC cells and VSMC, show a significant increase of proliferation and migration of VSMC cells.
Conclusion: Our data indicate that Prep1 deficiency improves endothelial function by increasing NO production and suggest Prep1 as a novel possible candidate in the vascular complication of type 2 diabetes.
Disclosure: **I. Cimmino:** None.

1170

Disturbance of the cytosolic proteome and dominant methylglyoxal-modified proteins in human aortal endothelial cells in high glucose concentration in vitro

P.J. Thornalley, A. Ashour, Z. Irshad, A. Shafie, N. Rabbani;
Warwick Medical School, University of Warwick, Coventry, UK.

Background and aims: Hyperglycemia-induced dysfunction of vascular endothelial cells is a driver of vascular complications of diabetes. Increased glucose metabolism by endothelial cells produces abnormal secretion and processing of extracellular matrix proteins, inflammation, oxidative stress, increased formation of advanced glycation endproducts (AGEs) and other processes. Insights into pathways driving these processes may be gained by quantitative cellular proteomics. The aim of this investigation was to incubate human aortal endothelial cells in primary culture in low and high glucose concentration (5 mM and 20 mM glucose, respectively), perform deep high resolution mass spectrometry proteomics of the cytosolic proteome and explore cell dysfunction through bioinformatics pathways analysis. We also investigated proteins modified by the AGE precursor, methylglyoxal (MG), which accumulates in endothelial cells in hyperglycemia.
Materials and methods: Human aortal endothelial cells (HAECs) were incubated in primary culture with 5 mM or 20 mM glucose for 3 days (n = 3). Cytosolic protein extracts were then preapared, reduced, alkylated and digested with trypsin. Tryptic peptides were analysed by nanoflow liquid chromatography-Orbitrap Fusion™ (Thermo) mass spectrometry and a relative quantification of protein concentration was performed using non-conflicting peptides in Progenesis QI™ software (Nonlinear Dynamics, Newcastle upon Tyne, U.K.). Protein ontology was evaluated using literature and Web-based tools (http://www.reactome.org/) to identify functional annotation to characterise molecular functions and biologic processes. Protein identification was based on at least 2 unique peptides and protein sequence coverage range was 5 - 40%.
Results: The mean number of proteins identified in cytosolic extracts of HAECs in low and high glucose concentration was 1893; 25 proteins were unique to low glucose concentration incubations and 12 proteins were unique to high glucose concentration incubations. There was 403 proteins upregulated in high glucose conditions. Reactome analysis indicated up-regulation of glycolysis and glucose metabolism ($P<0.001$). In these, the following proteins were up-regulated (fold increase): serine/threonine-protein phosphatase 2A (1.7 fold); pyruvate kinase (1.4 fold), phosphoglycerate kinase 1 (1.8 fold); Phosphoglycerate mutase 1 (1.4 fold); glyceraldehyde-3-phosphate dehydrogenase (1.2 fold); triosephosphate isomerase (1.5 fold); Fructose-bisphosphate aldolase C (1.6-fold); Fructose-bisphosphate aldolase A (1.3-fold); ATP-dependent 6-phosphofructokinase (1.2 fold); malate dehydrogenase, mitochondrial (1.6 fold); phosphoglucomutase-2 (1.6 fold); aspartate aminotransferase, cytoplasmic (2.9 fold). There were 3 proteins were found modified by MG: far upstream element-binding protein 2 FUBP2 (KH-type splicing regulatory protein) - an important regulator of multiple inherently instable mRNAs mostly coding for pro-inflammatory mediators; rho GDP-dissociation inhibitor 2; and isoform 2 of ADP-ribose pyrophosphatase, mitochondrial (NUDT9).
Conclusion: Quantitative proteomics revealed upregulation of enzymes of glucose metabolism and glycolysis in endothelial cells. A prominent MG-modified protein, FUBP2, is involved in mRNA processing of inflammatory mediators and may contribute to vascular inflammation.

1171

High glucose exposure induces cellular dysfunction and metabolic changes in endothelial colony forming cells

C.L. O'Neill, L.J. Eeles, A.W. Stitt, R.J. Medina;
The Wellcome-Wolfson Institute for Experimental Medicine, Belfast, UK.

Background and aims: Endothelial dysfunction is a common problem in diabetes resulting in diminished vascular regeneration and progression of vascular complications. Recent clinical trials demonstrate that Endothelial Progenitor Cells (EPCs) play important roles in vascular repair and therefore represent an ideal candidate for therapeutic revascularisation. However, it has recently been shown that EPCs may

be impaired in diabetes. It has also been demonstrated that the number and function of circulating EPCs are reduced in patients with cardiovascular risk factors such as hyperglycaemia. The purpose of this study was to examine the effect of a diabetic milieu on a subset of well-defined EPCs called Endothelial Colony Forming Cells (ECFCs), by exposing them to high glucose.

Materials and methods: ECFCs were exposed to short-term (3-5 days) or long term high D-Glucose (DG) (25mM), control medium (5mM DG) or osmotic control (5mM DG+20mM L-Glucose (LG). Changes in ECFC functionality were measured using a scratch wound migration assay and a 3D Matrigel model of angiogenesis. The Seahorse Bioscience XFe96 analyser was used to compare the Oxygen Consumption Rate (OCR) and Extracellular Acidification Rate (ECAR) of short and long term high DG treatment.

Results: Short-term (3-5 days) exposure to high D-Glucose (DG) (25mM) resulted in a significant increase in ECFC tubule formation when compared to control medium (5mM DG) or osmotic control (5mM DG+ 20mM LG). On the contrary, long-term (4 week) exposure to high DG resulted in a significant decrease in ECFC tubulogenic capacity ($p \leq 0.001$). Long-term high DG also negatively affected ECFC function, as shown by a significant reduction in ECFC migratory capacity using an in vitro scratch wound assay ($p \leq 0.001$). Interestingly, long-term exposure to high DG resulted in premature senescence of ECFCs, which was characterised by a significant increase in senescence-associated β-galactosidase activity ($p \leq 0.001$); and a significant increase in 53BP1 foci ($p \leq 0.05$). The glycolytic reserve, measured using the Seahorse bioanalyser was exclusively diminished by long term exposure to high DG as cells failed to increase ECAR after ATP synthase inhibition by Oligomycin, which was not seen with chronic LG treatment. In addition, basal OCR and ECAR values were reduced by chronic treatment with either LG or DG indicating that metabolism is partially altered by the osmotic effect of glucose.

Conclusion: Our results demonstrate the deleterious effect of high DG on ECFC functionality and indicate that this effect may be due to the induction of premature senescence mechanisms. This finding is important as it indicates that ECFCs isolated from diabetic patients may be dysfunctional and therefore, will require functional evaluation, and consecutive repair if found to be dysfunctional, before using them as an autologous cell therapy.

1172

A diabetic microenvironment renders monocytes and myeloid angiogenic cells less pro-angiogenic

K.J. Mcloughlin, S. Chambers, C.L. O'Neill, J. Guduric-Fuchs, A.W. Stitt, R.J. Medina;
School of Medicine, Dentistry and Biomedical Science, Queen's University Belfast, Belfast, UK.

Background and aims: Myeloid angiogenic cells (MACs) promote revascularisation of ischaemic tissues in pre-clinical models by the paracrine release of angiogenic factors such as MMP-9, IL-8 and MCP-1. IL-8 is key to this process by stimulating angiogenesis in a concentration-dependent manner. These pro-angiogenic properties of MACs have been harnessed to develop a novel cell therapy for ischaemic diseases. However, MACs were suggested to be dysfunctional in diabetes. An investigation was therefore led to observe how a diabetic milieu can affect the immunophenotype and function of MACs.

Materials and methods: MACs were isolated from peripheral blood and exposed to either 25mM D-Glucose (DG), control media (5mM DG) or an osmotic control (5mM DG + 20mM L-Glucose) for 4 days. RNA was extracted using Qiazol and converted to cDNA for use in RT-PCR. Flow cytometry was performed by staining mononuclear cells from patients and volunteers with anti-CD14 and anti-CD16 antibodies before running on Attune NxT flow cytometer. Gating was set by using appropriate isotype controls for each flurophore.

Results: Our evidence demonstrates MACs are a distinct subtype of macrophage that shares M2 anti-inflammatory and pro-angiogenic characteristics, but can be distinguished from M2 macrophages based on their significantly high expression of CD163, both in terms of RNA and cell surface protein expression. Results indicate that both MACs and MACs conditioned medium (MACs-CM) significantly reduced their *in vitro* pro-angiogenic capacity following a 4-day high DG treatment. IL1β mRNA and protein were significantly increased in MACs under high DG conditions. By blocking IL1β, the pro-angiogenic function associated with MACS-CM was rescued. Most importantly, IL1β was also significantly up-regulated in MACs isolated from type 1 diabetic patients with microvascular complications when compared to MACs from patients without microvascular complications or non-diabetic volunteers. Evaluating the immunophenotype of macrophage precursors (monocytes) from circulating blood suggested phenotypic changes in the mononuclear cell fraction in patients with type 1 diabetes without complications, with an increase in classical (CD14++/CD16-) and non-classical (CD14+/CD16+) monocytes observed compared to age and sex matched healthy donors. This is indicative of an inflammatory response in diabetic patients.

Conclusion: IL1β inhibition presents an attractive therapeutic target in restoring MACs vasoreparative function in diabetic conditions. As monocytes are the precursors to macrophages upon entering localised tissues, these data suggest that monocytes may be "primed" by the diabetic microenvironment to shift towards an M1 pro-inflammatory phenotype. This could potentially account for the loss of MACs pro-angiogenic function when isolated and exposed to high DG conditions.

O-GlcNAcylation of FoxO1 is crucial for the overexpression of Angiopoietin 2 in NDPK B depleted endothelial cells

Y. Feng[1], S. Shan[1], A. Chatterjee[1], H.-P. Hammes[2], T. Wieland[1];
[1]Institute of Experimental and Clinical Pharmacology and Toxicology, [2]Fifth Medical Department, Medical Faculty of Mannheim, University of Heidelberg, Mannheim, Germany.

Background and aims: Protein O-GlcNAc modification is involved in plenty of protein functions in various diseases such as diabetes mellitus, cancer, neurodegenerative and cardiovascular disease. Elevated protein O-GlcNAc modification has been found *in vivo* in the NDPK B-deficient mouse retinas which demonstrated vasoregression mimicking diabetic retinopathy, and *in vitro* in NDPK B depleted endothelial cells (ECs). Angiopoietin-2 (Ang-2), the crucial factor for initiation of retinal vasoregression, was found to be concomitantly upregulated. In this study, we investigated the role of FoxO1, an upstream regulator of Ang-2 upon NDPK B depletion in ECs.

Materials and methods: Human umbilical endothelial cells were used. Depletion of NDPK B was achieved by gene knockdown with NDPK B siRNA using Lipofectamine. Suitable non-specific siRNAs served as controls. The expression of NDPK B, Ang-2, FoxO1, protein phosphorylation and protein GlcNAc modification was assessed by Western blot and/or immunofluorescence using specific antibodies. Subcellular fractions were used to analyze FoxO1 translocation. FoxO1 GlcNAc modification was assessed by co-immunoprecipitation. O-GlcNAc inhibitors were used to evaluate the role of FOXO GlcNacylation.

Results: Phosphorylation of FoxO1 was significantly increased whereas total FoxO1 increased concomitantly in NDPK B depleted ECs. Translocation of FoxO1 was not altered upon NDPK B depletion. Neither the phosphorylation of AKT/SGK, nor the phosphorylation of JNK, p38 and ERK was changed in NDPK B depleted ECs compared with controls. Similar to the FoxO1 expression pattern, O-GlcNAc was detected mainly in the nucleus and few in the cytoplasm. Unexpectedly,

O-GlcNAc and FoxO1 were partially colocalized. Immunoprecipitation experiments demonstrated that FoxO1 was O-GlcNacylated in NDPK B depletion conditions. Moreover, inhibition of protein O-GlcNAcylation with O-GlcNAc inhibitors eliminated upregulation of FoxO1 and Ang-2 induced by NDPK B depletion.
Conclusion: We demonstrate in this study that upregulated Ang-2 in NDPK B depleted ECs is associated with O-GlcNAcylation of FoxO1. Our data supply evidence for the role of protein O- GlcNAcylation in NDPK B associated endothelial damage, indicating protein O-GlcNAcylation as a novel target in retinal vasoregression.

Circulating Endothelial Cells (EPC) and Endothelium-derived Microparticles (EdMPs) time-course throughout the natural history of type 2 diabetes

D. Lucchesi, L. Giusti, M. Garofolo, V. Sancho-Bornez, G. Daniele, A. Dardano, R. Miccoli, G. Penno, S. Del Prato;
Endocrinology and Metabolism, University of Pisa, Pisa, Italy.

Background and aims: Vessel health status may result from the balance between endothelial insult and injury repair. The balance between Endothelium derived Microparticles (EdMPs) and Endothelial Progenitor Cells (EPCs) has been proposed to reflect the concomitant processes of endothelial injury and vascular repair capacity. A deeper understanding of the mechanisms involved in the regulation of such a balance is crucial to improve the quantification of the cardiovascular risk. In this study we describe the changes in circulating EPCs, circulating EdMPs and the EdMPs/EPCs ratio across the progression of Type 2 diabetes mellitus (T2DM).
Materials and methods: Circulating EdMPs ($CD42^-CD31^+$) and circulating EPCs ($CD34^+CD133^+KDR^+$) were quantified by flow cytometric (FACS) analysis (M±SD) in the following four subjects categories: 196 individuals with T2DM (age 61.7±8.8 years, diabetes duration 28.1±11.8 years, BMI 30.8±6.1 kg/m^2, HbA1c 7.3±1.2%); 30 newly-diagnosed T2DM (nT2D; 54.8±9.5 years, BMI 29.5±5.2 kg/m^2, HbA1c 11.1 ±2.3%); 20 individuals with pre-diabetes (pT2D; 53.8±8.8 years, BMI 29.7±7.7 kg/m^2, HbA1c 5.9±0.2%) and 20 healthy controls (C, age 52.1 ±8.9 yrs, BMI 24.1±1.8 kg/m^2, HbA1c 5.5±0.3%).
Results: Compared to control subjects (Krukal-Wallis non-parametric test), stem cells ($CD34^+$ and $CD34^+CD133^+$: 2193±707 and 967±380 cells/ml, respectively) were marginally reduced in pT2D (1742±517 and 841±488 cells/ml, respectively) and nT2D (1686±979 and 796 ±496 cells/ml; p=0.028 and p=0.070 vs T2DM, respectively), but not in T2DM (2212±1262 and 1067±797 cells/ml, respectively). On the contrary, EPCs ($CD34^+KDR^+$ and $CD34^+CD133^+KDR^+$) progressively dropped from C (879±354 and 435±227 cells/ml) to pT2D (590±277 and 302±191 cells/ml), nT2D (496±487 and 263±282 cells/ml) and T2DM (408±338 and 222±207; p<0.001 and p=0.003, respectively). EdMPs increased, though in a not significant manner, from C (7903 ±2501 n/ml), to pT2D (11664±8050 n/ml) and T2DM (11261±15979 n/ml) to nT2D (14843±27238 n/ml). Therefore, EdMPs/EPCs ratio progressively increased from C (21.6±13.2) to pT2D, nT2D (55.0±46.9 and 56.9±50.5, respectively) and T2DM individuals (85.2±148.5; p=0.016 vs. C). By logistic regression analysis, crude odds ratios (ORs) for CD34+CD133+KDR+ cells below the median were 13.0 for nT2D (p=0.012) and 15.2 for T2DM (p=0.009) with ORs, covariated for gender, age, BMI, blood pressure, lipids, blood glucose, HbA1c, urinary albumin to creatinine ratio and CKD-EPI eGFR of 9.8 (p=0.048) and 9.0 (p=0.040), respectively; crude OR for EdMPs/EPCs above the median were 8.7 for nT2D (p=0.014) and 6.3 for T2D (p=0.019) with covariated ORs of 3.1 (ns) and 6.9 (p=0.029), respectively. Covariates showed no independent effects even when subjects category was removed from the regression.
Conclusion: Alteration in circulating endothelial progenitor cells (EPCs) and endothelium-derived microparticles (EdMPs) as also reflected by the EdMPs/EPCs ratio get progressively worse across the different stages of the disease. Stages of the disease were the only factor affecting changes in EPCs and EdMPs/EPCs with no significant effects of the conventional cardiovascular risk factors.

CD133 antigen expression in dermal microvascular endothelial cells in adults with type 1 diabetes

A. Adamska[1], A. Gandecka[1], S. Pilaciński[1], A. Grzelka[1], K. Kowalska[2], A. Malinska[2], A. Araszkiewicz[1], M. Nowicki[2], D. Zozulinska-Ziolkiewicz[1];
[1]Department of Internal Medicine and Diabetology, Poznan University of Medical Sciences, [2]Department of Histology and Embryology, Poznan University of Medical Sciences, Poznań, Poland.

Background and aims: CD133 (CD-cluster of differentiation) is a membrane glycoprotein responsible for regulating cell growth and cell differentiation. CD133 antigen expression is high in early endothelial cells and decreases as they mature and differentiate. In the presented study, CD133 antigen expression was used as a marker of skin angiogenesis in adult patients with type 1 diabetes (DM1). The aim of the study was to assess microvascular density (MVD) and maturity in skin biopsy of patients with DM1 and correlate these data with clinical features.
Materials and methods: The study included 78 patients [42 men, 36 women, median age 43 (35-54) years, diabetes duration 24 (18-30) years] with DM1. Inclusion criteria were: age> 18 years, duration of diabetes> 5 years, consent to participate in the study. Exclusion criteria were: coagulopathy (APTT> 37s, INR> 1.1, PLT <100G/ mm3 blood), anticoagulant or antiplatelet medication, skin lesions in the biopsy area. Skin biopsy specimen was taken at the distal end of the leg. All samples were exposed to monoclonal mouse anti-human antibody anti-CD133. MVD - averaged number of blood vessels per 1 mm² - was calculated using "hot spots" technique.
Results: Median HbA1c was 7.8 (7.1-9.2)%. The prevalence of chronic diabetic complications was assessed by standard methods. Retinopathy was diagnosed in 40 (51.3%) patients, diabetic kidney disease in 10 (13%), peripheral neuropathy in 35 (45%), autonomic neuropathy in 11 (14.1%). 36 (46.2%) individuals were diagnosed with hypertension and 20 (25.6%) smoked cigarettes. MVD for anti-CD133 for all tested specimens was 83.3/mm 2 (66.6-95.8). The exspression of endothelial cells CD 133 antigen was inversely associated with body mass index (Pearson R = -0.35 p = 0.001). In the multivariate linear regression model, the association was independent of sex, age, diabetes duration, smoking, HbA1c, LDL cholesterol, C-reactive protein and peripheral neuropathy (beta = -0.39, p = 0.007, R2 = 0.19).
Conclusion: Presented results suggest angiogenesis suppression in individuals with higher BMI. Presented study is in line with results from animal models. It is not yet clear whether this findings could play a role in pathogenesis of diabetic microangiopathy.

Proof-of-concept for an enhanced surrogate marker of endothelial function in diabetes

R. Dalan[1,2], S. Goh[3], S. Bing[4], C. Phua[5];
[1]Endocrinology, Tan Tock Seng Hospital, [2]Lee Kong Chian School of Medicine, [3]Bioinstrumentation, Nanyang Polytechnic University, [4]Clinical Research Office, Tan Tock Seng Hospital, [5]Bio Instrumentation, Nanyang Polytechnic University, Singapore, Singapore.

Background and aims: Diabetes affects distal small vessels earlier and to a larger extent than proximal vessels. Vascular disease starts from activation of the endothelial cells which if prolonged may lead to decrease in the distensibility of the blood vessel when maximally stimulated. Hence a device which measures distensibility of a distal vessel should be a good biomarker for subclinical disease. We developed a device with the capability to measure maximum possible pulse-wave-amplitude of the radial artery after a period of occlusion with the aim to see if the measurements correlate with traditional surrogate markers of cardiovascular risk in type 2 diabetes mellitus (T2DM)
Materials and methods: This device is based on the measurement of magnetic flux disturbance as blood flows through a uniformly applied magnetic field. Hemodynamic modulation is used to develop a mathematical model to quantify maximum possible dilatation using arterial form waveforms. The baseline waveforms from both hands is compared to waveforms obtained after a period of occlusion for 5 minutes in the occlusion arm to determine the radial-artery maximum distensibility index (RA-MDI). We recruited 96 subjects (46 patients with T2DM and 50 healthy volunteers) to study correlations of RA-MDI with cardiovascular risk factors, scoring systems, and carotid-artery-intima-media thickness (CIMT).
Results: The RA-MDI scores were significantly higher in T2DM (Median 0.76 (IQR:0.46)) compared to healthy individuals (Median: 0.28(IQR:0.13)); p<0.001. Linear regression analysis showed RA-MDI correlated with the risk scoring systems : a. Framingham Heart Study (lipids full CVD 30 years) : β=0.01 (95% CI: 0.01-0.01), p<0.001, b. UKPDS: β=1.6 (95% CI: 0.8-2.4), p<0.001, c. ADVANCE: β=9.67 (95% CI: 4.66-14.67), p<0.001 and CIMT: β=0.97 (95% CI: 0.61-1.32), p<0.001. Correlations with cardiovascular risk factors : HbA1c β=0.10 (95% CI: 0.06-0.15), p<0.001, Age β=0.02 (95% CI: 0.01-0.03), p<0.001, systolic BP β=0.01 (95% CI: 0.01-0.01), p<0.001, diastolic BP β=0.01 (95% CI: 0.01-0.02), p<0.001, and BMI β=0.03 (95% CI: 0.01-0.04), p=0.01.
Conclusion: We found that the RA-MDI correlated significantly with traditional cardiovascular risk factors, scoring systems and CIMT. Further large scale prospective studies need to be conducted to ascertain the correlations with hard cardiovascular outcomes.

Sulforaphane and pyridoxamine supplementation normalise endothelial dysfunction associated with type 2 diabetes

C.M. Sena[1], A. Pereira[1], R. Fernandes[2], J. Crisóstomo[1], R. Seiça[1];
[1]Institute of Physiology, IBILI, Faculty of Medicine, University of Coimbra, [2]Ophthalmology, IBILI, Faculty of Medicine, University of Coimbra, Coimbra, Portugal.

Background and aims: Nuclear factor erythroid 2-related factor 2 (Nrf2), a basic leucine zipper transcription factor, plays a critical role in the cellular defense system by mediating the coordinated upregulation of antioxidant responsive element-driven detoxification and antioxidant genes. To determine whether activators of Nrf2 can be used in addition with inhibitors of advanced glycation end products formation to attenuate oxidative stress and improve endothelial dysfunction in type 2 diabetes we investigate pyridoxamine (PM) and/or sulforaphane (SFN) as therapeutic interventions in endothelial dysfunction associated with type 2 diabetes in both aorta and mesenteric arteries.
Materials and methods: Goto-kakizaki (GK) rats, an animal model of non-obese type 2 diabetes and age-matched control Wistar rats were treated with or without PM (100 mg/kg/day) and /or SFN (1 mg/kg/day) during 8 weeks. At the end of the treatment, nitric oxide (NO)-dependent and independent vasorelaxation in isolated aorta and mesenteric arteries were evaluated. Metabolic profile, NO bioavailability and vascular oxidative stress and Nrf2 levels were also assessed.
Results: Diabetic GK rats presented significantly lower levels of Nrf2 and concomitantly exhibited higher levels of oxidative stress and endothelial dysfunction (associated with decrease NO bioavailability). PM and SFN as monotherapy were capable of significantly improving endothelial dysfunction (by 20 and 25 %, respectively) in aorta and mesenteric arteries decreasing vascular oxidative damage (accumulation of anion superoxide and 3-nitrotyrosine in aorta and mesentery arteries, respectively) and HbA1c levels. Furthermore, SFN+PM proved more effective reducing systemic free fatty acids levels, normalizing endothelial function and NO bioavailability in GK rats.
Conclusion: Activators of Nrf2 can be used therapeutically in association with inhibitors of AGE formation to normalize endothelial dysfunction in type 2 diabetes and prevent atherosclerosis progression.

Vascular protective effects of glucose-dependent insulinotropic polypeptide via the endothelial PKA/AMPK/eNOS pathway

Y. Mori, H. Kushima, M. Hiromura, K. Kohashi, M. Terasaki, M. Koshibu, T. Fukui, T. Hirano;
Diabetes, Metabolism, and Endocrinology, Showa Universtiy School of Medicine, Tokyo, Japan.

Background and aims: Restenosis is a complication that arises after percutaneous transluminal angioplasty, which is a widely used revascularization procedure. The main pathophysiology of restenosis is neointimal hyperplasia, comprising exaggerated regeneration of the damaged intima. Recent technological advances such as drug-eluting stents have drastically reduced the incidence of restenosis; however, diabetic patients remain at high risk for the condition. In the present study, we investigated the protective effects of glucose-dependent insulinotropic polypeptide (GIP) against restenosis, using a mouse model of restenosis.
Materials and methods: Eight-week-old male wild-type C57BL6 (control) and db/db mice were implanted with osmotic pumps for agent delivery, before undergoing left femoral artery wire injury. Arteries were collected for analysis 25 days after injury.
Results: In the wild-type C57BL6 mice, GIP treatment (25 and 50 nmol kg^{-1} day^{-1}) induced a dose-dependent reduction (approximately 25 and 50%, respectively) in the neointimal area without affecting physiological and biochemical parameters, and an associated reduction in cell proliferation in the intima and media ($r = 0.85$ and 0.53, respectively; $p < 0.01$). In contrast, treatment with inactive GIP (3-42) had no observed effect on either the neointimal area or cell proliferation. The protective effects of GIP were completely abrogated by co-administration of *N*-omega-nitro-l-arginine methyl ester, a general nitric oxide synthase (NOS) inhibitor. The db/db mice all developed obesity and diabetes (fasting blood glucose level >20 mmol/L) at the initiation of GIP treatment (50 nmol kg^{-1} day^{-1}), and neither glucose tolerance nor weight gain was affected by the treatment. Similar to the wild-type mice, GIP-treated db/db mice exhibited a significant reduction (approximately 50%) in the neointimal area and cell proliferation. *In vitro*, GIP treatment dose-dependently increased NO production in human umbilical vein endothelial cells, and this effect was inhibited by a protein kinase A (PKA) or AMP-activated protein kinase (AMPK) inhibitor, but not by an exchange protein directly activated by cAMP or Akt inhibitor. Similarly, GIP treatment also induced phosphorylation of AMPK and endothelial NOS, and this effect was blocked by a PKA inhibitor. Notably, the effect of GIP treatment on NO production was not impaired under hyperglycaemic culture conditions (25 mmol/L). In human aortic vascular smooth muscle cells, GIP treatment did not suppress platelet derived growth factor-induced cell proliferation. Finally, we investigated the effect of internal GIP enhanced by a dipeptidyl dipeptidase-4 inhibitor by using the mouse model. We found that vildagliptin treatment (3mg kg^{-1} day^{-1})suppressed neointimal hyperplasia. This effect was preserved by approximately 50% in the presence of a glucagon like peptide-1 (GLP-1) receptor antagonist alone, with the complete abrogation by co-administration of antagonists of GLP-1 and GIP receptors.
Conclusion: GIP treatment modulated endothelial NO via the PKA/AMPK/eNOS pathway, and thereby suppressed neointimal hyperplasia to exert a protective effect against restenosis. This vasoprotective effect was maintained under hyperglycaemic conditions.
Disclosure: **Y. Mori:** None.

The effect of methylglyoxal accumulation on angiogenesis in endothelial cells

A. Leone[1], C. Nigro[1], I. Prevenzano[1], A. Nicolò[1], F. Fiory[1], P.P. Nawroth[2], P. Formisano[1], F. Beguinot[1], C. Miele[1];
[1]URT-GDD, National Council of Research, Department of Translational Medical Sciences, Federico II University of Naples, Napoli, Italy, [2]Department of Medicine I and Clinical Chemistry, University Hospital Heidelberg, Heidelberg, Germany.

Background and aims: Diabetes mellitus (DM) is a metabolic disorder representing a leading health problem worldwide. The high mortality associated to DM is mainly caused by vascular defects. DM impairs physiological angiogenesis, leading to long-term complications, by molecular mechanisms that are not fully understood. Generation of Advanced Glycation End-products (AGEs) has an important role in the development of hyperglycemia-induced endothelial damage. It was demonstrated that exposure of endothelial cells to hyperglycemia induces sustained activation of the transcription factor nuclear-κB (NFκB), at least in part by the AGEs/RAGE pathways, leading to accelerated vascular disease. The major precursor of AGEs is Methylglyoxal (MG), a highly reactive dycarbonyl produced as a byproduct of glycolysis and detoxified by the Glyoxalase System of which Glyoxalase 1 (Glo1) is the rate limiting enzyme. MG concentration is increased 2 to 5-fold in diabetic patients. Several studies suggest that MG contributes to endothelial dysfunction and vascular complications, but the underlying mechanisms remain to be clarified. This work aims at evaluating MG effect on angiogenic process in endothelial cells and the molecular mechanisms involved.
Materials and methods: Proliferation, migration and invasion were evaluated by cell-growth curves and transwell assays in mouse aortic endothelial cells isolated from Glo1 knockdown mice (GloKD MAEC) and their wild type littermates (WT MAEC). Glo1, HoxA5 and NFκB mRNA levels were measured by Real Time PCR, while MG intracellular concentrations by HPLC. HoxA5 expression was silenced by the use of specific siRNAs. HoxA5 and VEGFR2 protein levels were evaluated by western blot. NFκB protein levels and activation were evaluated by western blot on protein lysates from cytosol/nuclear fractionation. Binding of NFκB to HoxA5 promoter was then analyzed by chromatin immunoprecipitation assay. NFκB activation was inhibited by the chemical inhibitor JSH-23.
Results: GloKD MAEC show a 50% reduction of Glo1 mRNA levels and a 5-fold increase of MG intracellular concentrations compared to WT MAEC *($p=0.001$)*. GloKD MAEC show a slower cell growth (*$p=0.01$*), a reduced migration (*$p=0.0002$*) and invasion ability (*$p=0.04$*) compared to WT MAEC. Both mRNA (*$p=0.001$*) and protein levels (*$p=0.04$*) of the anti-angiogenic gene HoxA5 are 2-fold increased in GloKD MAEC compared to WT MAEC, and its silencing improves both migration (*$p=0.03$*) and invasion (*$p=0.004$*) ability of GloKD MAEC. Moreover, GloKD MAEC show a reduced protein levels of HoxA5 target VEGFR2 (*$p=0.03$*) compared to WT MAEC. NFκB mRNA (*$p=0.001$*) and protein levels in both the cytosol and the nucleus of GloKD MAEC are ~2-fold increased compared to WT MAEC (*$p=0.04$*) and the binding of NFκB to HoxA5 promoter is 1.4-fold higher in GloKD MAEC compared to WT MAEC (*$p=0.02$*). Interestingly, NFκB inhibition reduces HoxA5 expression in GloKD MAEC (*$p=0.009$*).
Conclusion: This study demonstrates that high levels of MG impair angiogenic ability of MAECs via a mechanism involving NFκB and the antiangiogenic factor HoxA5.

Vascular actions of vitamin D with implications for endothelial dysfunction

F. Carrilho[1,2], A. Pereira[1], C. Carvalho[3], R. Seiça[1], I. Baldeiras[4,5], C. Sena[1];
[1]Institute of Physiology, IBILI, Faculty of Medicine, University of Coimbra, Coimbra, [2]Intensive care unit, Santarém Hospital, Santarém, [3]Center of Neuroscience and Cell Biology, University of Coimbra, Coimbra, [4]Laboratory of Neurochemistry, Coimbra University Hospital,

Coimbra, [5]Faculty of Medicine, University of Coimbra, Coimbra, Portugal.

Background and aims: Vitamin D deficiency has been associated with obesity, cardiovascular disease and type 2 diabetes. The present study was designed to investigate the effects of vitamin D deficiency on the metabolic profile, oxidative stress and endothelial function in normal Wistar (W) and type 2 diabetic Goto-Kakizaki (GK) rats.
Materials and methods: Normal W and diabetic GK rats were divided in eight experimental groups at 2 months of age and subjected to specific diets for four months (normal or atherogenic diets (AD) with normal or low levels of vitamin D). The effects of chronic vitamin D deficiency and AD diets were investigated on NO-dependent vasorelaxation in isolated rat aortic arteries from the different groups. NO bioavailability, vascular oxidative stress, vitamin D receptor (VDR) and systemic levels of 25-hydroxyvitamin D (25(OH)D) were also evaluated.
Results: AD induced endothelial dysfunction in normal W rats inhibiting maximal endothelium-mediated relaxation of phenylephrine-precontracted rings in response to ACh declined by ~22 % ($p<0.001$). AD also aggravated the endothelial dysfunction present in GK rats by 10% ($p<0.05$). Chronic vitamin D deficiency significantly deteriorated NO-dependent vasorelaxation in W and GK rats (by 20 and 14%, respectively) treated with normal diet but had no additional effect on rats treated with AD diet. Endothelial dysfunction was accompanied by a decrement in NO bioavailability and by a significant increment in vascular oxidative stress (as determined by superoxide anion immunofluorescence) in both AD treated (30 % increment) and vitamin D deficient groups of rats (45 % increment). In addition, diabetic and atherogenic diet groups with low vitamin D content presented significantly decreased systemic 25(OH)D levels and lower aorta VDR expression levels subsequently promoting oxidative stress.
Conclusion: These results indicate that vitamin D deficiency in the vasculature is an essential nutrient and its absence leads to endothelial dysfunction in normal rats and to a severe deterioration of NO-dependent vasorelaxation in type 2 diabetes mellitus thereby enhancing morbidity due to cardiovascular disease.

Effect of acute hyperinsulinaemia and postprandial state on the vascular reactivity in type 2 diabetes patients and metabolically healthy volunteers

J. Veleba, L. Belinova, H. Kahlevoa, H. Malinska, K. Velebova, E. Stolarikova, T. Pelikanova;
Departement of Diabetoology, Institute of Clinical and Experimental Medicine, Prague, Czech Republic.

Background and aims: Endothelial dysfunction has been linked to the pathogenesis of cardiovascular disease. Mechanisms involved in the regulation of vascular reactivity are not fully understood. The aim of the study was to test the effects of isolated acute hyperinsulinemia and postprandial state on the vascular reactivity and oxidative stress.
Materials and methods: We enrolled 30 patients with type two 2 diabetes (T2D) on metformin treatment and 30 volunteers (C) with overweight or obesity and with normal glucose metabolism. All subjects underwent the hyperinsulinemic euglycemic clamp combined with indirect calorimetry and meal test using standard breakfast. Parameters of the endothelial function - Augmentation Index (AI) and Reactive Hyperemia Index (RHI) were measured by finger pulse plethysmography before and during the clamp and before and after the meal test. Repeated-measures ANOVA models, multivariate regression using the method of orthogonal projections to latent structure (OPLS) and Pearson's correlation coefficient were used for for statistical analysis.
Results: AI did not change in response to hyperinsulinemia in either group. RHI tended to decrease in C (ΔRHI_C: -0.112±0.71, $p>0.05$), while there was a trend toward increase in T2D (ΔRHI_{T2D}: 0.084±0.062, $p>0.05$). There was a statistically significant difference between the groups over time (Gxt $p<0.05$). AI decreased in both groups in response to meal test (ΔAI_{T2D}: -10.5±2.781, $p<0.001$; ΔAI_C: -7.631±2.03, $p<0.01$), whereas RHI did not change. Activity of superoxid dismutase (SOD) increased in both groups during the meal test (ΔSOD_{T2D}: 0.566 ±0.383, $p<0.05$; ΔSOD_C: 0.295±0.344; $p<0.01$). RHI was one of the independent predictors of type 2 diabetes ($p<0.01$) along with glycated hemoglobin ($p<0.01$), fasting glycemia ($p<0.01$), rest energy expenditure ($p<0.01$) and fasting oxidation of carbohydrates($p<0.01$). See the figure.
Conclusion: Postprandial state changes decreases arterial stiffnes during meal test. Oxidative stress is possible mediator of this changes. RHI is strong predictor of type 2 diabetes.

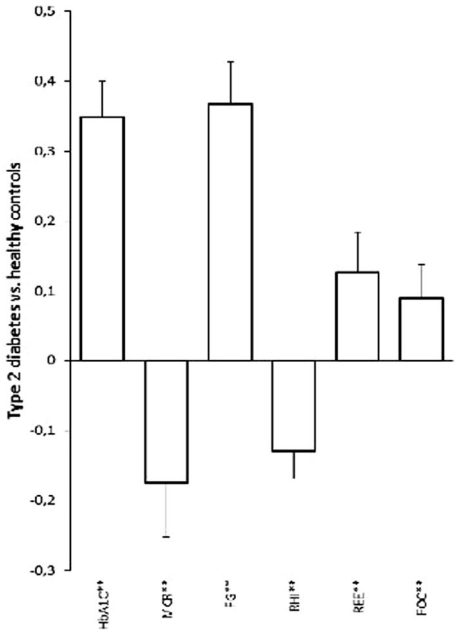

Fig. 2. The relationship between dependent metabolic variables and type 2 diabetes. HbA1c...glycated haemoglobin, MCR...metabolic clearance rate of glucose, FG...fasting plasma glucose, RHI... Exenatide LAR improves cardio-metabolic parameters independently of the presence of endothelial dysfunction in type 2 diabetic patients: an 8 month prospective study

C. Mannina[1], G. Castellino[1], A.M. Patti[1], A. Bonfiglio[1], R. Chianetta[1], R.V. Giglio[1], D. Nikolic[1], E. Corrado[1], R. Citarrella[1], A.A. Rizvi[2], G. Montalto[1], M. Rizzo[1,2];
[1]Biomedical Department of Internal Medicine and Medical Specialties, University of Palermo, Palermo, Italy, [2]Division of Endocrinology, Diabetes and Metabolism, University of South Carolina, School of Medicine, Columbia, USA.

Background and aims: Exenatide has been shown to augment endothelial function, few studies have examined the effects of exenatide once-

weekly (long-acting release, LAR) on endothelial function nor the dependence of these responses on baseline endothelial function. The aim of this study was to investigate: 1) the effect of exenatide LAR on cardio-metabolic parameters and endothelial function in patients with type 2 diabetes (T2DM) and 2) if such effects differ in the presence of endothelial dysfunction.

Materials and methods: Sixty subjects with T2DM (41 men and 19 women; 60±10 yrs) naïve to incretin-based therapies, and treated with exenatide LAR as add-on to metformin (from 1500 up to 3000 mg/day) for 8 months, were included in this prospective study. Exclusion criteria included the presence of a previous major cardiovascular (CV) event, as well as moderate and severe renal and liver function. Fasting blood samples were collected at baseline and after 8 months for routine biochemical analysis. The cohort of patients was subdivided in those with endothelial dysfunction (flow mediated dilation (FMD) ≤7%, n=30) and those without endothelial dysfunction (FDM >7%, n=30). Carotid intima-media thickness (cIMT) was assessed by B-mode real-time ultrasound.

Results: Statistical analysis was performed by paired t-test and ANOVA. After 8 months of exenatide therapy, glycemic and cardio-metabolic parameters improved in both groups, independently of the presence of endothelial dysfunction (Table).

Conclusion: It seems that exenatide LAR provides additional glycemic and cardio-metabolic control when added to metformin in diabetic patients with or without endothelial dysfunction. More studies of a longer duration are needed to confirm this encouraging finding.

Effects of vildagliptin combined with metformin on vascular endothelial function and systemic metabolism in patients with type 2 diabetes

T. Takase[1], N. Kitao[1], H. Miyoshi[1], T. Furumoto[2], K. Ono[3], H. Nomoto[1], A. Miya[1], C. Yamamoto[1], A. Inoue[4], K. Tsuchida[5], K.Y. Cho[1], A. Nakamura[1], Y. Kurihara[6], S. Aoki[7], T. Atsumi[1];
[1]Division of Rheumatology, Endocrinology and Nephrology, Hokkaido University Graduate School of Medicine, [2]Cardiovascular Medicine, NTT East Japan Sapporo Hospital, [3]Clinical Research and Medical Innovation Center, Hokkaido University Hospital, [4]Diabetes and Metabolism, Japan Community Healthcare and Organization Hokkaido Hospital, [5]Diabetes and Metabolism, Manda Memorial Hospital, [6]Diabetes and Metabolism, Kurihara Clinic, Sapporo, Japan, [7]Diabetes and Metabolism, Aoki Clinic, Sapporo, Japan.

Background and aims: We investigated the impact of vildagliptin and metformin combination (Vilda-add) compared with high-dose metformin (high-Met) on vascular endothelial function in patients with type 2 diabetes mellitus.

Materials and methods: This was multicenter, open-labeled prospective randomized, parallel-group comparison study. We enrolled 97 subjects with type 2 diabetes mellitus, HbA1c levels between 7.0% and 8.5% in the absence of a history of arteriosclerotic diseases. Patients were administered metformin (500 to 750 mg/day) in addition to diet and exercise therapy. Sulfonylureas and/or glinides use was allowed throughout the study in any patient. After acquiring consent, patients were assigned to the Vilda-add or high-Met group according to age, body mass index (BMI), HbA1c and flow-mediated dilation (FMD) at the assignment agency. In the Vilda-add group, vildagliptin (100 mg/day) was administered to patients taking metformin (500 to 750 mg/day). In the high-Met group, the metformin dose used before the study was doubled (1000-1500 mg/day). Strict blood glucose control was performed for 12 weeks. The primary endpoint, FMD, was analyzed at our hospital before and after the trial by the same technician who was blinded to the treatment groups. In addition, assessments of glycemic control and metabolic parameters were conducted.

Results: Ninety-seven subjects (58.7 ± 11.0 years of age; BMI, 25.9 ± 4.4 kg/m^2; HbA1c, 7.3 ± 0.5%; FMD, 5.8 ± 2.6%) were enrolled and randomized. Eight subjects dropped out by the end of the study. After 3 months, HbA1c significantly improved in the Vilda-add group compared with that in the high-Met (−0.87 ± 0.38% vs. −0.40 ± 0.47%, respectively; p <0.01). However, there were no significant differences in FMD between those two groups(−0.93 ± 2.18% vs. −0.86 ± 2.75%; p = 0.89). The apoB/apoA1 ratio was significantly improved in the Vilda-add compared with that at baseline (0.676±0.175 vs. 0.635±0.182; p<0.01), but the change did not significantly differ between the two groups (−0.041 ± 0.084 vs. −0.026 ± 0.079; p=0.38). Adiponectin levels were significantly increased in the Vilda-add compared with those of the high-Met (0.750 ± 1.072 μg/ml vs. 0.012 ± 0.872 μg/ml; p <0.01). There were no significant differences in other lipid profile or oxidative stress parameters.

Conclusion: Combination therapy of vildagliptin and metformin did not further improve vascular endothelial function compared with that of high dose metformin administration.

Comparison of acute and chronic effects of sitagliptin vs glimepiride on endothelial dysfunction during an oral glucose loading in drug naive patients with type 2 diabetes

S. Sakurai, T. Jojima, M. Sagara, T. Iijima, K. Suzuki, Y. Aso;
Department of Endocrinology and Metabolism, Dokkyo Medical University, Mibu, Japan.

Background and aims: Recently, we have reported that administration of sitagliptin, a DPP-4 inhibitor, for 12 weeks significantly increases the number of endothelial progenitor cells (EPCs) in people with type 2 diabetes, compared with glimepiride, a sulfonylurea. However, no reports have examined acute and chronic effects of DPP-4 inhibitors on endothelial function. The aims of our randomized, prospective, parallel design study were to investigate whether a single administration of sitagliptin (50 mg) can improve acute endothelial dysfunction evaluated by both flow-mediated dilatation (FMD) of the brachial artery and reactive hyperemia index (RHI) and increased the number of circulating EPCs during oral glucose loading (OGTT) in drug naïve patients with type 2 diabetes, and

to evaluate endothelial function after 12 weeks treatment with sitagliptin (50 mg/day) and glimepiride (1.0 mg/day).
Materials and methods: Fourteen drug-naïve diabetic patients were randomized into a sitagliptin 50 mg (N=9) or a glimepiride 1 mg (N=5) treatment group. At baseline and day 1 (acute dosing) after each treatment, endothelial function (FMD and RHI) and the number of EPCs (CD34+CXCR4+ cells measured by flow cytometry) were measured at 0, 30, 60,120, and 180 min during 75g OGTT. We also measured FMD and RHI after 12-week treatments.
Results: During the OGTT, in the sitagliptin group, both FMD and RHI trended to be increased at 60 min (P=0.286, 0.398 , respectively), while in the glimepiride group they tended to be decreased (P= 0.730, 0.287 , respectively). In the sitagliptin group, the number of EPCs tended to be decreased during the OGTT, while in the glimepiride group, it showed no significant changes. After 12 weeks of each treatment, both FMD and RHI showed an increasing tendency in the two groups.
Conclusion: Acute dosing of sitagliptin, but not glimepiride, improved endothelial function evaluated by FMD and RHI during the OGTT, while it tended to reduce the number of EPCs, suggesting acute effects of sitagliptin on endothelial function may be not associated with the number of circulating EPCs. Acute and chronic administration of sitagliptin may improve endothelial dysfunction in drug-naïve people with type 2 diabetes.

Dapagliflozin acutely restores endothelial dysfunction, reduces aortic stiffness and renal resistive index in type 2 diabetic patients: a pilot study

M. Seghieri[1], L. Giannini[1], E. Vitolo[1], S. Taddei[1], L. Ghiadoni[1], R.M. Bruno[1], A. Solini[2];
[1]Clinical and Experimental Medicine, University of Pisa, [2]Surgical, Medical, Molecular and Critical Area Pathology, University of Pisa, Pisa, Italy.

Background and aims: Sodium-glucose co-transporter-2 inhibitors reduce blood pressure (BP) and renal and cardiovascular events in patients with type 2 diabetes (T2DM) through not fully elucidated mechanisms. Aim of this study was to investigate whether dapagliflozin (Dapa) is able to acutely modify systemic and renal vascular function and improve endothelial function, whose amelioration by pharmacologic intervention may represent an ancillary goal in the treatment of T2DM.
Materials and methods: Neuro-hormonal and vascular variables, together with 24h-diuresis, urinary electrolytes, glucose, 8-isoprostanes and free-water clearance were assessed before (Visit 0) and after (Visit 1) a 2-day treatment with Dapa 10 mg QD in sixteen T2DM patients. Brachial artery endothelium-dependent and independent vasodilation (by flow-mediated dilation) and pulse wave velocity were assessed. Renal resistive index was obtained at baseline and after glyceril trinitrate administration.
Results: As expected by its mode of action, Dapa decreased systolic BP (from 130.6±12.8 to 125.4±11.2 mmHg, p=0.02) and induced an increase in 24h-diuresis (from 1400[750] to 2000[750] ml/24h, p=0.004) and 24h-urinary glucose output (406[3465] to 66239[43780] mg/24h, p<0.0001). Reduction in fasting plasma glucose did not reach the significance; interestingly, serum magnesium rose after Dapa treatment (from 1.92±0.19 to 2.04±0.17 mg/dl, p<0.0003), while no changes in the urinary electrolytes excretion, including sodium, were observed. Dapa administration resulted in a significant decline of plasma renin activity (p=0.03), but did not influence aldosterone levels, as well as the neuro-hormonal pattern, given that noradrenaline and adrenaline concentrations were unmodified. Oxidative stress was reduced, as by a decline in urinary isoprostanes (from 1659±1029 to 1157±663 pg/ml, p=0.04). Among the vascular variables, flow-mediated dilation was significantly increased (from 2.8±2.2 to 4.0±2.1%, p<0.05), while pulse-wave-velocity was reduced (from 10.1±1.6 to 8.9±1.6 m/s, p<0.05), even after correction for mean BP (Figure 1). Renal resistive index decreased (0.62±0.04 to 0.59±0.05, p<0.05), as well as its response to nitrates.
Conclusion: An acute treatment with Dapa significantly improves systemic endothelial function, arterial stiffness and renal resistive index; this effect is independent of changes in BP and occurs in the presence of stable natriuresis and plasma glucose levels, indicating a fast, direct beneficial effect on the vasculature, possibly mediated by a reduced oxidative stress. A minor contribute of serum magnesium increase to vascular protection might be suggested.

Association of the atherosclerosis candidate-genes polymorphism with endothelial function and atorvastatin response in type 2 diabetes

N.O. Lebedeva[1], O.K. Vikulova[2,1], M.V. Shestakova[2,1], M.S. Shamkhalova[2], A.G. Nikitin[3];
[1]I.M. Sechenov First Moscow State Medical University, [2]Endocrinology Research Center, [3]FSCC FMBA, Moscow, Russian Federation.

Background and aims: To estimate the association of the endothelial dysfunction (ED) and the lipid-lowering response to atorvastatin therapy in T2D patients with genetic markers of atherosclerosis.
Materials and methods: We include 122 T2D statin-naïve patients: M/F 23/77; mean age 64 yr. Drug: atorvastatin, dose: 10-20 mg, treatment period: 12 month. 97 patients are completed clinical protocol. Before and after of statin therapy, patients had fasting lipid profiles and ED parameters performed. Assessment of endothelial function was performed by non-invasive peripheral arterial tonometry. The endothelial improvement was estimate as the postocclusive wave amplitude (Apw) increase. The genotypes for a complex of polymorphic markers were identified by PCR in real time with the TaqMan probes. Statistic analysis was evaluated using the Mann-Whitney, Wilcoxon tests, p <0,05.
Results: With statin therapy, PPARG2Pro/Pro had significantly TC, LDL-C lowering compared with PPARG2Pro/Ala, PPARG2 Ala/Ala patients (for TC: 20.74% vs. 4.6% and 5.61%; p = 0.04, respectively; for LDL-C: 26.00% vs. 6.11% and 7.32 %; p = 0.029, respectively). The % of Apw increase on atorvastatin was greater in GG vs GA carries of TNFα G(238)A: +8,16% vs. -0,93%, p=0,04; and GA vs. GG of TNFα G(308)A: +44% vs. -4.4%, p=0,004. The % of Apw and TC, LDL-C improvement didn't depend on age, diabetes duration, basal lipids levels and HbA1c. There were statistically significant differences in the genotypes distribution in the maximum and minimum lipid-lowering effect groups: in the group with the maximum decrease in lipids: all patients (100%) were carries of the two genotypes associated with the best lipid-lowering effect (*E4E4, E3E3, ProPro* - named as genotypes responders), among them 75% of patients were carries of the two genotypes associated with the Apw improvement (*GA* carries of *TNF-α G(-308)A* and *GG* carries of *TNF-α G (-238)A*), other 25% of patients were carries of the genotypes associated with the Apw decrease (*GG* carries of *TNF-α G(-308)A* and *GA* carries of *TNF-α G (-238)A*). Conversely, in the group of resistant patients who did not respond to statin therapy with lipid reduction: there didn't carries of the two genotypes responders, there were 75% of one genotype responder carries and 25% of genotypes non-responders carries (*E2E4, E3E4, E2E3, ProAla, AlaAla*), among them only 22,2% of patients were carries of the two genotypes associated with the Apw improvement, other 77,8% of patients were carries of the genotypes associated with the Apw decrease.
Conclusion: The result of statin therapy, both clinical - lipid-lowering effect, and pathogenetic - improvement of endothelial function, has genetic determinants and associated with *PPARG2 Pro12Ala*, *APOE E2/E3/E4* and *TNF-α* polymorphisms, that might be used for the personalized evaluation of cardiovascular prognosis improvement on statin therapy in type 2 diabetic patients.

Modification of cardiac morphology was associated with impaired myocardial sensitivity to ischaemia-reperfusion injury in a diet-induced metabolic syndrome model

N. Fourny, C. Lan, F. Kober, M. Bernard, M. Desrois;
Aix-Marseille Université, CNRS, CRMBM, Marseille, France.

Background and aims: Metabolic Syndrome (MetS) is defined by multiple risk factors that predict type 2 diabetes and cardiovascular complications, such as myocardial infarction, especially in women. Consequently the aim of this study was to investigate in vivo and ex vivo the effects of a high-fat-high-sucrose diet (HFHSD) on the development of metabolic syndrome (MetS), cardiac morphology and sensitivity to ischemia-reperfusion injury of female Wistar rat.
Materials and methods: Female Wistar rats, subjected to HFHSD (FHFD) or Normal Diet (FND) during 5 months, were explored in vivo every month with multimodal cardiovascular magnetic resonance (CMR). Cine-MRI (Magnetic Resonance Imaging) and arterial spin labeling (ASL-FAIR) techniques were used to determine cardiac morphology, function and perfusion. Triglyceride (TG) content in heart and liver was also evaluated with ^{1}H Magnetic Resonance Spectroscopy (MRS). Sub-cutaneous and visceral adipose tissues were measured with ^{1}H MRI. Then, rats underwent an intraperitoneal glucose tolerance test (IPGTT) to determine glycemic status. Finally, isolated heart were perfused with a physiological buffer containing 0.4 mM palmitate for 24 minutes before switching to 1.2 mM palmitate during 32 minutes low-flow (0.5 mL/min/g wet wt) ischemia. Next, flow was restored with 0.4 mM palmitate buffer for 32 minutes. High-energy phosphates and intracellular pH were measured during the experimental course by ^{31}P magnetic resonance spectroscopy with simultaneous measurement of contractile function. Coronary flow was measured before and after ischemia. At the end of experiments, hearts were freeze-clamped for biochemical assays.
Results: In FHFD vs. FND, CMR showed an increase of systolic wall thickness over time ($p<0.05$) and diastolic wall thickness at 3 and 5 months ($p<0.01$); ^{1}H MRS showed that hepatic TG content was increased ($p<0.01$) at 5 month but myocardial TG content was not different. IPGTT showed a significant glucose intolerance ($p<0.001$) and plasma free fatty acids were increased ($p<0.05$) in FHFD vs. FND. At 5 months, weight was not different between groups but FHFD exhibited an abdominal obesity with increased visceral adipose tissue ($p<0.05$), % fat ($p<0.05$) and % visceral fat ($p<0.05$) compared with FND. Ex vivo myocardial function was impaired in FHFD vs. FND before ($p<0.01$) and after ischemia ($p<0.05$).
Conclusion: HFHSD-induced MetS was characterized by glucose intolerance, abdominal obesity, hepatic fat deposit which were associated with modification of cardiac morphology and higher myocardial sensitivity to ischemia-reperfusion injury. These results may be related to higher risk of cardiovascular complications among type 2 diabetic obese women.

Riluzole rescues the high-fat diet-induced depression in mice: the role of hippocampal glial glutamate transporters

T.-F. Wang[1,2], P.-S. Chen[2], S.-F. Tsai[3], Y.-M. Kuo[3,4];
[1]Taiwan International Graduate Program in Interdisciplinary Neuroscience, National Cheng Kung University and Academia Sinica, Taipei City, [2]Department of Psychiatry, College of Medicine, National Cheng Kung University, Tainan City, [3]Institute of Basic Medical Sciences, College of Medicine, National Cheng Kung University, Tainan City, [4]Department of Cell Biology and Anatomy, College of Medicine, National Cheng Kung University, Tainan City, Taiwan.

Background and aims: Epidemiological studies indicate an association between metabolic disorders and depression. We recently found that diet-induced obesity mice exhibit depression-like behaviors. Maladaptation of reward circuit is a major cause of depression. An over-activated glutamatergic output projecting from the hippocampus is known to cause depression. The hippocampus is also a region vulnerable to metabolism disturbances. Here, we characterized the role of hippocampal glutamatergic transmission in the pathogenesis of high-fat diet (HFD)-induced depression. We also investigated the therapeutic effect of riluzole, a glutamatergic transmission normalizer, on HFD-induced depression.
Materials and methods: Eight-week-old male B6 mice were divided into Chow and HFD groups which were respectively fed with normal diet and HFD for 12 weeks. Forced swimming test (FST) and sucrose preference test (SPT) were used to assay the depression-like behaviors. The hippocampal expression of glutamatergic transmission-related proteins was measured. In testing the therapeutic effect of riluzole on depression, the mice were treated with daily injection of riluzole (4 mg/kg body weight, i.p.) for 21 days starting from the 10^{th} week of the 12-week feeding period.
Results: HFD increased the body weights (g, 28.7 ± 0.8 vs. 44.2 ± 1.1, $p < 0.0001$) and induced systemic insulin resistance (fasting plasma glucose: mg/dL, 128.6 ± 7.4 vs. 99.2 ± 7.8, $p < 0.05$; fasting plasma insulin: ng/mL, 1.5 ± 0.1 vs. 0.4 ± 0.0, $p < 0.0001$; HOMA-IR, 3.6 ± 04 vs. 0.7 ± 0.0, $p < 0.0001$) in mice. HFD also induced depression-like behaviors (FST: immobility %, 72.8 ± 4.0 vs. 42.1 ± 10.3, $p < 0.05$; SPT: sucrose preference %, 58.9 ± 1.8 vs. 68.8 ± 2.4, $p < 0.05$) in mice. Moreover, HFD decreased the expression of glial glutamate transporters, i.e. GLAST (relative expression, 0.4 ± 0.0 vs. 1.0 ± 0.1, $p < 0.001$) and GLT-1 (relative expression, 0.6 ± 0.1 vs. 1.0 ± 0.1, $p < 0.05$), in the hippocampus without obvious morphological changes in astrocytes and microglia. The 21-day riluzole treatment restored the hippocampal expression of GLAST (relative expression, 0.7 ± 0.1 vs. 0.2 ± 0.1, $p < 0.05$) and GLT-1 (relative expression, 0.8 ± 0.1 vs. 0.3 ± 0.1, $p < 0.05$), and rescued the HFD-induced depression-like behaviors (FST: immobility %, 28.7 ± 5.4 vs. 63.5 ± 3.3, $p < 0.05$; SPT: sucrose preference %, 63.0 ± 1.1 vs. 55.5 ± 2.4, $p < 0.05$).
Conclusion: HFD concurrently reduces the hippocampal levels of GLAST and GLT-1 and induces depression-like behaviors in mice. Riluzole restores the expression levels of GLAST and GLT-1 in the hippocampus and rescues the HFD-induced depression in mice. These results suggest that the decreased expression of the hippocampal GLAST and GLT-1 may be involved in the development of depression-like behaviors in animals with metabolic disorders.

Hyperglycaemia renders nigrostriatal dopaminergic neurons more vulnerable to damage in a mouse model of Parkinson's disease

I. Pérez-Taboada[1], R. Moratalla[2], M. Vallejo[1];
[1]Instituto de Investigaciones Biomédicas Alberto Sols, CSIC-UAM, and Ciberdem, [2]Instituto Cajal and Ciberned, Madrid, Spain.

Background and aims: Increasing evidence suggests that diabetic patients present a higher risk of developing neurodegenerative diseases as they age. For instance, it is well documented that diabetes can be associated to the development of cognitive impairment and Alzheimer's disease. In the case of Parkinson's disease, one of the most common neurodegenerative diseases characterized by the loss of dopaminergic cells in the substantia nigra that project to the striatum, this association is less well documented, and the underlying mechanisms by which hyperglycemia may result in increased neuronal damage are unknown. In the present study, we sought to investigate whether diabetes increases the vulnerability of neurons of the nigrostriatal dopaminergic system to neurodegeneration in mice.
Materials and methods: We used C57BL/6 mice in which diabetes was induced by repeated administration of streptozotocin. Mice were unilaterally injected with a reduced dose of the neurotoxin 6-hydroxydopamine (6-OHDA) into the striatum two weeks or one month after the onset of diabetes. A sub-threshold dose of 6-OHDA insufficient to cause motor impairment in normal non-diabetic animals was used. Motor function was measured with well-established tests widely used in animal models of Parkinson's disease. Neurodegeneration was monitored histologically. Molecular markers of neuronal function were determined by RT-qPCR.
Results: Motor performance was unaffected in control non-diabetic animals injected with 6-OHDA. In contrast, diabetic mice developed significant motor impairments. Immunohistochemical analysis of 6-OHDA-injected striata showed that the content of tyrosine hydroxylase, a molecular marker of nigrostriatal innervation, was significantly reduced in diabetic as compared with non-diabetic animals. The number of tyrosine hydroxylase positive cells in the substantia nigra was determined stereologically in 6-OHDA injected mice, and a significant decrease was only observed in diabetic but not in non-diabetic animals. Two week-diabetic mice showed an intermediate phenotype between non-diabetic and one month-diabetic mice, suggesting a time-dependent effect of hyperglycemia. Expression of phenotypic markers of substantia nigra neurons was not affected by diabetes, but expression of neurotransmission-related genes was reduced. Furthermore, we observed a marked deregulation of genes encoding free-radical scavenging enzymes, suggesting increased oxidative stress in these neurons as a consequence of diabetes.
Conclusion: Our data indicate that hyperglycemia increases the vulnerability of dopaminergic neurons to neurodegenerative damage leading to motor impairment, thus providing new insights into the pathophysiology of a possible relationship between diabetes and Parkinson's disease.

Cardiac effects of combined SGLT1/2 inhibition following myocardial infarction

R.E. Gilbert, Y. Zhang, K. Thai, G. Kabir, J.-F. Desjardins, K. Connelly; St. Michael's Hospital, University of Toronto, Toronto, Canada.

Background and aims: Dual SGLT1/2 inhibition offers the potential to not only increase glucosuria beyond that seen with selective SGLT2 inhibition alone but to reduce glucose absorption from that gut as well and to thereby also stimulate glucagon-like peptide 1 (GLP-1) secretion. However, beyond the kidney and gut, SGLT1 is expressed in a range of other organs including the heart where it potentially assists GLUT-mediated glucose transport. Since cardiac myocytes become more reliant on glucose as a fuel source in the setting of stress, the present study sought to compare the effects of dual SGLT1/2 inhibition with selective SGLT2 inhibition in the normal and diseased heart.
Materials and methods: Hyperglycaemic (plasma glucose 10-15 mmol/l) Fischer F344 rats were randomized to receive either vehicle, the dual SGLT1/2 inhibitor, T-1095 (150 mg/kg/d p.o.), or the selective SGLT2 inhibitor, dapagliflozin (1 mg/kg/d p.o.). Animals were then further randomized to undergo sham surgery or ligation of the left anterior descending (LAD) coronary artery to induce infarction of the left ventricle (LV). Cardiac function was assessed by echocardiography and conductance catheterisation just prior to termination 4 weeks later that was followed by assessment of cardiac structure.
Results: Dapagliflozin and T-1095 induced glucosuria to a similar extent in both the control and myocardial infarction settings with similar effects on glycaemia as assessed by serum fructosamine. Neither dapagliflozin nor T-1095 had any demonstrable effect on cardiac function or structure in the control setting. Following myocardial infarction, however, significant ($p<0.05$) differences were noted. When compared with vehicle or dapagliflozin-treated animals, rats that received T-1095 displayed worse cardiac function in both systole and diastole as evidenced by (i) lower

ejection fraction, (ii) reduced maximal rate of LV pressure rise in early systole (dP/dt max), (iii) impaired isovolumic relaxation in diastole (dP/dt min), (iv) prolongation of the early, energy-dependent phase of relaxation in diastole (Tau), and (v) reduced passive LV compliance as measured by an increase in the end-diastolic pressure volume relationship (EDPVR). While vehicle and dapagliflozin-treated rats underwent hypertrophic changes following myocardial infarction this did not occur in animals that had received T-1095 where LV mass and cardiac myocyte cross-sectional area were similar to those of control, uninfarcted rats. Following myocardial infarction, lung weight, a marker of interstitial/alveolar oedema was also higher in T-1095 treated rats than in those animals that had received either vehicle of dapagliflozin.

Conclusion: Dual SGLT1/2 inhibition with T-1095 prevented the hypertrophic response following experimental myocardial infarction in the rat with adverse consequences on both systolic and diastolic function. These findings suggest that the heart may be more reliant on SGLT1-mediated glucose transport in the disease setting. The gap between animal and human studies notwithstanding, these findings further suggest the need for caution with dual SGLT1/2 inhibition in patients with diabetes at high cardiovascular risk.

Effect of insulin or metformin on the wound healing process in rats with streptozotocin-induced diabetes

B. Mrozikiewicz-Rakowska[1], M. Mieczkowski[1], T. Siwko[1], M. Bujalska-Zadrożny[2], R. Wolińska[2], A. de Corde[2], T. Grzela[3], P. Foltyński[4], L. Czupryniak[1];
[1]Internal Diseases and Diabetology, Medical University of Warsaw, [2]Department of Pharmacodynamics, Medical University of Warsaw, [3]Department of Histology and Embryology, Medical University of Warsaw, [4]Institute of Biocybernetics and Biomedical Engineering, Polish Academy of Sciences, Warsaw, Poland.

Background and aims: Good glycemic control is crucial for the proper wound healing in patients with diabetes. We conducted a study aiming at assessing the effect of insulin and metformin administration on the wound healing wounds in an experimental model in rats with streptozotocin induced diabetes.

Materials and methods: The study was performed on a group of 80 male Wistar rats with streptozotocin-induced diabetes. In the first step, 45 rats were divided into 3 groups: group 1 received human NPH insulin intraperitoneally (5 j.m./kg m.c.) once daily, group 2 received metformin intragastrically (500 mg/kg m.c.) once daily, and group 3 (controls) were given saline intraperitoneally. The treatment goal was to achieve blood glucose levels of 350-450 mg/dl in order to reflect hyperglycemic conditions often associated with wound development. After 30 days of treatment the rats had the thin layer of the skin cut out from the dorsal skin 2x2 cm and sutured with a silicone disc with a hole in the centre in order to stabilize the skin and standardize the process of healing. The wounds were assessed every 3 days: digital photography was performed and a wound surface biopsy was conducted. The wounds healing was followed up for 9 days. Biopsy samples were subject to H+E staining and immunohistochemical asssays were conducted to evaluate the expression of the proliferation marker - Ki67 antigen. Metformin or insulin were administered during the wound healing follow-up time.

Results: Analysis of variance revealed significant influence of treatment type (insulin, control or metformin) on the relative wound area ($p < 0.001$). Mean changes of relative wound area for 3 types of treatments at 3 moments are presented in Table 1. Healing in the rats treated with insulin was more advanced than in the control group after 3 days, and it was more advanced than metformin after 6 and 9 days. There were no differences between the metformin and control groups at any stage of the study. Wound tissue samples taken from the insulin treated animals presented with significantly lower level of inflammatory infiltratio than those obtained from the rats treated with metformin. Immunohistochemical assessment showed the greatest density of centers of profileration in insulin treated animals.

Conclusion: The results of our experimental study suggest that insulin treatment is more beneficial than metformin for accelerating wound healing process in animal model. As the observations were made at a similar level of hyperglycemia in all groups, it might be speculated that there is an additional effect of insulin treatment on wound healing beyond glucose lowering action.

Table 1. Mean decrease of wound area in three studied groups during follow-up.

Follow-up	Insulin	Control	Metformin
3 days	-28.2 ± 6.5%	-26.2 ± 9.4%	-22.2 ± 3.9%
6 days	-39.0 ± 11.5%	-33.8 ± 6.6%	-26.5 ± 6.3%
9 days	-66.8 ± 9.7%	-48.0 ± 9.8%	-40.4 ± 15.8%

data are given as mean ± SD

Beneficial effects of combination therapy with pioglitazone and dapagliflozin on diabetic nephropathy in db/db mice

E. Han[1], Y. Cho[2], Y.-H. Lee[2], B.-W. Lee[2], E. Kang[2], B.-S. Cha[2];
[1]Keimyung University School of Medicine, Daegu, [2]Yonsei University College of Medicine, Seoul, Republic of Korea.

Background and aims: Although dapagliflozin and pioglitazone have glucose lowering and anti-inflammatory effects, the therapeutic efficacy of combination therapy on diabetic nephropathy has not been investigated. The aim of this study was to investigate the therapeutic effect of combination therapy in an animal model to support the experimental rationale for the combination therapy of dapagliflozin and pioglitazone.

Materials and methods: 9-week-old male db/db mice were randomly assigned to four groups with (1) vehicle, (2) dapagliflozin-, (3) pioglitazone-, (4) dapagliflozin and pioglitazone combination-treated groups. Dapagliflozin (2 mg/kg/day), and pioglitazone (30 mg/kg/day), and combination (dapagliflozin 2 mg/kg/day + pioglitazone 30 mg/kg/day) were administrated by oral gavage for 9 weeks. To further understand cellular mechanisms underlying the protective effect of combination treatment, protein expressions and cell survival of HK-2 cells were studied.

Results: The mean random blood glucose and urine albumin-creatinine ratio were lowered in all treatment groups ($P<0.05$). Glomerular tuft area and mesangial expansion of kidney were the most suppressed in the combination group. Podocyte foot process width and glomerular basement membrane thickness were decreased regardless of the treatment, and the combination group showed the lowest renal hypertrophy progression ($P<0.05$). The combination treatment decreased the expression of TGF-beta, type IV collagen, and type 1 collagen in renal cortex. High glucose and palmitic acid upregulated TGF-beta and IL-6, and stimulated angiotensinogen and renin expressions. Treated HK-2 cell with those 3 medications inhibited TGF-beta expression (all $P<0.05$), only combination treatment decreased angiotensinogen expression ($P=0.033$). Furthermore, combination treatment enhanced cell survival in the presence of high glucose and palmitic acid ($P=0.001$).

Conclusion: Dapagliflozin and pioglitazone treatment preserved renal function in db/db mice and the combination therapy showed the best beneficial effects. These findings suggest that the combination therapy might prevent the progression of diabetic nephropathy in patients with type 2 diabetes.

Topical linagliptin is on par to systemically acting linagliptin in improving diabetic wound healing in db/db mice

T. Klein[1], D. Maucher[1,2], M. Mark[1], S. Frank[2];
[1]Department of CardioMetabolic Disease Research, Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, [2]Pharmazentrum Frankfurt, Klinikum der Johann Wolfgang Goethe-Universität, Frankfurt am Main, Germany.

Background and aims: Linagliptin is a potent dipeptidyl peptidase (DPP)-4 inhibitor, approved as an oral treatment for patients with type 2 diabetes mellitus. We recently reported that linagliptin improved diabetic wound healing disorders in obese (*ob/ob*) mice. The observed improved re-epithelialization of the wounded skin was associated with an improved glucose tolerance in the animals and also with a reduction in inflammatory polymorphonuclear neutrophil infiltration. In order to discriminate the anti-hyperglycaemic effect from potential other effects, we tested different topical formulations of linagliptin which caused either relevant systemic exposure of linagliptin in the plasma, or not. The aim of this study was to evaluate whether linagliptin exerts direct effects on the skin which are not mediated via improved glucose control.
Materials and methods: 8 to 12 week old female diabetic *db/db* mice or CD-1 mice (Charles River) were wounded with 4 full excisional wounds on the back of each animal. Oil/water emulsions of Linagliptin (0.5%, 0.01%, and 0.001%) were prepared and administered (~1 mg every second day) with a sterile applicator to each wound. Wound closure and histology were monitored after 10 days. For drug monitoring in plasma, blood was taken 3 hours after last application. DPP-4 activity, glucose, and active glucagon-like peptide-1 (GLP-1) were also monitored.
Results: In the pilot study in CD-1 mice, we aimed to define topical linagliptin formulations which did and did not show systemic DPP-4 inhibition. DPP-4 activity (relative fluorescence unit [RFU]) in plasma was 1284±43.8 RFU with vehicle and significantly ($p<0.01$) reduced with the 0.5% (272.5±6.3 RFU) and the 0.01% (500.5±13.4 RFU) linagliptin formulations, but there was no reduction with the 0.001% formulation (1206±42 RFU). Topical formulations of 0.5% and 0.001% were subsequently used in *db/db* mice. Wound closure in vehicle-treated *db/db* mice was 18.7±2.8% after 10 days, which was significantly ($p<0.01$) improved in animals receiving the 0.5% (74±6.6%) and 0.001% (64.7±15.9%) formulations. In contrast, active GLP-1 was only increased with the 0.5% formulation (0.73±0.19 ng/ml, $p<0.001$) compared with controls (0.067 ±0.02 ng/ml) and the 0.001% formulation (0.17±0.12 ng/ml, n.s). In line with this observation, there was no reduction of DPP-4 activity in vehicle- (1857±142 RFU) and 0.001%-treated mice (1882±272.1 RFU) and a significant reduction in 0.5%-treated mice (528.8±68.2 RFU, $p<0.0001$). Fed glucose levels were only significantly ($p<0.05$) reduced compared to vehicle in the 0.5%-treated group by 31 ± 2.6%.
Conclusion: Topical linagliptin at doses that were shown not to affect systemic DPP-4 activity nor active GLP-1 levels was equipotent to systemically acting linagliptin at improving diabetic wound healing. These findings suggest a mechanism that involves local DPP-4 substrates rather than systemic DPP-4 inhibition and glucose control.

Linagliptin alleviates podocyte injury and enhances glomerular nephrin expression in a model of type 2 diabetes

A.I. Korbut[1], V.V. Klimontov[1], N.P. Bgatova[1], Y.S. Gavrilova[1], I.Y. Ischenko[1], N.B. Orlov[1], A.S. Dozenko[2], E.L. Zavjalov[2];
[1]Scientific Institute of Clinical and Experimental Lymphology, [2]Federal Research Center "Institute of Cytology and Genetics of SB RAS", Novosibirsk, Russian Federation.

Background and aims: A growing body of evidences indicates the potency of dipeptidyl peptidase-4 (DPP-4) inhibitors for reducing of albuminuria in diabetes. It have been demonstrated that the disturbances in podocyte function can be responsible for elevation of albumin excretion rate at initial stages of diabetic nephropathy. Expression of nephrin and other key podocyte-specific proteins are downregulated in diabetes. Therefore, the aim of our study was to assess the effect of DPP-4 inhibitor linagliptin on podocyte structure and glomerular nephrin expression in db/db diabetic mice.
Materials and methods: Eight-week-old male diabetic db/db mice (BKS.Cg-Dock7^{m}+/+Lepr^{db}/J) were treated with linagliptin (10 mg/kg per day by gavage) or vehicle for 8 weeks. Non-diabetic heterozygous db/+ mice were acted as control. The concentrations of insulin, glucagon, leptin and resistin in blood plasma were determined by Multiplex analysis, and body composition was assessed by MRI at week 0 and 8 of experiment. Renal structural changes were analyzed quantitatively from the light and electron microscopic images. Nephrin staining in glomeruli was assessed by immunohistochemistry.
Results: Severe hyperglycemia and obesity developed prior to the beginning of experiment in db/db mice. These mice demonstrated substantially elevated serum levels of leptin and insulin and increased fat percentage at week 0 and week 8 (all $p<0.00001$). The blood glucose levels remained markedly elevated throughout the experiment in both linagliptin and vehicle groups. Nevertheless, linagliptin-treated mice, as compared to vehicle-treated animals, demonstrated attenuated mesangial expansion estimated by fractional mesangial volume ($p=0.03$). The width of glomerular and tubular basement membrane was diminished by linagliptin significantly ($p=0.03$ and $p=0.007$ respectively). Podocytopathy in diabetic mice was manifested by the foot process effacement. In linagliptin group, as compared to placebo, the mean width of podocyte foot process was reduced and the number of podocyte foot processes was increased significantly (both $p<0.01$). Vehicle-treated diabetic mice had weak staining for nephrin in glomeruli. Meantime, the volumetric density of nephrin-expressing glomeruli was increased markedly in linagliptin group ($p=0.02$).
Conclusion: The data from the current study demonstrate that DPP-4 inhibitor linagliptin ameliorates podocyte injury and enhances glomerular expression of nephrin in a model of type 2 diabetic nephropathy. The data provide further explanation for the mechanism of antialbuminuric effect of DPP4 inhibitors in diabetes.

Differential effects of experimental diabetes versus chronic polyuria on the rat bladder transcriptome

E.A. Hindi, L.A. Zeef, A.S. Woolf, N.J. Gardiner;
The University of Manchester, Manchester, UK.

Background and aims: Polyuria occurs in both clinical and experimental diabetes. Early symptoms of diabetic bladder dysfunction manifest clinically as overactive bladder (e.g. urgency, increased frequency of urination). Whilst at later stages diabetic cystopathy is associated with decreased sensation, overflow incontinence and micturition problems. A high post-void residual urine volume can predispose patients to lower urinary tract infections and increase risk of kidney damage. Late stage changes may reflect more chronic effects of hyperglycaemia on the bladder. The aim of this study was to compare the impact of long-term (16 weeks) experimental diabetes (with associated polyuria) to polyuria alone on the transcriptome of the rat urinary bladder.
Materials and methods: Adult male Wister rats (starting weight 289-425g) were either left untreated, treated with streptozotocin (STZ; 55mg/kg, i.p.) or with 5% sucrose in their drinking water for 16 weeks in accordance with the UK Animals Scientific Procedure Act (1986) and institutional regulations. Water consumption was monitored for the

duration of the study. After 16 weeks, the rats were culled, bladders were removed, weighed and processed for either histology or RNA analysis by Affymetrix GeneChip® rat genome 230 2.0 array. dChip (V2005) was used to perform the outlier analysis and check technical quality. Quintile normalisation and background correction were conducted using RMA. GeneVene and Ingenuity Pathway Analysis (IPA) software were used to analyse data and identify over-represented pathways with differentially expressed genes ($p<0.05$; with fold change>1.3). Statistical Analysis was performed using Graphpad Prism.

Results: Both STZ-diabetic and sucrose-treated rats rapidly developed polydipsia, drinking significantly more than age-matched non-diabetic control rats, and this was associated with a significant increase in the weight of the bladders in both groups compared to non-diabetic controls ($p<0.05$). GeneChip analysis revealed that STZ-induced diabetes caused significant dysregulation of 1467 transcripts in the bladder compared with non-diabetic control rats (56.9% upregulated; 43.1% downregulated). The 5 most upregulated transcripts were *Grem1* (+27.9), *Sgcg* (+10.9), *Ildr2* (+7.7), *Bdnf* (+7.4) and *Adprhl1* (+4.7). Sucrose-treatment caused fewer (366) transcripts to significantly change compared to control rats (34.7% upregulated; 65.3% downregulated). The 5 most upregulated transcripts were *Grem1* (+4.2), *Ildr2* (+3.2), *Cyr61* (+3.0), *Ctgf* (+2.5) and *Acta2///Actc1* (+2.5). GeneVenn analysis revealed 1298 differentially expressed transcripts were exclusively affected by experimental diabetes, while only 197 transcripts were exclusively related to sucrose-treatment. Interestingly, IPA analysis revealed significant dysregulation of 45 pathways in the bladders of STZ-diabetic rats compared with non-diabetic controls, including 'Axonal Growth-Related' and 'Extracellular Matrix-Related' pathways.

Conclusion: Late-stage pathogenic changes have not been thoroughly characterised in the STZ-rat urinary bladder to date, nor compared to diuresis-induced remodelling. Our data provide a detailed comparison of the distinct effects of diabetes and of polyuria on the urinary bladder that reveal specific transcriptomic changes that may contribute to diabetic bladders dysfunction.

PS 107 A complicated story: complications of diabetes

1196

An under-recognised complication: the presence of cheiroarthropathy in the type 1 diabetes exchange

G. Aleppo[1], N. Foster[2], M. Wu[2], M. Clements[3], M. Rickels[4], R. Beck[2]; [1]Northwestern University, Chicago, [2]Jaeb Center for Health Research, Tampa, [3]Children's Mercy Hospital, Kansas City, [4]University of Pennsylvania Perelman School of Medicine, Philadelphia, USA.

Background and aims: Diabetic cheiroarthropathy is a long-term complication of diabetes that often causes significant morbidity with impaired ability to complete activities of daily life. This complication has not been well studied in individuals with type 1 diabetes (T1D). To quantify the frequency of cheiroarthropathy in adults (≥18 yrs old) with T1D, T1D Exchange registry participants were invited to complete a survey to address this question as well as to assess participant and clinical characteristics associated with the diagnosis.

Materials and methods: 6,200 adults in the T1D Exchange clinic registry were invited to complete an internet-based survey inquiring about the diagnosis of cheiroathropathy- specifically asking about the diagnosis and treatment of frozen shoulder, carpal tunnel syndrome, trigger finger, Dupuytren's contracture, and limited joint mobility. 1,912 adults (62% female, 90% non-Hispanic White, mean age 40 yrs, median diabetes duration 20 yrs, mean HbA1c 7.8%) responded (response rate 32%).

Results: 586 (31%) adults indicated diagnosis of 1 or more joint problem; 293 (50%) were diagnosed with frozen shoulder, 293 (50%) with trigger finger, and 261 (45%) with carpal tunnel, thus showing the concomitant presence of multiple joints involvement in some participants. Only 92 (16%) and 66 (11%) were diagnosed with Dupuytren's contracture and limited joint mobility, respectively. Adults diagnosed with joint disease were more likely to be older (mean 53 yrs vs. 34 yrs; $P<0.001$) and had longer duration of diabetes (median 35 yrs vs. 16 yrs; $P<0.001$). 333 (57%) participants were treated through physical therapy, 293 (50%) through surgery, and 234 (40%) with steroids, highlighting the fact that multiple therapy modalities have been used for some survey participants. HbA1c levels at the time of survey completion were 7.6% in participants with cheiroarthropathy vs 7.9% in participants who did not report cheiroarthropathy.

Conclusion: With one-third of survey respondents noting a history of the condition, cheiroarthropathy is common in adults with type 1 diabetes. Development of standards of care for early recognition and treatment of diabetic cheiroarthropathy is needed, particularly for older adults and individuals with long-term diabetes. Counseling on the risk of cheiroarthropathy is warranted in clinical practice so patients are aware that they should seek medical attention should symptoms arise.

1197

Lower limb amputation in diabetes: incidence estimates and patients characterisation

A. Déruaz-Luyet[1], C. Raabe[2], L.L. Lavery[3], K.G. Brodovicz[4]; [1]Boehringer Ingelheim, [2]Global Epidemiology, Boehringer Ingelheim, Ingelheim am Rhein, Germany, [3]Wound Care Clinic, University of Texas Southwestern, Dallas, [4]Global Epidemiology, Boehringer Ingelheim Pharmaceuticals Inc, Ridgefield, USA.

Background and aims: Diabetes Mellitus (DM) is the leading cause of lower limb amputation (LLA) in adults in the US. It is not clear how the incidence of LLA varies between type 1 (T1DM) and type 2 DM (T2DM). Using data from the Truven Health MarketScan databases, we evaluated the incidence rate of LLA in patients with and without T1DM or T2DM and assessed the presence of comorbidities at the time of the LLA.

Materials and methods: Using the Aetion evidence platform (Aetion, Inc., New York, New York, USA), we analysed data from 2010-2014. Four cohorts of patients were defined based on the presence of DM claims: no-diabetes, any DM, T1DM and T2DM. Cases of non-traumatic LLA were identified using diagnosis and procedure codes. All patients had at least one year of enrollment prior to cohort entry. Analyses were restricted to patients with no history of lower limb amputation. We evaluated the incidence rate per 1000 person-year (PY), and 95% confidence interval (CI), by DM cohort and sex. We also assessed the presence of comorbidities in the 4 weeks preceding the LLA.
Results: Mean age (SD) was 42.8 years (17.1) in the no-diabetes, 56.8 years (14.0) in the any DM, 50.6 years (18.2) in the T1DM and 57.8 years (12.3) in the T2DM cohorts. Proportion of men was between 47.2% in the no-diabetes and 53.5% in the T1DM cohorts. Crude overall incidence rates and confidence interval of LLA were 0.08 (0.08, 0.09) in the no-diabetes, 1.50 (1.48, 1.52) in the any diabetes, 5.79 (5.56, 6.03) in the T1DM and 1.62 (1.59, 1.65) in the T2DM cohorts. In all three diabetes cohorts, LLA incidence was about 1.5 to 2 times higher in men than women. In the four weeks preceding the LLA, compared to non-diabetics, patients with DM more often had a claim for Charcot foot (1.8% vs 0.2%), foot and leg ulcers (73.3% vs 39.7%), and cellulites (56.5% vs 29.3%) or osteomyelitis (65.0% vs 34.8%). Foot deformities were in contrast more often reported in non-diabetics (16.7% vs 5.4%). Claims for end-stage renal disease were most frequently reported in association with LLA in T1DM patients (29.4%).
Conclusion: We observed a higher incidence rate of LLA in T1DM than T2DM and in men than women when measured over the same period in a US-based insurance claims database. This could be due to differences in stage of the disease or imbalances in risk factors between groups, such as smoking status which could not be assessed.

	Number of cases of LLA	Person-years (PY) follow up	Incidence Rate in 1000 PY
No Diabetes			
Overall	6,322	75,464,818	0.08 (0.08,0.09)

Less cortical folding in adult patients with longstanding type 1 diabetes is related to cognition and diabetes duration

R.G. IJzerman[1], M.D. Steenwijk[2], J. Landeira-Fernandez[3], M. Klein[4], F. Barkhof[2], A.C. Moll[5], M. Diamant[1], F.J. Snoek[4], E. van Duinkerken[1,6];
[1]Amsterdam Diabetes Centre / Department of Internal Medicine, VU University Medical Centre, , [2]Department of Radiology and Nuclear Medicine, VU University Medical Centre, Amsterdam, Netherlands, [3]Department of Psychology, Pontifícia Universidade Católica Rio de Janeiro, Rio de Janeiro, Brazil, [4]Department of Medical Psychology, VU University Medical Centre, Amsterdam, [5]Department of Ophthalmology, VU University Medical Centre, Amsterdam, Netherlands, [6]Department of Functional Neuroimaging, Instituto Estadual do Cérebro Paulo Niemeyer Rio de Janeiro, Rio de Janeiro, Brazil.

Background and aims: In adults with type 1 diabetes (T1DM) mild subcortical volume loss with intact thickness has been previously found. Until early adulthood the cortical structure shows fast developmental changes. Cortical gyrification, the folding of the cortex, on the other hand takes place in the 3rd trimester of pregnancy and remains stable during childhood development. Folding is important for intellectual and cognitive functioning in other populations and may also be related to cognitive decrements in T1DM.
Materials and methods: Thus, cortical gyrification was calculated using FreeSurfer5.3 in 51 adult T1DM patients with and 53 without proliferative retinopathy, and 49 controls. Additionally, the longitudinal 4-year trajectory of folding changes was determined in 25 randomly selected patients with complications and 25 matched controls. Differences in folding were correlated to cognition and disease variables in the patient group as a whole. Analyses were corrected for age, sex, systolic blood pressure, and depressive symptoms. Corrections for multiple vertex testing was performed using the strict Family Wise Error (FWE) method.
Results: At baseline, relative to controls, all patients as a group showed lower gyrification in the left supramarginal and inferior parietal cortices, as well as in the right supramarginal, frontal, and temporal lobe. Patients with complications drove these effects, although in the temporal lobe folding was lower in patients without complications versus controls as well (all $P_{FWE}<0.05$). There were no between patient group differences or changes in gyrification over 4 years in the 25 patients with complications relative to controls. Lower right hemisphere cortical folding at baseline was related to lower attention ($\beta=0.248$), higher age ($\beta=-0.197$), being female ($\beta=-0.292$), longer disease duration ($\beta=-0.235$), having proliferative retinopathy ($\beta=-0.214$), and greater left carotid intima media thickness ($\beta=-0.220$), with age and sex as the strongest predictors (all $P<0.05$), but did not predict changes in cognition after 4 years.
Conclusion: Cortical gyrification, which is characterized by the relative absence of developmental changes, is affected by T1DM and additionally proliferative retinopathy. No progression in loss of cortical folding was found in this middle-aged adult sample of patients with proliferative retinopathy.

hMT/V5 is more affected with age than other brain regions in patients with type 2 diabetes

M.S. Al-Rawi[1], J.V. Duarte[2], M. Castelo-Branco[2];
[1]Universidade de Aveiro, Aveiro, [2]Universidade de Coimbra, Coimbra, Portugal.

Background and aims: Type 2 Diabetes (T2D) may derive potential complications to several organs in humans. In this study, we investigated T2D brain complications using spatially separated speeds as stimuli to infer if the age is associated with complications in the visual cortex. The results are compared to Brodmann Area 7 (BA7; which has a role in locating objects in space) and the cingulate gyrus (CG; which has a role in emotion formation and processing, learning and memory). hMT/V5, BA7, and CG showed higher significance than more than 30 other brain regions that we have investigated in this study.
Materials and methods: Each stimulus contained two spatially separated dots moving back-and-forth in a maximally ambiguous difficult task, where both dots moved with the same speed and the subjects clicked a button to indicate the side of the faster dot. The other control-stimulus was a fixation point. The two dots are projected on different visual hemifields and hemispheres. The size of the image in the screen-pad was 22.62º × 17.06º visual angles and the subjects viewed the image at 50cm distance through a mirror, had their head movements restricted and viewed the stimuli monocularly with the dominant eye while the other eye was covered with an opaque eye-patch. Using a 3 Tesla scanner, functional and structural MRI have been acquired for 56 T2D patients aged (mean: 47.9

± 6.2; max: 73) and 73 healthy aged (mean: 58.2 ± 8.6; max: 71) healthy controls.

Results: For each functional MRI volume, we performed de-trending; skull stripping using FSL (FMRIB Software Library); motion correction, coregistration and normalization using SPM8 (Statistical Parametric Mapping). Anatomical ROIs have been generated in MNI space using the WFU PickAtlas. Moreover, we used pattern classification (Princeton MVPA toolbox) to predict the stimuli presented to each subject. We performed N-way Analysis of Variance (ANOVA) on the classification results that showed differences, via independent samples t-test, between T2D and controls in BA7, p(BA7L)=0.00003 and p(BA7R)=0.002; CG, p(CGL)=0.0006 and p(CGR)=00.04; and hMT/V5, p(hMT/V5-L)=0.00005 and p(hMT/V5-R)=0.00005. The results showed that the age significantly affects hMT/V5 more than BA7 and CG in T2D patients, as illustrated in Table 1.

Conclusion: This study has shown that the age may provoke more complications to hMT/V5 than other brain regions in T2D. We also performed similar analysis on the insula and BA6 and we found no relation with age in T2D (not reported due to lack of space). To confirm how much the age-provoked brain complications are related to diabetic retinopathy that exists in some patients of the used T2D sample, diabetic retinopathy scores have been used in the analysis. N-way ANOVA showed no relation between T2D and controls with regard to the age and the scores of diabetic retinopathy estimated using ETDRS schema scaled from 10 to 90 (age factor; F = 0.1, Prob>F is 0.7526). This clearly indicates that the detected hMT/V5 age-complications in T2D are not necessarily related to diabetic retinopathy.

Table 1. N-Way analysis of variance of T2D versus healthy subjects

The implications of insulin like growth factor 1 receptor in type 2 diabetes-related injuries of brain structure and function

F. Su;
Southeast University, Nanjing, China.

Background and aims: Patients with type 2 diabetes (T2D) showed significantly increased risk for various neurological and psychiatric disorders, such as major depression and dementia, which result from injuries of brain structure and function. Previous epidemiological and molecular investigations have highlighted the importance of insulin like growth factor 1 receptor (IGF1R) in maintaining normal brain function. However, the corresponding in vivo neurobiology of IGF1R was poorly understood. The present study aimed to reveal the associations between IGF1R and brain structure and neural function in T2D patients via genetic-imaging approach.

Materials and methods: A total of 168 patients with T2D were enrolled in the study, and every participant went through clinical evaluations, structural and functional magnetic resonance imaging (MRI) scans. High-throughput sequencing of *IGF1R* gene was utilized, and 23 single nucleotide polymorphisms (SNPs) entered the further genetic-imaging analysis after quality control. The associations with *IGF1R* polymorphisms and brain structure and function were investigated.

Results: In terms of brain structure, both rs17847195 (β = -0.44, FDR-corrected P = 0.023) and rs2684788 (β = -0.38, FDR-corrected P = 0.039) showed significantly associations with total brain volume. Furthermore, rs1815009 had significantly influence on volume of entorhinal cortex (β = -0.36, FDR-corrected P = 0.043). Regarding the neural activity, interactions were detected with rs2016347 and neural activity within right praecuneus (β = -0.58, FDR-corrected P = 0.013). Moreover, rs1815009 also modified the neural activity within left medial prefrontal cortex (β = -0.49, FDR-corrected P = 0.019).

Conclusion: The genetic-imaging approach expanded our understanding for the mechanisms underlying the implications of IGF1R in T2D-related injuries of brain structure and function, and alleviating the dysfunction of IGF1R may be a promising approach to relieve neurological and psychiatric disorders for patients with T2D.

The relationship between blood glucose control and xanthine oxidoreductase activity in patients with diabetes

K. Washio[1], Y. Kusunoki[1], F. Ochi[1], K. Osugi[1], M. Ohigashi[1], T. Sukenaga[1], T. Murase[2], T. Nakamura[2], T. Matsuo[1], M. Miuchi[1], T. Katsuno[1], M. Namba[1], H. Koyama[1];
[1]Division of Diabetes, Endocrinology and Metabolism, Hyogo College of Medicine, Nishinomiya, [2]Sanwa Kagaku Kenkyusho, Mie, Japan.

Background and aims: The enzyme xanthine oxidoreductase (XOR) catalyzes the formation of uric acid (UA) from hypoxanthine and xanthine, which in turn are products of purine metabolism starting from ribose-5-phosphate. Besides the synthesis of UA, basic research has suggested that XOR is involved in the regulation of reactive oxygen species, adipogenesis, and peroxisome proliferator-activated receptor-γ (PPAR-γ). Indeed, it has been reported that XOR activity is associated with development of cardiovascular events and the progression of nephropathy. XOR activity has been shown to be much lower in humans than in rodents, which makes its accurate measurement difficult. A novel method that uses mass spectrometry to measure [$^{13}C_2$,$^{15}N_2$]UA using [$^{13}C_2$,$^{15}N_2$]xanthine as a substrate has been recently established to accurately determine plasma XOR activity in humans. We applied this novel method to accurately measure plasma XOR activity in patients with diabetes and evaluated its relationship with clinical parameters including glycemic control, diabetes type, body mass index (BMI), and uric acid metabolism.

Materials and methods: A total of 71 patients (females, 38; males, 33; mean age, 48.5 ± 16.3 years), including 36 with type 1 diabetes and 35 with type 2 diabetes, were enrolled. Blood samples were collected under fasting conditions in the early morning to measure plasma XOR activity and other parameters.

Results: The natural logarithmic value of XOR activity (ln-XOR) in the plasma was 3.8 ± 1.0 pmol/h/mL, while serum UA levels were 5.0 ± 1.5 mg/dL. Positive significant correlations ($p < 0.05$) of ln-XOR with HbA1c and BMI were observed (r = 0.249; HbA1c, r = 0.336; BMI). Multiple regression analysis revealed that both HbA1c ($\beta = 0.276$, $p = 0.031$) and BMI ($\beta = 0.326$, $p = 0.022$) were useful predictors of ln-XOR activity and that serum UA levels had a negative correlation with HbA1c ($\beta = -0.256$, $p < 0.01$).
Conclusion: Plasma XOR activity is associated both with worsening of glycemic control and adiposity, but not with serum UA in patients with diabetes. This raises the possibility that even with low serum UA levels, increased XOR activity may induce oxidative stress in patients with poor glycemic control.

Development of the metabolic syndrome after orthotopic liver transplantation and relation with morbidity and mortality: a five year follow-up study

M.E. Lunati[1], R. Caccia[1], V. Grancini[1], V. Resi[1], E. Palmieri[1], A. Gaglio[1], G. Pugliese[2], E. Orsi[1];
[1]Department of Clinical Sciences and Community Health, University of Milan, Endocrinology and Diabetology Unit, IRCCS Fundation Ca' Granda H Maggiore Policlinico, Milan, [2]Department of Clinical and Molecular Medicine, Università degli Studi di Roma La Sapienza Facoltà di Medicina e Psicologia, Rome, Italy.

Background and aims: The metabolic syndrome (MS) is a well-known complication of orthotopic liver transplantation (OLT) and may contribute to morbidity and mortality, especially by increasing the risk of cardiovascular disease (CVD). The present is a prospective study that was conducted to evaluate the development of the MS after OLT and its impact on morbidity and mortality over a 5-year follow-up.
Materials and methods: Eighty-four cirrhotic patients (75% male, mean age 53.9 ± 9.3 years) were evaluated at baseline and yearly for 5 years after OLT. The MS was defined according to the 2004 Adult Treatment Panel-III criteria. Complications, including major CVD events, infections, de novo malignancy and acute graft rejection, were recorded.
Results: Prevalence of the MS increased from 14/84 (16.6%) at baseline to 32/81 (39.5%) at year 1. During this period, 2 patients died (one with and one without the MS) and one was lost at follow-up. During the following 4 years, prevalence of the MS further increased to 34/73 (46.6%). Of patients with the MS at year 1, 9 reversed it, 18 did not, and 3 died. Of those without the MS, 14 developed the MS, 20 did not, and 5 died. Prevalence of obesity, arterial hypertension and hypertriglyceridemia progressively increased from year 1 to year 5 (obesity from 14.8% to 19.2%; arterial hypertension from 56.8% to 68.5%; hypertriglyceridemia from 25.9% to 30.1%).Conversely, prevalence of diabetes mellitus (DM) and low-HDL decreased from year 1 to year 5 (DM from 44.4%, 36/81, to 34.2%, 25/73; low-HDL from 34.5%, 28/81, to 27.4%, 20/73). Of patients with DM at year 1, 8 (22.2%) regressed and 4 died. DM regression was more frequent in patients without than in those with the MS (17.1% vs. 3%, p=0.05) and correlated inversely with the presence of the MS (r=-0.24, p=0.04). Of patients without DM at year 1, only one, who was affected by the MS, developed DM de novo. Age (p=0.04), BMI (p<0.001) and DM (p=0.03) at year 1 post-OLT were identified as independent variables associated with development of the MS during the subsequent 4 years. Patients who did not have the MS at any time from year 1 to year 5 showed a lower prevalence of major CVD events (10.0% vs.16.2%; p=0.31) and infections (40.0% vs. 55.8%; p=0.09) and a higher prevalence of graft rejection (30% vs. 27.2%; p=0.50) and de novo malignancy development (16.6% vs. 9.3%; p=0.30), as compared with those with the MS, though these differences did not achieve statistical significance. Major CVD events positively correlated with cyclosporine-based immunosuppressant therapy.
Conclusion: Even if development of the MS is an early phenomenon, its prevalence continues to increase for many years after OLT. Life-style intervention and individualization of immunosuppressant therapy may lead to improved outcomes in OLT patients.

Type 2 diabetes is complicated by obesity and sleep apnoea syndrome: focussing in comorbidities

S. Kawasaki[1], H. Shibata[1], H. Misawa[1], Y. Tamura[1], T. Kondo[2], Y. Kondo[3], Y. Terauchi[3];
[1]Department of Endocrinology and Metabolism, Shonan Fujisawa Tokushukai Hospital, [2]Department of Respiratory Medicine, Shonan Fujisawa Tokushukai Hospital, Fujisawa, [3]Department of Endocrinology and Metabolism, Yokohama City University, Yokohama, Japan.

Background and aims: Diabetes is characterized by high levels of blood glucose, which can cause both microangiopathies, including retinopathy and nephropathy, and macroangiopathies, including cerebral infarction, angina pectoris/myocardial infarction, and peripheral arterial disease. On the other hand, it has been reported that patients with sleep apnea syndrome (SAS), which is characterized by repeated episodes of apnea and hypopnea, are more likely to suffer from stroke, diabetes, and circulatory diseases, including hypertension, angina pectoris, myocardial infarction, chronic heart failure, and arrhythmia, compared to healthy subjects. Vascular complications are a common comorbidity in diabetes patients, which often results in absences from the workplace. It is therefore important to routinely evaluate and, where appropriate, treat diabetes patients for SAS. In this study, we focused on obesity, a known risk factor for SAS, and investigated the relationship between demographic and clinical variables on the one hand, and SAS and associated comorbidities on the other, in clinically obese type 2 diabetes mellitus patients.
Materials and methods: We evaluated 1367 ambulant patients with type 2 diabetes mellitus with a BMI ≧ 30 kg/m2. Their demographic and clinical data were recorded, as well as the presence of any systemic diseases. Their Apnea-Hypopnea Index (AHI) was determined using a portable sleep polygraph, and they were assessed for SAS and associated comorbidities.
Results: Fifty-six patients (33 males, 23 females) were retained for this study. The characteristics of the sample were as follows: average age, 56.7 ± 14.0 years; disease duration, 11.4 ± 8.4 years; BMI, 33.6 ± 2.9 kg/m2; waist circumference, 110.3 ± 9.7 cm; blood pressure, 136 ± 13 mmHg (systolic) and 78 ± 11 mmHg (diastolic); 25% (14/56) were alcohol consumers; 50% (28/56) were smokers; FBS, 165 ± 74 mg/dL; HbA1c, 7 .7±1.7%; fasting blood CPR, 4.3 ± 1.9 ng/mL; HOMA-IR, 12 .7 ± 20.4; Cr, 0.88 ± 0.29 mg/dL; and AHI 27.9 ± 22.1 (male, 30.3 ± 19.1; female, 24.6 ± 25.5). We found that 6 patients (10.7%) had a history of intracranial lesions, 7 cases (12.5%) had a respiratory comorbidity, 17 cases (30.4%) suffered from a circulatory disease, and 4 cases (7.1%) had comorbid cancer. The prevalence of SAS (AHI ≧ 15) was 75.8% (25/33) in males and 56.5% (13/23) in females. Among patients with an AHI ≧ 15, there was a higher proportion of intracranial lesions, including a history of cerebral infarction and encephalitis, subarachnoid hemorrhage or subdural hemorrhage, and pituitary tumor, than among patients with an AHI < 15 ($p < 0.05$). In addition, multivariable analysis adjusted to age, sex, and BMI identified intracranial lesions as an independent risk factor for the development of SAS.
Conclusion: There was a high prevalence of SAS in both male and female patients with type 2 diabetes mellitus and a BMI ≧ 30 kg/m2. In addition, our study demonstrates that SAS is found in patients with intracranial lesions, and that an important proportion of patients with type 2 diabetes mellitus have a history of intracranial lesions. This is likely related to the ageing of the Japanese society and strongly indicative of a need to routinely evaluate and treat diabetes patients for SAS.

Pancreatic size and fat content in diabetes: a systematic review and meta-analysis of imaging studies

C.B. Leitao[1], T.S. Garcia[2], T.H. Rech[3];
[1]Endocrine Division, Universidade Federal do Rio Grande do Sul, [2]Universidade Federal do Rio Grande do Sul, [3]Critical Care Division, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil.

Background and aims: Imaging studies are expected to produce reliable information regarding the size and fat content of the pancreas. However, the available information have produced inconclusive results. The aim of this study was to perform a systematic review and meta-analysis of imaging studies assessing pancreas size and fat content in patients with type 1 and type 2 diabetes.
Materials and methods: Medline and Embase databases search was performed. Studies evaluating pancreatic size (diameter, area or volume) and/or fat content by ultrasound, computed tomography, or magnetic resonance imaging in patients with type 1 diabetes and/or type 2 diabetes as compared to healthy controls were selected. Sixteen studies including 2,593 subjects (284 with type 1 diabetes, 1,069 with type 2 diabetes, and 1,240 control subjects) were included in meta-analyses. Pancreas diameter, area, volume, density, and fat percentage were evaluated.
Results: Pancreatic volume was reduced in type 1 diabetes (-38.72 cm3, 95%CI: -52.25 to -25.19, I2=70.2%, p for heterogeneity=0.018) and type 2 diabetes (-12.18 cm3, 95%CI: -19.1 to -5.25, I2=79.3%, p for heterogeneity=0.001) in comparison with controls (FIGURE). Fat content was higher in type 2 diabetes vs. controls (+2.73%, 95%CI 0.55 to 4.91, I^2=82.0%, p for heterogeneity<0.001).
Conclusion: Individuals with both types of diabetes have reduced pancreas size in comparison with control subjects. Patients with type 2 diabetes have increased pancreatic fat content. Further longitudinal studies are required to elucidate the cause and effect relationship between pancreatic size and diabetes, as well as the possible causes of pancreas shrinkage and fat deposition. A better understanding of the mechanisms of altered pancreas morphology and fat deposition in diabetes may lead to new insights in preventing, predicting, and treating diabetes.

Risk of DKA with Hamman's syndrome: a case control study and a systematic review with a single case report

Y. Namiki, H. Sasaki, Y. Takano, H. Takamine, K. Inazumi, U.N. Osada; Saiseikai Yokohama City Nanbu Hospital, Yokohama, Japan.

Background and aims: Hamman's syndrome is spontaneous mediastinal emphysema which often occurs during labor. It is also reported as a rare complication of diabetic ketoacidosis (DKA). The primary component of the pathophysiology is believed to be air leak from alveoli followed by high intrathoracic pressure from vomiting or hyperventilation. Impaired surfactant of alveolar surface induced by severe acidemia may also be another cause. We recently experienced a 40 year-old female diagnosed with DKA presenting Hamman's syndrome. She showed severe acidemia and compensatory hyperventilation (pH 6.956, pCO2 13.7mmHg, respiratory rate 32/min). With an aim to reveal the clinical characteristics and the risk factors of DKA with Hamman's syndrome, we conducted a systematic literature review and a case control study.
Materials and methods: The case was defined as DKA with Hamman's syndrome. In addition to our case, we searched case reports through two electronic databases (PubMed and Ichushi) with language restriction to English and Japanese. Keywords were "Hamman's syndrome", {"mediastinal emphysema" and "diabetes"} or {"pneumomediastinum" and "diabetes"}. We manually reviewed the literature by two physicians to confirm the diagnosis of DKA and Hamman's syndrome. As for DKA control without Hamman's syndrome, we included all the patients treated in our hospital from April 2009 to January 2017. We excluded patients under age 20 years old since pediatric DKA is seldom referred to our hospital. We tested inter-group differences of the clinical characteristics by two-sided t test. We also performed logistic regression analysis to elucidate an independent risk factor of DKA with Hamman's syndrome.
Results: Among 100 cases pooled from 85 papers, 64% were male, median pH and pCO2 were 7.13 and 15.9 mmHg respectively. Median respiratory rate was 32/min. Adult cases accounted for 63% (n=63) and were compared with 85 controls as shown in the table below. Hamman's syndrome was more prevalent in younger age group and also in type 1 diabetes. The cases exhibited frequent heart rate and respiratory rate. Blood gas analysis showed excessive acidemia and hypocapnia in Hamman's syndrome. Logistic regression analysis revealed the independent risk factors were younger age (Coefficient= -0.25, p<0.0001), faster heart rate (Coefficient=0.07, p=0.01), lower pH and pCO2 (Coefficient= -22.1, p=0.02, Coefficient= -0.41, p=0.02). Respiratory rate was not a significant factor possibly due to limited available data (n=22).
Conclusion: Younger aged DKA with severe acidemia and hypocapnia may be at the increased risk of Hamman's syndrome.

PS 108 The bones in diabetes

1206

Usefulness of FRAX to predict the risk of fractures in a diabetic Portuguese population

C. de Mello-Sampayo[1], H. Canhão[2], A. Rodrigues[2], J. Branco[2], M.C. Marques[1];
[1]Pharmacological Sc, Faculdade de Farmácia da Universidade de Lisboa, [2]Nova Medical School, UNL, Lisboa, Portugal.

Background and aims: Several studies have shown that Diabetes Mellitus is associated with an increased risk of fracture. In Portugal, it is estimated that diabetes affects about 13% of the adult population. Osteoporosis is characterised by an increased risk of fracture due to a decrease in bone mass and/or deterioration of bone microarchitecture. The WHO fracture risk assessment tool (FRAX), used in the decision to institute anti-osteoporotic therapy, is an algorithm that estimates the probability of occurrence of fracture (major and hip) at 10 years taking into account variables such as age, gender, previous fracture, family history, low weight, body mass index, continued glucocorticoid therapy, rheumatoid arthritis, smoking, excessive alcohol consumption, adjusted, or not, with bone mineral density (BMD). The aim of this study is to analyse the power of the FRAX algorithm in the Portuguese diabetic population without/with Dual-energy X-ray absorptiometry in the subpopulation - diabetic women over 50.
Materials and methods: Individuals from the EpiReumaPt study (2011-2013, 10,661 adults) with FRAX data (n=3545) were selected and divided according presence/absence of diabetes. The population was further stratified by gender and age and the data analysed by non-parametric Mann-Whitney test (males) and t-student. A 95% confidence interval was considered.
Results: The EpireumaPt data revealed a sample population with a diabetes prevalence of 13,3%. The FRAX computed without BMD data, was higher in the diabetic group (n=474) for both major and hip fractures compared to non-diabetic (n=3071) (5.42±0.24 vs 3.90±0.08, p<0.05 and 2.10±0.16 vs. 1.26±0.05, p<0.05, respectively). Nonetheless, the subpopulations aged 50 or less years reveal a similar 10-year likelihood of both types of fractures between diabetic and non-diabetic males (1.95 ±0.45 vs 0.92±0.05, p=0.569 and 0.22 ±0.08 vs 0.11±0.01, p=0.325), females (2.07±0.32 vs 1.89±0.03, p=0.577 and 0.21±0.06 vs 0.16±0.01, p=0.470) as well as for males aged over 50 years (3.60±0.19 vs 3.29 ±0.11, p=0.180 and 1.49±0.14 vs 1.28±0.08, p=0.217). Simply diabetic women aged >50 years (n=248) have a significantly higher FRAX for major and hip fractures compared to non-diabetic (n=1161) (6.80±0.41 vs 5.65±0.17, p=0.005 and 2.67±0.29 vs. 2.06±0.11, p=0.028). However, when FRAX was adjusted with bone mineral density data, a similar 10-year likelihood of both fractures types between diabetic (n=57) and non-diabetic (n=189) is observed (7.92±0.89 vs 9.11±0.47, p=0.226 and 3. 09 ±0.53 vs 3.83±0.36, p=0.300).
Conclusion: In a population sample with the same diabetes prevalence as the Portuguese population, FRAX underestimates the risk of fractures in diabetic patients except in diabetic women over 50. However, in those diabetic women when bone mineral density is accounted the FRAX power of discerning fracture risk is lost. These results empower the recently suggested risk underestimation of the FRAX algorithm in diabetic population primarily when computed with bone mineral density.

1207

Estimating the risk of osteoporosis related fractures in a post-menopause type 2 diabetic Portuguese population

M.C. Marques[1], C. de Mello-Sampayo[2], H. Canhão[3];
[1]Pharmacological Sc, Faculdade Farmácia da Universidade de Lisboa, [2]Pharmacological Sc, Faculdade Farmácia da Universidade de Lisboa, [3]Nova Medical School, Universidade Nova Lisboa, Lisboa, Portugal.

Background and aims: Like diabetes (with an estimated prevalence of 13% of the adult population in Portugal), in particular type 2 diabetes, osteoporosis is an increasingly prevalent disease. Post-menopause osteoporosis is characterised by an increased risk of fracture due to an accelerated decrease in bone mass and/or deterioration of bone microarchitecture. Several studies have shown that type 2 diabetes is associated with a poor bone quality and increased risk of fragility fractures. The WHO fracture risk assessment tool (FRAX), adapted for Portuguese population in 2013, and used in the decision to institute anti-osteoporotic therapy, is an algorithm that estimates the probability of occurrence of fracture (major and hip) at 10 years taking into account, or not, the bone mineral density (BMD). FRAX provides valid prediction without BMD values although its accuracy increases when BMD is considered. The aim of this study is to verify the accuracy of the FRAX algorithm when computed, or not, with BMD in a Portuguese post-menopause female population with and without type 2 diabetes.
Materials and methods: A female sample population aged between 50 and 81 years old (2016-17, n=159) from Sintra, a neighbourhood city of the Portuguese capital, was assessed for the FRAX algorithm variables (age, gender, previous fracture, family history, low weight, body mass index, continued glucocorticoid therapy, rheumatoid arthritis, smoking, excessive alcohol consumption) and the Dual-energy X-ray absorptiometry evaluated using GE-Lunar. Patients with co-morbidities were excluded and the data divided according presence (n=67)/absence (n=84) of type 2 diabetes. The data was analysed by (paired or not) t-student. A 95% confidence interval was considered.
Results: The FRAX computed without BMD data was higher in the type 2 diabetes female group for both major and hip fractures compared to non-diabetic (6.5±0.5 vs 4.7±0.4, p=0.004 and 2.0±0.2 vs. 1.4±0.2, p=0.043). When FRAX was adjusted with BMD data, a similar 10-year likelihood of both fractures types between type 2 diabetes and non-diabetic was observed (5.9±0.4 vs 5.1±0.4, p=0.158 and 1.6±0.2 vs 1.4 ±0.2, p=0.446). In order to further understand these results, the undertaken analysis within each population group revealed a significantly lower FRAX for major and hip fractures in type 2 diabetes group when using DMO to compute it (5.9±0.4 vs 6.5±0.5, p=0.037 and 1.6±0.2 vs. 2.0 ±0.2, p=0.025) while that of controls was significantly higher for major fractures (5.3±0.3 vs 4.7±0.4 p=0.028) and similar for hip fractures (1.4 ±0.2 vs 1.4±0.2 p=0.841).
Conclusion: The obtained results suggest that in a female population sample over 50 years old, with no other identified morbidities except for type 2 diabetes, the use of DMO as a FRAX variable underestimates the risk of osteoporosis related fractures, which contrasts with the significant impact of its use to compute the major fractures FRAX of non-diabetic patients (increase). However the accuracy of FRAX to predict hip fractures is not affected by the use of BMD when considered morbidities are absent. These results suggest that for type 2 diabetes patients BMD might be a confounding factor to estimate the risk of fractures.

Low skeletal muscle mass is at increased risk of all-cause mortality in patients with type 2 diabetes

H. Miyake, I. Kanazawa, T. Sugimoto;
Internal Medicine 1, Shimane University Faculty of Medicine, Izumo, Japan.

Background and aims: Skeletal muscle is known to be an important tissue for insulin action and glucose metabolism. It is considered that the disturbance of glucose metabolism leads to loss of skeletal muscle in type 2 diabetes mellitus (T2DM) and vice versa. Thus, loss of muscle mass is a serious problem in patients with T2DM. It has been shown that patients with diabetes have low muscle mass of limbs, which may affect the increased mortality. However, there is no evidence to show whether the muscle mass reduction is associated with the mortality risk in patients

with T2DM. This study thus aimed to examine whether skeletal muscle mass index (SMI) were associated with the mortality rate in patients with T2DM.

Materials and methods: This is a historical cohort study with the endpoint of all-cause mortality in T2DM. A total of 141 postmenopausal women and 163 men (mean age of 66.1 and 64.4 years at baseline, respectively) were recruited whose appendicular skeletal muscle mass (ASM) was evaluated by dual-energy X-ray absorptiometry at Shimane University Hospital. SMI was calculated by the following formula: ASM / height^2. Low skeletal muscle mass was defined as SMI <5.4 kg/m^2 for women and <7.0 kg/m^2 for men according to the criteria of Asian Working Group for Sarcopenia. The participants were observed up to 7 years from the start of this study, and the association between SMI at baseline and the mortality rate was examined by the Kaplan-Meier method, the logrank test, and Cox regression analysis.

Results: The numbers of postmenopausal women and men with lower SMI were 17 (12.1%) and 69 (42.3%), respectively. During the follow-up period (average 6.2 years for postmenopausal women and 5.9 years for men), 14 postmenopausal women (9.9%) and 32 men (19.6%) died, respectively. Postmenopausal women with lower SMI had significant lower body mass index (BMI) compared to those with higher SMI (20.1 ± 2.4 kg/m^2 v.s 25.3 ± 4.4 kg/m^2, $p < 0.001$). Men with lower SMI had significant lower BMI and lower fasting C-peptide levels compared to those with higher SMI (BMI: 20.8 ± 2.5 kg/m^2 v.s 24.6 ± 2.6 kg/m^2, $p < 0.001$; C-peptide, 1.4 ± 0.7 ng/mL v.s 1.8 ± 1.1 ng/mL, $p = 0.021$). The Kaplan-Meier method and the logrank test indicated that lower SMI levels were significantly associated with higher mortality risk both in men and postmenopausal women ($p = 0.008$ and $p = 0.014$, respectively). In the Cox regression analysis adjusted for age, duration of T2DM, HbA1c, serum creatinine, and fasting C-peptide, SMI was significantly and inversely associated with the mortality risk [for postmenopausal women, hazard ratio (HR) = 6.20, 95% confidence interval (CI) = 1.46-26.28, $p = 0.013$; for men, HR = 2.46, 95%CI = 1.13-5.37, $p = 0.023$]. Moreover, after additional adjustment for BMI, the association remained significant in postmenopausal women (HR = 5.97, 95%CI = 1.04-34.37, $p = 0.045$) and marginal association was shown in men (HR = 2.38, 95%CI = 0.92-6.14, $p = 0.074$).

Conclusion: The present study showed that lower SMI was associated with the increased all-cause mortality in patients with T2DM. Furthermore, BMI-independent association was found in postmenopausal women. Therefore, the preservation of skeletal muscle mass is important to protect against the increased mortality risk in patients with T2DM, especially postmenopausal women.

Age at first childbirth and sarcopenic obesity in postmenopausal women with diabetes: the Korean National Health and Nutrition Examination Survey 2009-2010

J. Kim, H. Ahn, J. Kim, S. Kim, H. Bae;
Division of Endocrinology and Metabolism, Chosun university Hospital, Gwangju, Republic of Korea.

Background and aims: Sarcopenic obesity is a double burden for older people because it carries the cumulative risk of functional abnormality, metabolic, cardiovascular risk, and mortality. The objective of the present study was to determine whether there was an association between age at first childbirth and sarcopenic obesity in postmenopausal women with diabetes.

Materials and methods: This study was based on data from the Korean National Health and Nutrition Examination Survey (KNHANES) from 2009 to 2010. Subjects were subdivided according to their age at first childbirth as follows: ≤ 19 years, 20-24 years, 25-29 years, and ≥ 30 years.

Results: Sarcopenic obesity prevalence differed significantly between the subgroups and increased with earlier age at first childbirth, with 11.7% in subjects ≥ 30 years at first childbirth and 30.7% in subjects ≤ 19 years at first childbirth. After fully adjusting for confounding factors, including chronic diseases, sociodemographic influences, lifestyle differences, serum 25(OH)D levels, and reproductive issues, women ≤ 19 years at first childbirth were significantly associated with sarcopenic obesity (odds ratio [OR] 1.719 [95% CI 1.091-2.711]).

Conclusion: Women's age at first childbirth influenced the sarcopenic obesity risk in postmenopausal women with diabetes, and adolescent pregnancy was independently associated with a higher risk of sarcopenic obesity in postmenopausal women with diabetes.

Disclosure: **J. Kim:** None.

Osteoporosis and vertebral fracture are associated with deterioration of ADL and QOL in patients with type 2 diabetes independently of other diabetic complications

I. Kanazawa[1], A. Takeno[1], K.-I. Tanaka[1], Y. Yamane[2], T. Sugimoto[1];
[1]Internal Medicine 1, Shimane University Faculty of Medicine, Izumo, [2]Internal Medicine, Yamane Hospital, Hamada, Japan.

Background and aims: Osteoporosis has been recognized as one of diabetic complications. However, because patients with diabetes usually have various complications such as micro- and macrovascular diseases, it is unclear whether the diabetes-related osteoporosis independently contributes to the deterioration of ADL and QOL. This cross-sectional study thus aimed to investigate the association between osteoporosis and assessment of ADL and QOL in type 2 diabetes mellitus (T2DM).

Materials and methods: The participants were 309 Japanese patients with T2DM (mean age; 65.3 years, mean duration of T2DM; 12.2 years, male; 63.4%). ADL and QOL were assessed by Barthel index (BI) and SF36 questionnaires, respectively. According to the Japanese diagnostic criteria, the presence of osteoporosis and vertebral fracture were diagnosed. Grading of vertebral fracture was performed using Genant Semiquantitative criteria. Statistical evaluations for differences among the groups were carried out using unpaired t test and Jonckheere-Terpstra trend test. Multiple logistic regression analyses adjusted for age, sex, T2DM duration, body mass index, HbA1c, estimated GFR, the presence of other diabetic complication (neuropathy, retinopathy, nephropathy, cardiovascular and cerebrovascular diseases, and peripheral artery diseases), and anti-diabetic treatments were performed to examine the association of the presence of osteoporosis or vertebral fracture with deteriorated ADL (below BI 99 scores) and QOL [below median for each component; physical functioning (PF), role physical (RP), bodily pain (BP), general health (GH), vitality (VT), social functioning (SF), role emotional (RE), and mental health (MH)].

Results: The numbers of patients with osteoporosis or vertebral fracture were 166 (53.7%) and 118 (38.2%), respectively. Compared to patients without osteoporosis, patients with osteoporosis were significantly older and had longer T2DM duration and lower scores of BI, PF, RF, SF, and RE ($p<0.05$ at least). Moreover, multiple logistic regression analysis showed that the presence of osteoporosis was significantly and independently associated with lower GH, SF, and RE [odds ratio (OR); 2.56, 1.79, and 1.92, respectively, $p<0.05$ at least] and trended to be associated with lower BI (OR 2.39, $p=0.068$). According to severity of vertebral fracture grade, patients with severe vertebral fracture were older and had longer T2DM duration and lower scores of BI, PF, RP, GH, and RE (p-trend<0.05 at least). Moreover, the presence of vertebral fracture grade 2 or 3 was significantly and independently associated with lower BI, BP, GH, VT, SF, and RE (OR; 2.58, 2.01, 3.64, 1.99, 2.18, and 1.97, $p<0.05$ at least).

Conclusion: The present study is the first to show that the presence of osteoporosis and severe vertebral fracture was associated with the deterioration of ADL and QOL independently of age, HbA1c levels, renal function, other diabetic complications and anti-diabetes treatments in patients with T2DM. Therefore, the management for diabetes-related

osteoporosis is an important task to protect against the deterioration of ADL and QOL in patients with T2DM.

Efficacy of anti-osteoporotic therapies in patients with type 1 and type 2 diabetes: a systematic review

P. Anagnostis[1,2], S.A. Paschou[1,3], D. Stogiannou[2], N. Gekas[2], A. Artzouchaltzi[2], K. Christou[2], A. Vryonidou[3], D.G. Goulis[1];
[1]Unit of Reproductive Endocrinology, First Department of Obstetrics and Gynecology, Medical School, Aristotle University of Thessaloniki, Thessaloniki, [2]Police Medical Center, Thessaloniki, [3]Department of Endocrinology and Diabetes, Hellenic Red Cross Hospital, Athens, Greece.

Background and aims: Both type 1 (T1DM) and type 2 diabetes mellitus (T2DM) have been associated with bone fragility and increased fracture risk. However, little is known regarding the effect of anti-osteoporotic treatment on bone mineral density (BMD) and / or fracture risk in patients with diabetes mellitus (DM). The aim of this systematic review was to investigate the efficacy of the available anti-osteoporotic therapies in patients with DM.
Materials and methods: MEDLINE and Scopus databases were searched (up to 31st March 2017) for the efficacy of anti-osteoporotic therapies in patients with DM versus controls.
Results: After excluding duplicates, 2,890 articles were identified, ten of which fulfilled inclusion criteria [patients with T2DM (n=9) or either DM type (n=1)]. *Bisphosphonates (n=2):* In one population-based study, DM group (n=3,482) exposed to bisphosphonates demonstrated similar vertebral and non-vertebral fracture risk compared with controls (n=94,028), without difference between the two DM types. In another study, bisphosphonates (mostly alendronate for 12 months) induced similar increases in spine BMD (no difference in hip) in DM (n=35) and control (n=35) post-menopausal women. *Alendronate (n=3):* In a post-hoc analysis of a randomized controlled trial (RCT), alendronate led to equal increases in spine and hip BMD (compared with placebo) in DM (n=148) and control groups (n=3,087) after 36 months of treatment. Data from two (n=52, n=151) retrospective studies showed comparable increases in spine BMD in DM and control groups, with no benefit in hip and non-vertebral fractures. *Risedronate (n=1):* In a post-hoc analysis of three RCTs, risedronate resulted in equal increases in spine BMD in both DM (n=53) and control groups (n=832) after 12 months of treatment. *Raloxifene (n=4):* In two post-hoc analyses of RCTs and the aforementioned retrospective population-based study, DM group exposed to raloxifene demonstrated the same vertebral fracture risk reduction compared with control groups without effect on non-vertebral fractures in either treatment group. In one small, observational study in patients on hemodialysis, the effect on spine BMD was comparable. *Teriparatide (n=1)*: DM (n=133) and control groups (n=196) demonstrated similar increases in spine and total hip BMD, after treatment for 24 months. No difference between the two groups was noticed in the incidence of non-vertebral fractures. No eligible study was found for zoledronic acid, ibandronate, strontium ranelate, denosumab or bazedoxifene. The effect of the aforementioned therapies on bone turnover in DM and control groups was comparable.
Conclusion: Despite heterogeneity of data, all anti-osteoporotic therapies are equally effective in patients with DM compared with those without DM, with respect to BMD and vertebral fracture risk. Thus, DM does not alter anti-osteoporotic treatment response.

Impaired adhesion of human periodontal ligament fibroblast to collagen-I in model hyperglycaemia in vitro is corrected by Glo1 inducer

A.A.D. Ashour, P.J. Thornalley, N. Rabbani;
Division of Metabolic & Vascular Health, University of Warwick, Coventry, UK.

Background and aims: Diabetes and inflammation enhances periodontal bone loss through enhanced resorption and diminished bone formation. It has been shown that human PDL fibroblast (hPDLF) attachment and function to type 1 collagen was impaired by methylglyoxal (MG) modification *in vitro.* MG is a reactive dicarbonyl metabolite produced mainly as a byproduct of glycolysis and precursor of advanced glycation endproducts (AGEs). We found that increased hPDLF detachment and dysfunction is partly mediated by increased exposure to high glucose concentration with increased formation of MG, impaired MG metabolism by glyoxalase 1 (Glo1) of the cytoplasmic glyoxalase system and increased formation of MG-derived AGEs. The aim of this study was to evaluate the effects of Glo1 inducer in high and low glucose concentrations on the hPDLFs adhesion efficiency.
Materials and methods: Primary hPDLFs were purchased from ScienCell, Carlsbad, USA. They were cultured in Modified Eagles Medium (MEM) supplemented with L-alanyl-L-glutamine (2 mM), 10% FBS and 100 Units/ml penicillin and 100 μg/ml streptomycin at 37ºC. Cells were passaged every 3 days. For experiments performed in low and high glucose conditions, culture media was supplemented with 8 mM and 25 mM glucose, respectively. Primary hPDLFs were incubated with high and low glucose media in triplicate for 3 days with or without Glo1 inducers (10 μM)): trans-resveratrol (tRES), hesperetin (HESP) and tREV and HESP combined (tRES-HESP). Cells were then incubated in a collagen-I coated cell adhesion assay plate for 3 h. After removing the unattached cells, adhesion efficiency was measured by quantifying attached cells.
Results: hPDLFs incubated in high glucose concentration gave a decreased adhesion to collagen-I: cell adhesion - 36 ± 9%, with respect to low glucose control ($P<0.05$, n = 3). Glo1 inducers, tRES, HESP and tRES-HESP combination improved cell adhesion in low glucose concentration cultures: cell adhesion + 52 ± 17%, +40 ± 7%, and + 57 ± 24%, respectively, with respect to low glucose control ($P<0.05$, n = 3). In high glucose concentration, Glo1 inducers corrected the decreased adhesion to collagen-I and improved cell adhesion to values higher than the low glucose control: tRES, + 87 ± 15%, HESP + 104 ± 20%, and tRES-HESP combination, + 60 ± 11%, with respect to low glucose control ($P<0.01$, n = 3; $P<0.001$ with respect to high glucose control). Similar incubations of control cells with collagen-I pre-incubated with conditioned medium with and without prior incubation with 500 μM aminoguanidine to scavenge MG suggested that MG in conditioned medium could also modified collagen-I to decreased cell adhesion. This was also prevented by Glo1 inducers.
Conclusion: We conclude that hPDLFs suffer dicarbonyl stress in high glucose concentration *in vitro* that impairs adhesion to collagen-I and this may be corrected by Glo1 inducer treatment. MG modification of collagen-I released from hPDLFs may also modify integrin binding sites and impair cell adhesion.

Glyoxalase-1 inducer corrects disturbance of the cytosolic proteome in human periodontal ligament fibroblasts in model hyperglycaemia in vitro

N. Rabbani, A. Ashour, S. Pasha, A. Shafie, P.J. Thornalley;
Clinical Sciences Research Laboratories, University of Warwick, Coventry, UK.

Background and aims: Hyperglycemia induces dysfunction in human periodontal ligament fibroblasts (hPDLFs) in diabetes which may be linked to increased risk of periodontitis. Cell dysfunction includes: abnormal accumulation of the glucose-derived reactive dicarbonyl metabolite,

methylglyoxal (MG) - dicarbonyl stress - and related increased formation of advanced glycation endproducts (AGEs), abnormal secretion and processing of extracellular matrix proteins, inflammation, oxidative stress, increased formation of advanced glycation endproducts (AGEs) and other processes. Insights into drivers of these processes may be gained by deep proteomics analysis and analysis of key proteomic pathways disturbed in hyperglycemia. The aim of this study was to analyse the cytosolic proteome of hPDLFs incubated in low and high glucose concentrations - the latter to model hyperglycemia - and study the possible reversible of effects in high glucose by treatment with glyoxalase inducer, trans-resveratrol-hesperetin combination (tRES-HESP).

Materials and methods: Primary cultures of hPDLFs were incubated in low and high glucose concentration media (8 mM and 25 mM, respectively) for three days with and without Glo1 inducer, tRES-HESP (10 μM); n = 3. Cytosolic protein was reduced, alkylated and digested with Lys-C and trypsin. Peptides were analysed by nanoflow liquid chromatography-Orbitrap Fusion™ (Thermo) mass spectrometry and a relative quantification of protein concentration was performed using non-conflicting peptides in Progenesis QI™ software (Nonlinear Dynamics, Newcastle upon Tyne, U.K.). Protein ontology was evaluated using literature and Web-based tools (http://www.reactome.org/) to identify functional annotation to characterise molecular functions and biologic processes. Protein identification was based on at least 2 unique peptides and protein sequence coverage range was 5 - 40%.

Results: In hPDLF cytosolic extracts, deep proteomics analysis detected 1077 proteins. Twenty-two cytosolic proteins were downregulated and 17 upregulated in high glucose incubations. Twenty of these proteins were significantly normalised by the Glo1 inducer. Many of the down-regulated proteins in high glucose concentration cultures that were normalised by Glo1 inducer were shown to be associated with the coatomer (COP)-mediated vesicle transportation pathway (P = 0.036). Additionally, in high glucose concentration cultures insulin-degrading enzyme (IDE) was decreased 43%, with respect to low glucose concentration cultures. This was normalised by Glo1 inducer treatment. IDE exhibits heat shock protein-like activity in association with the 26S proteasome to clear damaged proteins.

Conclusion: There were selected increases and decreases of proteins in the cytosolic proteins of hPDLFs exposed to high glucose concentration. Glo1 inducer corrected most of the changes. Disturbance of the cytosolic proteome in hyperglycemia may explain deficits in vesicle transport and proteostasis of hPDLFs in diabetes.

Serum potassium control and patiromer taken without or with food in hyperkalaemic patients with diabetes

P. Rossignol[1], C. Gross[2], D.M. Spiegel[2], J. Yuan[2], P.E. Pergola[3];
[1]Inserm 1433 CIC-P CHRU de Nancy, University of Lorraine and FCRIN INI-CRCT, Nancy, France, [2]Relypsa, Inc., a Vifor Pharma Company, Redwood City, [3]Renal Associates P.A., San Antonio, USA.

Background and aims: Patiromer, a sodium-free, nonabsorbed potassium (K^+)-binding polymer that uses calcium as the counter exchange ion, is approved in the U.S. for the treatment of hyperkalemia (HK) and is under review in the E.U. Patiromer has been shown to significantly lower serum K^+ in several clinical trials, including in HK patients with diabetes mellitus (DM) and CKD in the AMETHYST-DN study. The recommended starting dose of patiromer for hyperkalemia treatment is 8.4 g once daily (QD) with food. The recently completed TOURMALINE study was designed to assess the efficacy and safety of patiromer given QD without food compared to with food for the treatment of HK. Here we report the results of a pre-specified subgroup analysis of patients with Type 1 or 2 DM randomized in TOURMALINE.

Materials and methods: TOURMALINE was an open-label, randomized study of HK patients (2 screening K^+ values >5.0 mEq/L assessed locally using a point of care device). If patients were on RAAS inhibitors, beta-blockers, or diuretics, doses were required to be stable for 14 days before screening. Patients could have well-controlled DM (Type 1 or Type 2), heart failure, hypertension, and/or CKD but none were a requirement for study entry. Patients meeting eligibility criteria were randomized in a 1:1 ratio to receive patiromer 8.4 g QD initially, either without food (≥1 hr before or ≥2 hr after eating) or with food (from start of meal to 30 min after eating). Randomization was stratified by screening K^+, race, and history of DM. Endpoints were between-group comparison for the proportion (95% CI) of patients with week 3 or 4 serum K^+ in the target range (3.8-5.0 mEq/L) and the mean (±SE) change in serum K^+ from baseline to week 4.

Results: Of 114 randomized patients, 94 (82%) had DM (without food, n=48; with food, n=46); 84/94 (89%) completed the study. Two patients in the with-food group were excluded from efficacy analyses (1 did not receive ≥1 patiromer dose; and 1 had an important protocol violation and no post-baseline serum K^+); the former patient was also excluded from safety analyses. Of patients with DM, 87/92 had Type 2 DM; mean (SD) time since DM diagnosis was 17.2 (10.5) yr; 59% were on RAAS inhibitors and mean (SD) eGFR was 40.8 (25.1) ml/min/1.73 m^2. Overall, 83.7% (95% CI, 74.5-90.6) of DM patients achieved target serum K^+ at week 3 or 4 (81.3% [95% CI, 67.4-91.1] in the without-food group and 86.4% [95% CI, 72.6-94.8] in the with-food group; p=0.5072), consistent with results observed in the overall study population. The mean (±SE) change from baseline to week 4 in serum K^+ in the DM subgroup (-0.55 ±0.06 mEq/L) was consistent with the change in the overall population (-0.57±0.06 mEq/L). Consistent with prior patiromer trials, 45/93 (48%) of patients with DM had 1 or more adverse event (AE), with similar rates in the without-food and with-food groups. Gastrointestinal AEs were the most common AE class (none severe) in DM patients, including 6 (6.5%) with diarrhea and 3 (3.2%) with constipation. Four DM patients had serious AEs; none were considered by the investigator to be related to patiromer.

Conclusion: More than 80% of patients with DM achieved serum K^+ between 3.8-5.0 mEq/L with once-daily patiromer, with similar results when patiromer was given with or without food. Patiromer was generally well tolerated in patients with DM.

Role of gluten free diet in the preservation of insulin reserve in newly diagnosed type 1 diabetic children with coeliac disease

P. Toth-Heyn, V. Herczeg, A. Luczay, A. Körner, E. Szakmár, L. Madácsy;
Ist Department of Paediatrics, Semmelweis University, Budapest, Hungary.

Background and aims: Experimental results suggest that dietary gluten may play a role in the progression of type 1 diabetes mellitus (T1DM). Based on clinical data, it can be assumed that gluten-free diet (GFD) could delay the progression of T1DM. T1DM is frequently associated with celiac disease (CD). We hypothesized that diabetic patients with CD on GFD would have different insulin requirement as compared to diabetic peers consuming gluten. Our aim was to assess whether GFD started at the diagnosis of T1DM has any impact on increasing insulin need in the remission phase of T1DM.
Materials and methods: Pediatric patients with T1DM and CD from the Ist Department of Pediatrics, Semmelweis University were enrolled in the study (31 girls, 15 boys, age at the time of T1DM diagnosis 6.9 ± 3.9 years). Four patients were also enrolled who were on GFD without the diagnosis of CD. Patients were divided in two groups: I. GFD started within two months after the diagnosis of T1DM (group GFD +, n = 27) and II. GFD started some years later or not kept (group GFD-, n = 19). Gluten consumption was presumed based on anamnestic data and/or positive serology for transglutaminase autoantibodies. Insulin requirements were evaluated retrospectively during the first three years after the diagnosis of T1DM, and the difference between the two study groups was compared every six months. Data were analyzed by parametric statistical tests and repeated measures analysis of variance.
Results: Mean (± SEM) insulin requirement of the GFD- group increased from 0.40 ± 0.18 U/kg to 0.72 ± 0.14 U/kg in 3 years ($p < 0.001$). In the GFD+ group the insulin dose increased similarly from 0.41 ± 0 ,20 U/kg to 0.71 ± 0.13 U/kg in 3 years ($p < 0.001$). The rise in insulin requirement was significant after 1 year in the GFD- group, and after 2 years in the GFD+ group. Insulin requirements were different in GFD+ and GFD- groups 1 and 1.5 years following the diagnosis of T1DM (0.43 ± 0.04 U/kg vs. 0.64 ± 0.07 U/kg, $p < 0.01$; and 0.5 ± 0.04 U/kg versus 0.7 ± 0.06 U/kg, $p < 0.01$, respectively).
Conclusion: Insulin requirements of diabetic children on GFD increases slower during the first two years post-diagnosis of T1DM as compared to diabetic children consuming gluten. Insulin requirements under GFD are lower after 1 and 1.5 years. During the remission phase, the increase in insulin requirement reflects the evolution of endogenous insulin reserve. GFD, therefore, likely helps to conserve endogenous insulin. The longer remission phase is of clinical relevance having impact on the long-term metabolic control of diabetic children.
Disclosure: **P. Toth-Heyn:** None.

Preserved C-peptide levels in overweight or obese children with newly diagnosed type 1 diabetes

A. Szypowska[1], L. Groele[1], M. Wysocka-Mincewicz[2], A. Mazur[3], L. Lisowicz[3], I. Beń-Skowronek[4], J. Sieniawska[4], B. Klonowska[5], D. Charemska[5], J. Nawrotek[6], I. Jałowiec[6], A. Bossowski[7], M. Jamiołkowska[7], B. Pyrzak[1], M. Szalecki[2];
[1]Medical University of Warsaw, [2]Children's Memorial Health Institute, Warsaw, [3]Medical Faculty University of Rzeszow, Rzeszów, [4]Medical University of Lublin, Lublin, [5]University of Warmia and Mazury in Olsztyn, Olsztyn, [6]General District Hospital, Kielce, [7]Medical University in Białystok, Białystok, Poland.

Background and aims: The number of children with overweight and obesity has been rapidly increased in Poland. Some authors suggest that increased weight may be an accelerator of type 1 diabetes (T1D) onset, others did not support this hypothesis. The aim of our study was to investigate if Polish overweight or obese children might develop T1D early despite preserved C-peptide value.
Materials and methods: The study included 1098 children aged 2-17 with newly recognized T1D. The following data were retrospectively collected from seven Polish hospitals: date of birth, fasting C-peptide, HbA1c, sex, weight, height at the time of diabetes onset. Based on the WHO standards, patients were categorized as underweight (≤-2 Z-scores), normal weight (+1 to -1 Z-scores), overweight (≥+1 Z-score), or obese (≥+2 Z-scores).
Results: In our study 11.3% children were overweight or obese at T1D onset. Overweight or obese children had more residual beta-cell function and lower HbA1c than did normal weight or underweight children (Table 1). Children with obesity (1.8%) had the youngest median age and the highest fasting C-peptide levels. There was a correlation between fasting C-peptide and BMI-SDS ($p=0.0001$), age ($p=0.0001$), and a negative correlation with HbA1c ($p=0.0001$).
Conclusion: Children with obesity and overweight are diagnosed with type 1 diabetes at an early stage with largely preserved C-peptide levels and might be good responders to immune therapy.

Tight glucose control in critically ill pediatric patients: a network meta-analysis of randomised controlled trials

T. Yamada, N. Shojima, T. Yamauchi, T. Kadowaki;
University of Tokyo, Tokyo, Japan.

Background and aims: Our recent network meta-analysis of randomized trials in critically ill adults showed no reduction of mortality by tight glycemic control (blood glucose: 4.4-<6.1 mmol/l) with intensive insulin therapy, although hypoglycemia was 5 times more frequent versus mild control (7.8-<10.0 mmol/l) or very mild control (10.0-<12.2 mmol/l) (Intensive Care Medicine 2017). On the other hand, it is still unclear whether tight glycemic control is warranted in critically ill pediatric patients. We employed network meta-analysis to examine the risk of secondary infection and hypoglycemia associated with different glycemic control targets in critically ill pediatric patients.
Materials and methods: Electronic databases were searched up to 2017 for randomized controlled trials comparing various insulin regimens in critically ill pediatric patients. Two reviewers extracted information and evaluated its quality with the Cochrane risk-of-bias tool. Three glycemic control groups were compared: tight (blood glucose: 4.4 < 6.1 mmol/l), mild (7.8 < 10.0 mmol/l), and very mild (10.0 to < 12.2 mmol/l). Network meta-analysis was performed by a frequentist-based approach with multivariate random effects meta-analysis. Inconsistency of the network model was estimated by using inconsistency factors and their uncertainty. In addition, ranking plots (rankograms) were constructed using the probability that a given treatment had the highest event rate for each outcome. The surface under the cumulative ranking curve (SUCRA), which is a simple transformation of the mean rank, was used to set the hierarchy of the treatments.
Results: Four randomized trials were identified (3,235 patients, 359 secondary infection events, 391 hypoglycemia events, and 127 severe hypoglycemia events). Compared with very mild control, there was borderline reduction of the risk of infection (sepsis) with tight control [pooled odds ratio (OR) 0.79 (95% CI 0.62-1.00), $p=0.05$]. However, hypoglycemia and severe hypoglycemia were more frequent with tight control than very mild control [OR 5.9 (1.63-21.3), $p=0.007$ for hypoglycemia; OR 4.76 (2.84-7.97), $p<0.001$ for severe hypoglycemia]. There was also a higher risk of severe hypoglycemia with tight control than mild control [OR 3.76 (1.58-8.96), $p=0.003$].

Conclusion: In critically ill pediatric patients, network meta-analysis showed a borderline benefit of reduced secondary infection risk with tight glycemic control relative to very mild control, but the risk of hypoglycemia and severe hypoglycemia was 5 times higher versus very mild control.

IGF-I at diagnosis and subsequent years in adolescents with type 1 diabetes

S. Chisalita[1], J. Ludvigsson[2];
[1]Department of Endocrinoloy and Diabetes, University Hospital, Linköping, Sweden, [2]Div. of Pediatrics, Department of Clinical and Experimental Medicine, Linköping University, Linköping, Sweden.

Background and aims: Type 1 diabetes (T1D) in adolescents is associated with alterations in the IGFsystem probably caused both by a deranged metabolism and insulinopenia in the portal vein.We aim to study how the circulating IGF-I is affected at diagnosis and subsequent years in adolescents with T1D.

Materials and methods: Ten girls and ten boys with type 1 diabetes (T1D), age 13.0 ±1.4 (mean ±SD) years at diagnosis took part in the study. Blood samples were drawn at diagnosis, and after 3, 9, 18 and 48 months. HbA1c, total IGF-I and C-peptide were measured.

Results: At diagnosis the patients had high HbA1c, low IGF-I and measurable C-peptide. After start of insulin treatment maximal improvement in glycemic control and IGF-I occurred within 3 months and then both tended to deteriorate, i.e. HbA1c to increase and IGF-I to decrease. C-peptide decreased with time and after 4 years half of the patients were C-peptide negative. At diagnosis C-peptide correlated positively to IGF-I ($r=0.50$; $p<0.03$). C-peptide correlated negatively with insulin dose (U/kg) after 18 and 48 months from diagnosis ($r=-0.50$; $p<0.03$ and $r=-0.72$; $p<0.001$, respectively).

Conclusion: In newly diagnosed adolescents with type 1 diabetes and deranged metabolism IGF-I levels are low but improves with insulin treatment and are positively influenced by residual beta cell function. It is concluded that it is important to preserve beta cell function to keep low HbA1c and IGF-I as normal as possible.

Analysis of rehabilitation for 2001 children and adolescents with diabetes

R. Schiel[1], T. Perenthaler[1], A. Steveling[2];
[1]Department of Diabetes and Metabolic Diseases, MEDIGREIF Inselklinik Heringsdorf GmbH, Ostseebad Heringsdorf, [2]Internal Medicine A, University of Greifswald, Medical School, Greifswald, Germany.

Background and aims: Medical rehabilitation is a special concept in the treatment of diabetes mellitus: It plays an important role in the therapeutic concepts of children and adolescents. Services can be applied, which are difficult to implement in an out-patient or an acute in-patient setting. The study analyzes rehabilitation in 2001 patients over a period 12 years.

Materials and methods: All (n = 2001) children and adolescents with diabetes mellitus (52% girls, age 12.6 ± 4.9 years) were examined, who were admitted to a specialist clinic for rehabilitation during the period 01/2004-12/2016.

Results: The duration of medical rehabilitation was 27.3 ± 6.1 days. 1980/2001 (98.9%) children and adolescents had type 1, 21/2001 (1.1%) had type 2 diabetes mellitus. Mean HbA1c was 7.87±1.47%. 1897/2001 (95%) patients had an intensified insulin therapy, of which 633 (32%) used insulin pumps (CSII). They injected 0.86±0.47 I.E. Insulin/kg body weight/d and performed 37.6±11.4 blood glucose self-tests/week by. Over the follow-up period of 12 years parameters of the metabolic control (HbA1c, incidence of acute complications) changed hardly. The proportion of patients with CSII increased ($p<0.05$). In particular young children used CSII more frequently (age <4 59% vs 24% age ≥16 <17 years, $p<0.05$). Changes also occurred in cultural status: the percentage of patients from German families decreased ($p<0.05$), the proportion of patients from mixed-cultural families increased ($p<0.05$). The number of patients living together with both parents also decreased ($p<0.05$ for the tendency), the number of patients living with single parents increased ($p<0.05$ for the tendency). In young children HbA1c values were the lowest. From the beginning of puberty (about 10 years) HbA1c increased (8.5±1.9% in 16 to 17-year-olds). There were no correlations/associations between metabolic control and the incidences of hypoglycaemia/ketoacidoses.

Conclusion: There is a change in medical rehabilitation: the proportion of patients using CSII increased, the number of patients living with single parents and the percentage of patients from a culturally mixed families increased too. Hence, more and more patients showed psychological alterations. These need special care and therapy

Delivery of exenatide by subdermal placement of ITCA 650 in a nonclinical juvenile rabbit model to determine exposure and tolerability

D.T. Zane[1], L. Kjems[2], A. Hoberman[3], R. Fielding[4], J. Shelton[1], R. Singh[1], M. Baron[2], T. Alessi[1];
[1]Development, Technology and Engineering, Intarcia Therapeutics, Hayward, [2]Clinical, Intarcia Therapeutics, Boston, [3]Charles River Laboratories, Horsham, [4]Biologistic Services, Boulder, USA.

Background and aims: The incidence of type 2 diabetes (T2D) in children and adolescent is increasing globally. The deterioration of beta cell function is more progressive in pediatric T2D compared to adult T2D. This, combined with the obesity component, highlights the need for a safe and efficacious treatment with a high adherence rate in the pediatric population. ITCA 650 is an osmotic mini-pump that delivers a continuous rate of exenatide subcutaneously, following subdermal placement in the abdominal wall for up to 6 months. Juvenile toxicity data are required in support of a planned human pediatric study. For the class of GLP-1 RAs and use in a pediatric T2D population, potential concerns relate to accelerated sexual maturation, precocious puberty and growth. Studies with ITCA 650 in juvenile rats are not feasible due to their small size postnatal. The rabbit was chosen because the stages of development/puberty most closely match those of the rodent and based on historical data and direct experience with ITCA 650 in rabbits.

Materials and methods: In a dose-finding juvenile toxicity study, rabbits received ITCA 650 placed subdermally at exenatide doses of 0 (ITCA placebo), 0 (pair fed) 3, 10, 20, 40, and 60 mcg/d from postnatal days (PND) 28 through 90 to determine tolerability, exposure, and immunogenicity of exenatide.

Results: Plasma exenatide levels increased in proportion to dose and were similar in males and females. Anti-exenatide antibodies were detected at low levels (titer ≤45) in 33% of the ITCA 650 animals on PND 90 with no relationship between incidence, dose or gender. Juvenile rabbit-human exposure multiples for the 3, 10, and 20 mcg/d dose levels ranged between 0.41-6.45. There was no indication of acceleration in sexual maturity. Sexual maturation was comparable between groups for vaginal patency (32.0-35.0 d) in females and for preputial separation (79.3-91.7 d) in males. Growth, measured by mean femur length, was comparable between groups (83.7-87.4 mm in males and 83.0-87.4 mm in females). No gross lesions related to ITCA 650 occurred. Body weights (BW) on PND 90 ranged from 89.9-94.9% of the control group 0 (ITCA

placebo) for the 0 (pair fed), 3, 10, and 20 mcg/d groups in males, and from 97.2-102.7% in females. Doses of ITCA 650 as high as 60 mcg/d did not affect the organ weight or ratio of the organ weight to the terminal BW but did result in identifiable toxicity. Adverse clinical observations (thin appearance, dehydration, ungroomed fur, liquid feces and weight loss) were observed in the 40 and 60 mcg/d group (either individual rabbits or all rabbits in a group) and resulted in early death or animals to be euthanized.

Conclusion: ITCA 650 at doses up to 60 mcg/d did not accelerate sexual maturation or impact growth. Adverse clinical reactions, reduced BW gains and food consumption occurred in all groups exposed to exenatide due to its known pharmacological activity. These results will inform the definitive juvenile rabbit toxicity study in support of the clinical pediatric program.

PS 110 Cancer risk and diabetes

1221

Can we identify people with higher pancreatic cancer risk who present with type 2 diabetes?

E.L. Badrick[1], H. Lennon[1], M. Sperrin[1], T. Van Staa[1], D. O'Reilly[2], I. Buchan[1], A. Renehan[2];
[1]Division of Informatics, Imaging and Data Science, University of Manchester, [2]School of Medical Sciences, University of Manchester, Manchester, UK.

Background and aims: Type 2 Diabetes (T2D) is associated with increased risks of developing several cancer types, including pancreatic cancer. A unique relationship may exist between new onset T2D, together with other symptoms like weight loss, and pancreatic cancer diagnosis. This would suggest an opportunity to develop risk models after diagnosis of T2D as an early cancer diagnosis strategy. Previous studies on this topic have been limited by using primary care datasets only, failing to link with cancer registries, and therefore (i) commonly underestimate cancer incidence by 9% to 25%; and (ii) may misclassify date of cancer diagnosis.

Materials and methods: We used primary care data from the Clinical Practice Research Datalink (1990-2011), on 330,311 individuals with T2D from 372 GPs in the UK, and linked these with the National Cancer Registration and Analysis Service, yielding 57,910 individual cancers.We developed logistic regression models to determine the pancreatic cancer occurrence within 6 months of T2D diagnosis. Covariates included were sex, age (continuous and in 5 year bands), smoking status, body mass index (BMI), weight loss, alcohol, government office region and Index of Multiple Deprivation (IMD).We benchmarked our results against the UK National Institute of Health and Care Excellence (NICE) 3% Positive Predictive Value (PPV) in their guidance on immediate referral with symptoms suspicious for cancer.Performance of the model was assessed using the area under the ROC curve (AUC_{ROC}).

Results: There were 130015 men and 141075 women with a new diagnosis of T2D, with 88 and 101 pancreatic cancers (respectively) within 6 months. In models that incorporated age, sex smoking status, current BMI, alcohol consumption, region, and deprivation, we attained an AUC_{ROC} of 0.7962, but no individuals had a risk above the 3% threshold. In models where indicators of weight loss were added this improved the AUC_{ROC} to 0.8034; here, 16 people were classified as having a cancer risk above the 3% threshold, but only one was a true positive. All models had poor sensitivity and high specificity.

Conclusion: There are opportunities to develop a risk model of pancreatic cancer occurrence within the first 6 months after diagnosis of T2D, but this was at a price of poor sensitivity and high specificity. Future developments will include external validation approaches and testing emerging hypotheses for example, a new diagnosis of T2D without the presence of obesity may indicate a strategy of enhanced cancer investigations. Pancreatic cancer has a poor prognosis, and any opportunities for earlier detection should be explored to improve survival.

The effect of type 2 diabetes on selected clinical parameters and disease outcome in patients with colorectal cancer

L. Pacal[1], D. Valik[2], D. Maluskova[3], J. Jarkovsky[3], P. Klika[3], R. Obermannova[2], L. Dusek[3], K. Kankova[1,2];
[1]Department of Pathophysiology, Faculty of Medicine, [2]Regional Centre for Applied Molecular Oncology, [3]Institute of Biostatistics and Analyses, Brno, Czech Republic.

Background and aims: Recent epidemiological evidence indicates increased incidence of certain cancer types in patients with type 2 diabetes

mellitus (T2DM), worse outcomes and also certain modifying effect of various glucose-lowering therapies. Given the population prevalence of both T2DM and colorectal cancer (CRC) their relationship is particularly relevant. Study objective was to analyse tumour-, patient- and treatment-related characteristics explaining possible difference in selected outcomes between CRC subjects with and without pre-existing diabetes by means of in-depth epidemiological analysis of all consecutive patients diagnosed and treated for CRC over the past 10 years (stratified by the presence/absence of T2DM) in the largest cancer centre in Czech Republic - Masaryk Memorial Cancer Institute (MMCI) in Brno.

Materials and methods: Retrospective data-mining of all available data from electronic health records of MMCI Brno and National Cancer Registry revealed a total of 8860 CRC cases during 2004-13 period, of which a subset of 3371 CRC subjects underwent the entire CRC treatment including diagnosis in MMCI. Inclusion criteria were: CRC and eventual T2DM diagnosis classified by ICD-10 code as C18 - C20 and E11 and/or presence of anti-diabetic medication (ATC group A10B (oral antidiabetics) or A10A (insulins)). Exclusion criteria: other co-existing tumour (as a disease outcome confounder). Statistical analyses based-on on probabilistic and time-to-event analysis to determine the effect of pre-existing diabetes, its treatment modality and their interactions on following outcomes: disease-free interval, recurrence rate, cancer-specific mortality, all-cause mortality were used.

Results: 41.2% of CRC cases were in stage I+II and 44.8% in stage III+IV. Prevalence of T2DM was approximately 10% in this sample and time period, median survival time 8.4 years. T2DM subjects were more frequently men, significantly older and had higher clinical CRC stage ($P<0.05$, chi-square or Mann-Whitney test). Significant differences in the overall and CRC-specific survival between diabetic and non-diabetic ($P<0.001$, log-rank test) independent of age and stage at baseline were revealed with T2DM having significantly shorter median survival.

Conclusion: Using a large cohort of clinically well characterised CRC subjects we confirmed that T2DM represents significant risk of adverse CRC outcomes. Detail analysis of tumour type- and site- and treatment-specific effects is warranted in this cohort to provide a complex and personalised estimation of the risk existing T2DM possess at the time of CRC diagnosis.

Pre-existing diabetes and all-cause mortality of cancer patients: a register-based study in Latvia

I. Strele[1], S. Pildava[2], I. Repsa[3], U. Kojalo[1], J. Vilmanis[4,1], G. Brigis[1];
[1]Riga Stradins University, [2]Centre for Disease Prevention and Control, [3]National Health Service, [4]Pauls Stradins Clinical University Hospital, Riga, Latvia.

Background and aims: Most studies from high income countries consistently report that pre-existing diabetes reduces overall survival of cancer patients. Our preliminary analysis, presented at the EASD meeting in 2012, showed atypical results: in Latvia, among men, diabetes was associated with a better survival in the first years of follow-up. We re-examined this research question in a retrospective cohort study by using two different population-based data sets.

Materials and methods: The Cancer Register in linkage with the Diabetes Register and the Causes of Death Data Base was the first data source. The analysis included 25,043 men and 27,081 women registered with incident cancers from 2009 to 2013; of those 1,910 (7.6%) men and 2,802 (10.4%) women had prior diabetes. Follow-up ended on 28 February 2015. The National Health Service data served as the second source for selection of 10,725 men and 13,779 women, discharged from specialized oncology hospitals from 2009 to 2012, with cancer as the main diagnosis. Of those, 951 (8.9%) men and 1,521 (11.0%) women had records of dispensed reimbursed antidiabetic medications before the hospital admission, indicating prior diabetes. Their follow-up ended on 31 December 2013. The Cox proportional hazards model was used to assess association between pre-existing diabetes and all-cause mortality, adjusted for age, presented as HR (95% CI).

Results: In men, according to the disease-registers data, cancer patients with diabetes experienced lower mortality than their non-diabetic counterparts (age-adjusted HR 0.86; 0.79-0.93) during the first year after cancer diagnosis. The mortality difference levelled off in the next two years; but after the third year of follow-up, diabetes was associated with a higher risk of dying (HR 1.60; 1.28-1.99). In the health service data, diabetic men also had lower mortality than cancer patients without diabetes during the first two years after the hospital discharge (HR 0.89; 0.80-0.98). After the first two follow-up years, diabetes had no association with mortality (HR 1.03; 0.74-1.43). In women, pre-existing diabetes was associated with slightly higher all-cause mortality during the entire follow-up: age-adjusted HR was 1.17 (1.10-1.24) in the disease-register data and 1.11 (1.02-1.21) in the health service data.

Conclusion: Our study confirmed that pre-existing diabetes was associated with a worse prognosis among women with cancer; whereas among men, the better overall survival of diabetic cancer patients in the first years after cancer diagnosis is an unusual finding. We hypothesize that limited access to health services, including preventive care, might give an advantage to diabetic patients who are in close contact with the healthcare system.

Disclosure: **I. Strele:** None.

1224

Within-class sulfonylurea differences and cancer risk (ZODIAC-55)

D. Schrijnders[1,2], G.H. de Bock[3], N. Kleefstra[2,4], K.J.J. van Hateren[2], H.J.G. Bilo[1,4], G.W.D. Landman[2,5];
[1]Diabetes Centre Isala, Zwolle, [2]Langerhans Medical Research Group, Zwolle, [3]Department of Epidemiology, University of Groningen, University Medical Centre Groningen, Groningen, [4]Department of Internal Medicine, University of Groningen, University Medical Centre Groningen, Groningen, [5]Department of Internal Medicine, Gelre Hospital, Apeldoorn, Netherlands.

Background and aims: Patients with type 2 diabetes (T2D) are at increased risk for developing cancer. There are within-class sulfonylurea (SU) differences concerning hypoglycaemia risk and probably also for cardiovascular safety. Several studies also reported within-class differences in cancer risk. In what way and to what degree cancer risk is modified by the use of specific SUs or whether methodological issues have been accounted for in previous studies is unclear. The aim of this study was to investigate within-class SU differences in obesity and all cancers risk.

Materials and methods: A primary care diabetes cohort, the prospective observational ZODIAC (Zwolle Outpatient Diabetes project Integrating Available Care) cohort study with annually collected diabetes and medication data was linked to the Dutch National Cancer Registry. Patients who received their first prescription of SU treatment at any point within ZODIAC where selected, this moment was defined as baseline. Patients using insulin at baseline were excluded. Primary outcomes were obesity related and all cancer risk, evaluated for men and women separately. Cox proportional hazard analyses adjusted for age, HbA1c, diabetes duration, BMI, creatinine, smoking, and metformin use were used for analysing the relationship between baseline SU use and cancer risk.

Results: Of the 28.096 patients selected, 49% were female, with a mean (SD) age of 67 (12), median (IQR) diabetes duration 7.6 (4.4 - 11) year, median HbA1c 6.8% (6.3 - 7.5), median BMI 28.9 (26.0 - 32.5) and a median follow-up of 3.3 years (1.3 - 5.6). Cumulative hazard ratios (HR) for women (panel A) and men (panel B) are shown in figure 1. Gliclazide was chosen as reference. For obesity related cancers, HR (95%CI) for women and men for glibenclamide were 0.69 (0.40 - 1.18) and 1.12

(0.64- 1.96), for glimepiride 0.76 (0.54 - 1.07) and 0.96 (0.65 - 1.42), and for tolbutamide 0.91 (0.67 - 1.23) and 0.92 (0.68 - 1.41). For all cancers, HR (95%CI) for glibenclamide were 0.80 (0.53 - 1.21) and 1.21 (0.87 - 1.68), for glimepiride 0.86 (0.66 - 1.13) and 0.95 (0.74 - 1.21), and for tolbutamide 0.96 (0.76 - 1.22) and 1.03 (0.83 - 1.28), for women and men respectively.

Conclusion: No significant within-class differences between baseline SU use and obesity related and all cancer risk were present. We could not rule out relevant differences, i.e. type 2 error. Fortunately, an update of the linkage in the next month will double the amount of patient-years and events. Another step is to integrate exposure duration by accounting for medication and clinical variables during follow and to perform time-dependent Cox regression analyses.

The influence on survival of glucocorticoid induced diabetes in cancer patients with metastatic spinal cord compression

H. Schultz[1], U. Pedersen-Bjergaard[1], A.E.K. Jensen[1,2], S.A. Engelholm[3], P.L. Kristensen[1];
[1]Nordsjællands Hospital, Hillerød, [2]Biostatistics, Institute of Public Health, University of Copenhagen, Copenhagen, [3]Rigshospitalet, Copenhagen, Denmark.

Background and aims: Glucocorticoids are used to treat edema in patients with metastatic spinal cord compression (MSCC) before and during radiotherapy. Hyperglycemia and diabetes are well known side effects to treatment with glucocorticoids, but the influence of hyperglycemia on survival is unknown.

Materials and methods: In a prospective, observational cohort study 131 patients with MSCC referred to radiotherapy, 30 Gy in 10 fractions, and treated with ≥ 100 mg prednisolone a day were followed with daily blood glucose measurements during radiotherapy and categorized as having no diabetes, diabetes by definition or insulin treated diabetes. The patients were followed for at least 5 months.

Results: During follow-up a total of 56 patients 43% (95% CI = 35%-52%) presented plasma glucose values diagnostic of diabetes. Sixteen patients who developed diabetes were treated with insulin, 12% (95% CI = [6%; 18%]) of the total population. In six months, from the first day of prednisolone, 60% of the patients died. The patients developing diabetes with need for insulin therapy during glucocorticoid therapy had a significantly increased mortality compared to those with normal glucose metabolism and with diabetes without need for therapy, hazard ratio = 2.1 (95% CI =1.08- 4.09, p = 0.0285).

Conclusion: The literature on the effect of glucocorticoid induced hyperglycemia/diabetes on survival in cancer patients is sparse and inconclusive. To our knowledge this is the first prospective study to describe the influence of glucocorticoid induced diabetes on survival in patients with MSCC from different primary tumors. The results indicate that development of diabetes during high-dose glucocorticoid therapy needing insulin treatment in patients with MSCC from different primary tumors is associated with reduced survival.

Metformin inhibits vistatin gene expression via HIF1 in PC3 prostate cancer cells: a potential role for visfatin as a non-invasive biomarker

S. Messineo[1], B. Arcidiacono[1], D.M. Corigliano[1], D. Foti[1], J.P. Castaño[2], R.M. Luque[2], A. Brunetti[1];
[1]Dept. of Health Sciences, University "Magna Græcia" of Catanzaro, Catanzaro, Italy, [2]Maimonides Institute of Biomedical Research of Cordoba (IMIBIC), Córdoba, Spain.

Background and aims: Hypoxia plays a pivotal role in the aggressiveness of solid cancers, including prostate cancer (PC). During cancer progression, hypoxia stimulates hypoxia-related gene expression and the production of glycolytic intermediates useful for cancer growth. In this setting, hypoxia-inducible factor 1 (HIF1) is the major transcription factor regulating hypoxia adaptive responses. Among the HIF1-inducible gene products, visfatin, both a NAD+ cycle enzyme, and an adipokine, plays an important role in promoting cancer cell proliferation. Metformin, commonly used for the management of type 2 diabetes and insulin resistance, has shown anti-proliferative effects in vitro and in vivo, leading to increasing interest in its potential use as an anti-tumoral agent. How metformin inhibits cell growth, however, remains still poorly understood. Aim of this study was to evaluate the effects of metformin on the HIF1/visfatin axis in prostate cancer PC3 cells. Furthermore, our purpose was to investigate the potential use of visfatin as a non-invasive prognostic biomarker in patients with PC.

Materials and methods: PC3 cells were cultured in RPMI plus 10% FBS, in the presence or absence of metformin, in normoxia or hypoxia (CoCl2 or 2%O2). Visfatin gene expression was evaluated by qRT-PCR. Reporter gene analysis was performed by dual luciferase assay after 48h transfection, using lipofectamine, with a plasmid containing the visfatin gene promoter. Western blots were carried out using a HIF1-α polyclonal antibody. Serum specimens were obtained from the "Biobanco" service of the IMIBIC Institute, and patients were engaged for the presence or absence of PC, metformin treatment, and sorted by Gleason score and BMI. Visfatin was measured by a competitive EIA visfatin kit.

Results: In PC3 cells, treatment with metformin caused a consistent, dose-dependent decrease in visfatin mRNA levels, both in normoxia and hypoxia ($p<0.05$; Mann-Whitney test). Also, in these cells, either under normoxia or hypoxia, metformin induced a significant, dose-dependent decrease in visfatin promoter activity ($p<0.001$; Mann-Whitney test), demonstrating a role on gene transcription. In parallel experiments, metformin-treated cells showed a decrease in HIF1α protein content ($p<0.001$; Mann-Whitney test). In patients with PC and poorer prognosis (Gleason score 9/10 vs Gleason score 6), serum visfatin was more elevated (2.64± 1.5ng/mL vs 1.05± 0.3ng/ml, respectively, p=0.0067; Kruskal-Wallis test; n=176). Furthermore, in metformin-treated patients, serum visfatin was significantly lower in each BMI range, compared to metformin-untreated patients. Visfatin levels were: in the normal weight group (BMI<25), 0.56±0.1 ng/mL vs 3.42±1.3 ng/mL p=0.005; in the overweight group (25<BMI<30), 0.98±0.18 ng/mL vs 1.14±0.23 ng/mL p=0.032; and in the obese group (BMI>30), 0.81 ±1.9 ng/mL vs 0.98±2.0 ng/mL p=0.033 (metformin-treated vs untreated patients, respectively; Mann-Whitney test).

Conclusion: Our data in PC3 cultured cells indicate that the anti-proliferative activity of metformin could be mediated, at least in part, through the HIF1/visfatin axis. Our findings also suggest that visfatin could serve as a non-invasive biomarker of aggressiveness in patients with PC.

Complex interplay between androgen, estrogen and insulin receptor gene expression in prostate cancer depending on diabetes status

S.Z. Lutz[1,2], J. Hennenlotter[3], M. Scharpf[4], A. Guirguis[1], A. Peter[1,2], H. Staiger[2,5], A. Fritsche[1,2], T. Todenhöfer[3], M. Heni[1,2], A. Stenzl[3], H.-U. Häring[1,2];
[1]Internal Medicine IV, University of Tuebingen, [2]Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Center Munich at the University of Tuebingen, [3]Department of Urology, University of Tuebingen, [4]Department of Pathology, University of Tuebingen, Tuebingen, [5]German Center for Diabetes Research (DZD), Munich-Neuherberg, Germany.

Background and aims: In contrast to many other malignancies, incidence of prostate cancer (PCa) is not elevated in patients with diabetes mellitus. However, PCa survival is markedly reduced in diabetic men. Prostate cell growth and prostate carcinogenesis are not only mediated by androgens, they are also depending on functional estrogen and insulin receptor signaling. To address potential underlying mechanisms for the reduced survival in diabetic men we looked for gene expression patterns of the androgen receptor (AR), insulin receptor A (IRa) and B (IRb), IGF1R, and the classical nuclear estrogen receptor β (ERβ) *(ESR2)* both in diabetic and nondiabetic patients. Moreover, as in diabetic men testosterone levels are reduced, the expression of the regulating enzymes for the non-canonical androgen receptor ligands 27-hydroxycholesterol and 24(S)-hydroxycholesterol, Cyp27A1 and Cyp46A1, respectively, were analyzed.
Materials and methods: 80 prostate tissue samples of diabetic patients (45 cancer, 35 tumor-adjacent benign tissue, and 86 samples of patients without diabetes (35 cancer, 51 tumor-adjacent benign tissue), who underwent a radical prostatectomy, carefully matched for age and BMI, were included in the study. mRNA expression of target genes was analyzed by RT-qPCR and normalized to *UBC* mRNA in duplicate.
Results: *AR* expression in tumor tissue was elevated only in men with diabetes (p=0.025), which went along with higher IRa/IRb ratio (p=0.001) and lower IRb/IGF1R ratio (p<0.0001). When correlated to the tumor content in the biopsies, we found an impressive reduction in *Cyp27A1* and *Cyp46A1* gene expression with increasing tumor content (p<0.0001 and p=0.0002, respectively). Only in diabetic men, the reduction of *Cyp27A1* expression went along with enhanced cell proliferation, measured by the expression of the proliferation marker Ki67 (p=0.0007), while the inverse correlation of *Cyp46A1* expression with Ki67 showed a trend (p=0.11). *ESR2* was inversely associated with IRa/IRb ratio (p<0.0001), and only in men with diabetes, inversely with *AR* (p=0.0007). Finally, *ESR2* expression went along with elevated *Cyp27A1* and *Cyp46A1* expression in diabetes (p=0.003 and 0.012, respectively).
Conclusion: In this study we could demonstrate an elevated *AR* expression in tumor only in diabetic men, associated with alterations of the insulin signaling cascade, and showing inverse association with the ERβ. Our results suggest a complex interplay between these signaling pathways in PCa, especially when diabetes is present. These changes may contribute to the reduced survival of diabetic men with PCa.

Glucose impairs tamoxifen responsiveness modulating CTGF (Connective Tissue Growth Factor) in breast cancer cells

M.R. Ambrosio[1], V. D'Esposito[1], V. Costa[2], D. Liguoro[1], G. Mosca[1], L. Grumetti[1], M. Lecce[1], F. Beguinot[1], A. Ciccodicola[2], P. Formisano[1];
[1]URT-GDD, National Council of Research, Department of Translational Medical Sciences, Federico II University of Naples, [2]Institute of Genetics and Biophysics, National Council of Research, Naples, Italy.

Background and aims: Type 2 diabetes (T2D) is associated with a 20% increased risk of breast cancer (BC) and up to 16% of BC patients suffer from T2D or impaired glucose tolerance. T2D promotes a more aggressive BC phenotype. Particularly, hyperglycemia is associated with a poorer therapeutic outcome and reduced drug response in BC. Thus, glucose may directly affect cancer cell responsiveness to chemotherapy. Moreover, glucose may affect surrounding stromal cells. BC cells are embedded in a adipocyte-rich microenvironment. Glucose is able to modify the secretory capability of adipocytes, enhancing BC cell proliferation and invasiveness. Nevertheless, adipocyte-derived factors potentially able to alter BC drug response have not been identified yet. Identifying the mechanisms that govern it will pave the way to new targeted strategies to overcome chemoresistance in T2D patients with BC. Thus, the aim of this study was to investigate the direct and indirect (i.e. adipose tissue-mediated) impact of glucose on BC cell responsiveness to tamoxifen (tam).
Materials and methods: MCF7 BC cells (ER^+) were cultured in high (MCF7 HG;25 mM) or in low (MCF7 LG;5.5 mM) glucose medium. Adipocyte conditioned media (hAdipo CM) system and co-coltures with human adipocytes were established. Cell viability upon tam treatment was assessed by sulforhodammine B assay or crystal violet. Cell transcriptome was characterized by RNA Sequencing on a Next Generation Sequencing platform (Illumina HiSeq 2000).
Results: In LG, tam reduced cell viability by about 50% while in HG drug sensitivity was 2 fold reduced (Pval<0.05). Shifting MCF7-HG to LG restored tam sensitivity, whereas the shift of MCF7-LG to HG reduced drug responsiveness. RNA-Sequencing revealed that glucose deregulates the expression of cell cycle-related genes (Pval<0.05). Particularly, *CTGF* expression was 2-fold reduced upon the shift in LG (Pval<0.001). Of note, in MCF7-HG responsiveness to tam was 2-fold increased (Pval<0.05) upon the knockdown of *CTGF* by siRNA. Consistently, the treatment with human recombinant CTGF (1μg/mL) reduced by about 4-fold MCF7-LG responsiveness to tam (Pval<0.05). Moreover, *CTGF* expression in MCF7-HG was 2.5-fold increased (Pval<0.05) in presence of CM collected from adipocytes pre-incubated in HG. Notably, MCF7-HG responsiveness to tam was worsened both in presence of hAdipo-CM and in co-colture with adipocytes (Pval<0.05). The inhibition of adipocyte-released IL8 reduced the effect of hAdipo-CM of about 2-fold (Pval<0.05) both on CTGF expression and on tam responsiveness. Accordingly, cell treatment with human recombinant IL8 (1μg/mL) induced CTGF expression (≈50%;Pval<0.05) and increased tam responsiveness (≈15% reduction of cell viability; Pval<0.05) mimicking the hAdipo-CM effects on BC cells
Conclusion: Glucose affects tam responsiveness modulating *CTGF* in BC cells, both directly and indirectly through adipocyte-released IL8. CTGF may be a diabetes-associated predictive marker for chemosensitivity and may represent a potential therapeutic target to overcome tam resistance in BC.

The link between diabetes and colorectal cancer: effect of diabetic microenvironment, metformin and 5-fluorouracil on AMPK activation, apoptosis and autophagy

K. Kuricová[1], L. Pácal[1], P. Müller[2], R. Hrstka[2], K. Kaňkova[1];

[1]Department of Pathophysiology, Masaryk university, [2]Regional Centre for Applied Molecular Oncology, Brno, Czech Republic.

Background and aims: Epidemiologic studies showed that (i) type 2 diabetes mellitus is associated with increased risk of development of certain cancers including colorectal cancer (CRC)and (ii) result of CRC treatment are worse in diabetics including higher mortality rates. On the other hand, antidiabetic treatment, specifically metformin, was associated with better prognosis and also increased efficacy of standard chemotherapeutic treatment of CRC. Despite the historical use, molecular mechanisms of anticancer effect of metformin are not fully understood yet. Activation of AMP-activated protein kinase (AMPK), the key regulator of glucose metabolism, orchestrates the pleiotropic effects of AMPK including cell cycle arrest, autophagy induction or apoptosis but also activation of survival metabolic pathways. It is therefore obvious that the final outcome of metformin action in cancer critically depends on the functionality of p53 as a key regulator of all above mentioned processes. Little is known about how hyperglycaemia/diabetic milieu affects AMPK pathway. Aim of the study was to study the effect of (i) diabetic microenvironment, (ii) metformin and (iii) first line CRC cytostatic agent 5-fluorouracil on AMPK signalling, autophagy and apoptosis *in vitro* in CRC with defined p53 status.
Materials and methods: HCT116 cell line with and without p53 (p53+/+ and p53-/-) was cultured 30 hours in following settings: 7.5 mmol/l or 25 mmol/l glucose in the medium with or without the addition of metformin (500 μmol/l) or 5-fluorouracil (5-FU, 5 μmol/l). Cell viability was assessed using resazurin. AMPKα activation was monitored using Western blot with phospho-specific antibody against threonine 172 (Cell Signaling Technology). Autophagy induction was detected using antibody against LC3 and apoptosis was detected using caspase-3 antibody (both from Cell Signaling Technology).
Results: Regardless commonly used milimolar concentrations of metformin in experiments we initially determined IC50 for metformin (and 5-fluorouracil), because physiologically relevant metformin concentrations are tens of micromoles. IC50 concentrations 500 μmol/l for metformin and 5 μmol/l for 5-FU were subsequently used in all experiments with cell line HCT116. We found that metformin decreases viability of HCT116 cells more profoundly in 53-/- compared to +/+ even in normoglycaemia. We also confirmed AMPKα activation by metformin, again more significant in HCT116 p53-/- cells. Caspase-3 expression was increased by 5-FU and also by combination of 5-FU + metformin in both normo- and hyperglycaemia in p53-/- but not in p53+/+ cells.
Conclusion: We confirmed stronger effect of metformin on viability and AMPKα activation in cancer cells without functional p53. Combination of metabolic/energetic stress and exposition to cytotoxic agents (5-fluorouracil as a typical first line chemotherapeutic for CRC treatment) might represent potentially effective approach to treatment of p53 deficient cancers.

Expressions of microRNA-30, 196 and 423 distinguish type 2 diabetes from diabetes associated with pancreatic cancer and chronic pancreatitis

P. Skrha[1], A. Horinek[2], P. Fric[3], M. Andel[1], J. Skrha[2];
[1]2nd Dept. of Internal Medicine, 3rd Faculty of Medicine, Charles University, [2]3rd Dept. of Internal Medicine, 1st Faculty of Medicine, Charles University, [3]Dept. of Internal Medicine, Military University Hospital, Charles University, Prague, Czech Republic.

Background and aims: Diabetes mellitus (DM) is frequently the first symptom of pancreatic cancer (PAC). The prevalence of DM in chronic pancreatitis (CHP) is elevated too. CHP is simultaneously one of the main risk factors for developing PAC. The aim of this study was to estimate if microRNA (miRNA) profiling in DM patients could improve PAC diagnosis and its distinguishing from CHP.
Materials and methods: Fifty eight diabetic patients with PAC, 15 diabetic patients with CHP, 39 type 2 diabetic patients (T2DM) without PAC or CHP, and 30 healthy controls were enrolled in our study. Diagnosis of PAC and CHP was done by high resolution imaging methods and confirmed by histological examination. Expressions of 8 miRNAs (miR-21, 30, 191, 192, 196, 200, 423 and 454) were determined in the serum by real-time PCR. MicroRNAs were then related to miRNA-191 and 454 that were set as endogenous controls. Kruskal-Wallis ANOVA test was performed to evaluate the results.
Results: The mean expressions of miR-21, 30, 192, 196 and 200 were significantly elevated (1,8-4,3 times) in PAC patients compared to healthy controls and T2DM group ($p<0,05$ to $p<0,0001$). On the contrary, miR-423 was significantly lower (4,6-6,5 times) in CHP patients compared to each of other groups ($p<0,0001$). MicroRNA-30, 196, 200 and 423 were able to distinguish PAC patients from CHP group. MicroRNA expressions in PAC, CHP and T2DM groups were compared with healthy controls having expression equal to 1,0. Significant differences between PAC and CHP groups are shown in the Figure.
Conclusion: Our study is the first that compares expressions of selected miRNAs in diabetic patients with PAC or CHP. While patients with CHP should be examined for tumour development, it is not easy to distinguish the cancer in the early stage. MicroRNA-30, 196 and 423 seem to become powerful markers in patients with diabetes mellitus in distinguishing pancreatic cancer from chronic pancreatitis.

Type 2 diabetes: induced MMPs promote pancreatic cancer progression

X. Tingting, J. Shenghong;
Department of Radiology,Zhongda Hospital, Medical School of Southeast University, Jiangsu Key Laboratory of Molecular and Functional Imaging, Nanjing, China.

Background and aims: Increasing epidemiologic evidence suggests that incidence of pancreatic cancer is associated with type 2 diabetes as well as certain risk factors of diabetes. In pancreatic cancer, diabetic conditions promotes the growth of tumor and increases the mortality rate. However,

the underlying mechanisms are poorly understood at present. Diabetes associated molecular changes in tumor potentially contribute to the cancer progression in type 2 diabetes patients. In most cancers, the expression of matrix metalloproteinases (MMPs) increased which involved in cancer progression, including angiogenesis, invasiveness, and metastasis. But MMPs in diabetic pancreatic cancer has not been previously explored.This study aims to investigate the key molecules MMPs in type 2 diabetes that may promote the pancreatic cancer using molecular imaging methods and assess whether these pancreatic-cancer-promoting molecules can be used as targets for targeted specific imaging and treatment in pancreatic cancer with type 2 diabetes. We expect to demonstrate and develop a specific approach that is individualized to treat the diabetes associated pancreatic cancers.

Materials and methods: Orthotopic pancreatic cancer models were established in db/db diabetic mice, Steptozotocin(STZ) induced diabetic mice and C57BL/6 mice. Based on the analysis of clinical human pancreatic tumor tissue samples collected in patients and the animal models for type 2 diabetes and pancreatic cancer, we performed the MMPs molecular imaging experiments and MMP inhibitors tumor therapy experiments in animal models followed by immune-histo-chemistry and pathological analyses.

Results: Pancreatic cancer grew faster in both diabetic mice models than in wild type mice. MMP-2 and MMP-9 expressed in pancreatic cancer with type 2 diabetes mellitus was significantly higher than in those without type 2 diabetes mellitus in clinical patients ($P < 0.05$). Besides, the expression of MMPs in diabetic pancreatic cancer mice models were also higher than that in wild type mice using MMPs NIRF imaging followed by immune-histo-chemistry and pathological analyses ($P < 0.05$). What is beyond our expectations is that tumor inhibition rate of selective MMP-2 and MMP-9 inhibition in wild type mice, STZ diabetic mice and db/db diabetic mice was 12.18%, 36.94%, 54.89%, respectively. It indicates that selective MMP-2 and MMP-9 inhibition reverses diabetes-induced pancreatic cancer growth monitored by MR imaging and MMPs molecular imaging in vivo.

Conclusion: In a conclusion, it suggests that type 2 diabetes aggravates pancreatic cancer by stimulating the expression of MMPs. MMPs can be used as targets for targeted specific imaging and treatment in pancreatic cancer with type 2 diabetes.

Insulin activates AKT pathway and promotes ECM production of PSC: implication for pancreatic fibrosis and cancer in type 2 diabetes

M. Zhi[1], X. Zhu[1], R. Waldron[2], A. Lugea[2], S. Pandol[2], L. Li[1];
[1]Zhongda Hospital of Southeast University, Nanjing, China, [2]VA Greater Los Angeles Health System, David Geffen School of Medicine at UCLA, Los Angeles, USA.

Background and aims: Type 2 diabetes has been demonstrated to be an independent risk of pancreatic cancer (PC). Insulin resistance, hyperglycemia, hyperinsulinemia, and abnormalities in insulin/IGF receptor pathways have been suggested to be related to diabetes-associated pancreatic cancer, and activated pancreatic stellate cells (PSC) are reported to be crucial effector cells responsible for development of pancreatic fibrogenesis and pancreatic cancer progression in type 2 diabetes. However, few researches have illuminated how high insulin promotes PSC proliferation, which plays a central role in fibrogenesis associated with pancreatitis and pancreatic cancer. AKT/mTOR/p70S6K and AKT/FoxO1 signaling pathway are classical pathways regulating cell proliferation, differentiation and protein synthesis. The aim of this study was to investigate the effects of high insulin on AKT/mTOR/p70S6K and AKT/FoxO1 signaling pathway enhancing proliferation and fibrosis responses in PSC.

Materials and methods: In primary mouse PSC and a novel immortalized mouse pancreatic stellate cell line (imPSC), the effects of insulin on AKT/mTOR/p70S6K and AKT/FoxO1 signaling pathway were examined. Cells were stimulated with high insulin (100 nmol/L), and cultured with metformin (2mmol/L). We measured extracellular matrix (ECM) synthesis of collagen I (Col-I) and fibronectin (FN), determined the expression signaling pathway components, analyzed their operation as profibrotic and/or proliferative pathways and assessed the potential contributions of PSC to a fibrogenic microenvironment.

Results: High insulin significantly increased Col-I and FN production ($P < 0.01$). Besides, the expression of FoxO1 in PSC was ascended by insulin ($P < 0.01$). Activated phosphorylation of the Akt, mTOR, P70S6K and inhibited phosphorylation of AMPK were completely caused by high insulin stimulation in PSC ($P < 0.01$). Meanwhile, high insulin promoted phosphorylation of FoxO1 in PSC ($P < 0.01$). However, metformin obviously activated AMPK and reduced AKT/mTOR/P70S6K phosphorylation ($P < 0.01$).

Conclusion: Our study showed that high insulin activated AKT/mTOR/p70S6K and AKT/FoxO1 signaling pathway and promoted ECM production of PSC, which suggested a potential key role of AKT pathway in development of pancreatic fibrosis responses in type 2 diabetes. Metformin is a hope for prevention of pancreatic fibrosis and cancer in type 2 diabetes.

Dietary advanced glycation end-products activate NF-κB, AKT1 and ERK1/2 linking cancer risk and diabetes

A.I. Serban[1], L. Stanca[1], O.I. Geicu[1,2], A. Dinischiotu[2];
[1]University of Agricultural Science and Veterinary Medicine, [2]University of Bucharest, Bucharest, Romania.

Background and aims: Recent evidence has suggested a positive correlation between type 2 diabetes and increased colorectal cancer risk. We explored the hypothesis that high dietary intake of advanced glycation end products (AGEs) may play a fundamental role in this association.

Materials and methods: Casein was glycated in vitro (30 min at 70 ºC, 4 sec at 140 ºC, in the presence of 116 mM lactose - 55 mM glucose-fructose. C2BBe1 colorectal carcinoma cells (enterocytes) were treated with 200 μg/ml glycated or control casein for 3 and 24 h. Additionally, we used anti TNF-α, anti RAGE and anti IL-1β antibodies to block the AGEs induced signaling that may involve these respective proteins. Phosphorilated extracellular signal-regulated kinases 1/2 (Erk1/2), RAC-alpha serine/threonine-protein kinase (AKT1), the p50 subunit of NF-κB, receptor for advanced glycation end products (RAGE) and interleukin 1β (IL-1β) protein expression were evaluated by western blot.

Results: AGEs content in glycated casein was 17.5 μg/mg protein. The 3 h AGEs exposure induced a significant ($p<0.05$) increase by 1.7 fold in Erk1/2 expression, and after 24 h Erk1/2 returned to control levels. The initial increase was fully prevented by the anti-TNF-α antibody co-

treatment, however, no significant contribution by the RAGE or IL-1β blocking antibodies. A similar expression profile was observed for p 50 subunit, albeit, the initial high expression was more pronounced (it increased by over 2.5 fold) and it was abolished in the presence of all antibody treatments. Both the AGEs and the anti-RAGE antibody - AGEs co-treatment induced at 24 h increased p 50 expression, which could be explained by the co-dependent nature of the NF-κB - RAGE relationship, also highlighted by the merely identical expression profile we noted for the RAGE receptor. AKT1 expression was unaffected after 3 h, although AGEs exposure increased its expression significantly after 24 h, and could not be controlled by any antibody treatments applied. IL-1β expression was increased dramatically at the 3 h interval by AGEs exposure and was diminished to control level by the antibody treatments. Notably, cell proliferation was increased after exposure to glycated casein by 1.4 fold after 24 h ($p<0.05$).

Conclusion: On the one hand, enterocytes are involved in creating a non-belligerent microenvironment in the gut, along with local immune-competent cells. They are routinely stimulated by antigens, and do not respond by triggering inflammation. However, our data seem to suggest, that AGEs can readily induce transient pro-inflammatory changes. These changes, such as the increased Erk1/2 expression, known to induce metalloproteinases, may contribute in the long term to compromise the barrier represented by enterocytes, and allow antigen access to the lamina propria, where full-scale inflammation could develop. On the other hand, the changes we observed in AKT1 expression could have profound implications, given the carcinogenic origin of the C2BBe1 cells we used. AKT1 is known to inhibit apoptosis and to activate NF-κB and antioxidant enzymes, and it is currently considered a primary target of cancer therapies. Its increase after 24 h could enhance cancer cells ability to cope with stressful stimuli and promote survival. In this way, a link between high dietary AGEs intake, human cancer biology and chronic inflammatory diseases involving the gut may be supported.

PS 112 Pathogenesis of non-alcoholic fatty liver disease: from mice to men

1234

Two mtDNA point mutations in complexes of the respiratory chain synergistically reduce mitochondrial fission and impair metabolism in liver

S. Schroeder, M. Tiedge, S. Baltrusch;
Institute of Medical Biochemistry and Molecularbiology, University Medical Center Rostock, Rostock, Germany.

Background and aims: Mutations in complexes of the respiratory chain, which are encoded in the mitochondrial genome (mtDNA), can facilitate the production of reactive oxygen species (ROS) and affect the mitochondrial live cycle during aging. Due to these effects on mitochondrial viability mtDNA mutations may result in metabolic liver dysfunction and thus, can contribute to the pathogenesis of type 2 diabetes mellitus (T2DM). Previous studies indicate that multiple mutations in the OXPHOS system predispose to hepatic steatosis. The aim of this study was to investigate fat and ROS accumulation as well as mitochondrial dynamics in liver tissue from conplastic mice carrying mutations in the cytochrome c oxidase (complex IV) and the NADH dehydrogenase (complex I).

Materials and methods: The conplastic mouse strains C57BL/6NTac-mtBPL/1J (NADH dehydrogenase mutation und cytochrome c oxidase mutation, mtBPL) and C57BL/6NTac-mtAKR/J (control; mtAKR) were analyzed at the age of 3, 6, 9 and 12 months. After in vivo MitoSox injection the hepatic mitochondrial ROS production was quantified in liver sections using fluorescence microscopy. In addition, we analyzed the gene expression of fission and fusion regulating proteins, namely MFN1, MFN2, OPA1, FIS1, MFF, DMN1L in liver tissue. Fat accumulation was determined by Oil Red O staining of liver sections. Total body weight and, liver and fat mass were ascertained. Furthermore blood glucose was measured.

Results: Blood glucose levels, body weight and liver fat accumulation of 12 months old mtBPL mice were significantly increased compared to the mtAKR control strain (6.8 vs. 5.7 mmol/l, $p < 0.05$; 39.3 vs. 36.2 g, $p < 0.05$; 18260 vs. 4100 pixel, $p < 0.001$). With aging, mtBPL mice showed a more pronounced increase in ROS accumulations as observed in mtAKR mice. The gene expression of FIS1 and MFF showed a significantly lower level in mtBPL mice compared to controls at all examined time points. In addition, at the age of 3 and 9 months the DNM1L gene expression in mtBPL mice was significantly reduced compared to controls. In contrast to these differences in fission proteins, the gene expression of fusion proteins was comparable between both mouse strains.

Conclusion: The mtDNA point mutations in two OXPHOS complexes, the NADH dehydrogenase and cytochrome c oxidase resulted in lipometabolic dysfunction in liver and higher blood glucose levels in 12 months old mtBPL mice without manifestation of diabetes. Our data suggest that these processes are triggered by reduced mitochondrial fission. Thus, OXPHOS mutations can induce tissue-specific impairments via changes in the mitochondrial network regulation. Whether hepatic steatosis implies insulin resistance and development of T2DM in old mtBPL mice is the purpose of our current research.

PTP1B deficiency in mice induces changes in gut microbiota and gut barrier permeability during NASH

C. Rubio[1,2], M. Puerto[3,4], J.J. García-Rodríguez[5], L. Menchén[3], R. Bañares[3,4], J.M. Carrascosa[6], Á.M. Valverde[1,2];
[1]IIBm Alberto Sols, [2]CIBERdem, [3]IIS Gregorio Marañón, [4]CIBERehd, [5]Departamento de Parasitologia, Facultad de Farmacia, Universidad Complutense de Madrid, [6]CBM Severo Ochoa, Madrid, Spain.

Background and aims: Mice deficient in protein tyrosine phosphatase 1B (PTP1B) have increased insulin sensitivity in the liver. However, the role of PTP1B in the dynamics of the gut barrier and associated changes in microbiota during non-alcoholic steatohepatitis (NASH) is unknown. We analyzed the effects of PTP1B deficiency in gut microbiota and intestinal permeability to understand the relation of the gut-liver axis in NASH.
Materials and methods: NASH was induced in 16-20 week-old male wild-type (WT) or PTP1B-deficient (KO) mice (C57Bl/6J) fed choline/methionine-deficient (MCD) diet up to 2 months. Control mice were fed chow diet. DNA was extracted from stool samples collected individually. Amplicons of the V3-V4 hypervariable regions of 16S were sequenced using Illumina-Myseq system. Microbiome analysis was performed with QUIIME program. In vivo permeability was measured through oral gavage of FITC-Dextran and its determination in blood 4 hours later.
Results: After one week on MCD diet, the PCoA analysis revealed a consistent change in microbiota composition due to differences in diet (MCD versus chow) and genotype (PTP1B KO versus WT).When we analyzed the beta diversity, the ratio Firmicutes/Bacteroidetes increased from 1.32 (±0.24) to 2.70 (±0.45) in WT and further in PTP1B KO 3.62 (±0.66). Also, in mice fed MCD diet changes in phyla Verrucomicrobia, Firmicutes and Bacteroidetes were time-dependent, whilst phyla Cianobacteria and Actinobacteria were dependent on the genotype. Histological analysis of duoden and colon did not show differences between groups. However, after one month on MCD diet, we observed a decrease in colon length in both genotypes ($p<0.001$) (WT chow 9.5 ±0.53cm, WT MCD 7.53±0.47cm; PTP1B KO chow 9.55±0.74cm, PTP1B KO MCD 7.4±0.46cm) and a reduction in colon diameter ($p<0.01$) which was more pronounced in PTP1B KO versus WT mice ($p<0.05$) (WT -27.85%±6.54; KO -38.51%±8.22). Both WT and PTP1B KO mice fed MCD diet showed increased circulating endotoxemia than their counterparts fed chow diet (WT chow 13.83ng/ml±2.77, WT MCD 29.51ng/ml±6.41; $p<0.001$), (PTP1B KO chow 13.67ng/ml±3.24; PTP1B KO MCD 19.70ng/ml±7.45; n.s), but endotoxemia was less elevated in PTP1B KO mice fed MCD compared to WT MCD group (WT MCD vs PTP1B KO MCD; $p<0.01$). Gut permeability was also measured by administration of FITC-Dextran by an oral gavage at different time-periods. Non significant differences were found in mice fed chow or MCD diet for 7 days. However, permeability was more elevated in WT mice fed MCD diet for one month compared to PTP1B KO mice ($p<0.05$) (WT basal 0.0024%±3,2E-06; WT 30 days 0.0056%±5,0E-06; PTP1B basal 0.0020%±2,1E-06; PTP1B 30 days 0.0050%±3,4E-06). Preliminary data showed increased proinflammatory markers (TNFα and IL1β) and a decline in tight junction proteins (E-cadherin and occluding) in WT fed MCD diet versus WT fed chow diet that were not observed in PTP1B KO mice.
Conclusion: Marked changes in gut microbiota composition and gut barrier permeability occur during the establishment of NASH in the MCD model. PTP1B deficiency induces substantial changes in gut microbiota and confers protection against alterations in gut barrier permeability during NASH.

JAZF zinc finger 1 ameliorates age- and diet-associated hepatic steatosis through SREBP-1c-dependent mechanism

X. Luo[1], L. Li[1], R. Liu[2], G. Yang[2];
[1]Key Laboratory of Diagnostic Medicine of Ministry of Education, School of Laboratory Mecicine, Chongqing Medical University, [2]Department of Endocrinology, the Second Affiliated Hospital, Chongqing Medical University, Chongqing, China.

Background and aims: Hepatic steatosis is characterised by an aberrant accumulation of triglycerides in the liver. However,the drivers of progressive steatohepatitis remain incompletely defined. Juxtaposed with another zinc finger gene 1 (JAZF1) has been reported to be involved in glucose and lipid metabolism. Therefore, the aim of this study was to investigate the influence of JAZF1 on age- and adipose-associated hepatosteatosis and the mechanism.
Materials and methods: Expression levels of JAZF1 gene/protein were examined in the liver tissues from obesity-associated mice. In vitro, lipid metabolism was analysed in hepatocytes with JAZF1 overexpression and suppression. In vivo, Wild-type C57BL/6 and age-matched JAZF1-Tg mice were randomized to chow or HFD. Liver triglyceride metabolism was analysed in mice by PCR , Histological examination, Oil Red O staining, and western blot. Culture of primary mouse hepatocytes and dual-luciferase reporter gene assay were used to further investigate the mechanism of JAZF1 activation in the regulation of triglyceride metabolism.
Results: In JAZF1-Tg mice, body fat content and hepatosteatosis were protected from HFD-induced steatosis, and accompanied by decreased lipogenesis gene expression. In hepatocytes, over-expression of JAZF1 attenuated, while knockdown of JAZF1 enhanced the expression of lipogenesis genes. The over-expressing of JAZF1 in hepatocytes displayed the increased AMPK phosphorylation and decreased sterol regulatory element-binding protein 1 (SREBP-1) expression. The roles of JAZF1 were partially attenuated by Compound C. Mechanistically, JAZF1 suppressed SREBP-1c expression through the inhibition of transcriptional activity of LXRE2 in the SREBP-1c promoter.we found that JAZF1 over-expression protected against the development of atherosclerosis in ApoE KO mice and attenuated the expression of pro-inflammatory cytokines in vivo and vitro. More recently, we further demonstrated that JAZF1 over-expression decreased hepatic glucose production (HGP) and increased phosphorylation of insulin signaling molecules in liver with a PI3-kinase/Akt-dependent manner.
Conclusion: Our data illustrate that JAZF1 plays a crucial role in the regulation of age- and nutrient- associated hepatosteatosis through an AMPK/SREBP-1-dependent mechanism.

Circulating PCSK9 is associated with pentraxin 3 concentration in patients with type 2 diabetes

M. Waluś[1], M. Kapusta[2], A. Trojak[3], P. Miarka[4], B. Idzior -Waluś[1], M.T. Malecki[1];
[1]Department of Metabolic Diseases, Jagiellonian University, [2]Department of Biochemistry, Jagiellonian University, [3]Jagiellonian University, [4]Department of Nephrology, Jagiellonian University, Kraków, Poland.

Background and aims: Nonalcoholic fatty liver disease (NAFLD) is present in up to 80%f of type 2 diabetic (DM2) patients. NAFLD exacerbates hepatic insulin resistance and is associated with obesity, hypertension and atherogenic dyslipidemia. Proprotein Convertase Subtilisin/Kexin type 9 (PCSK9) is a serine protease secreted by hepatocytes and involved in the regulation of LDL receptor expression. There is evidence that circulating PCSK9 increases with hepatic fat accumulation and correlates with the severity of steatosis, independently of metabolic confounders and liver damage. Pentraxin 3 (PTX3) is an essential component of innate immunity and a member of the long pentraxin superfamily, which are soluble proteins induced by various inflammatory stimuli. PTX3 is independently associated with the risk of vascular events. There is gathering evidence that plasma pentraxin 3 level is a novel marker for nonalcoholic steatohepatitis and severity of liver fibrosis. There are data that PTX3 also possess anti-microbial, anti-inflammatory

and cardioprotective properties. In this study we aimed to determine factors associated with PCSK9 in a group of patients with DMt2.
Materials and methods: Material included 116 consecutive patients with DMt2, 79 with NAFLD and 39 with coronary artery disease (cad). In each patient standardized questionnaire, anthropometric measurements, fasting serum lipids, apolipoprotein C3 (apo C3), glucose, glycated hemoglobin HbA1c, cytokeratin-18 fragments (CK-18), a marker of NAFLD, PTX3 serum concentration and circulating PCSK9 were determined. NAFLD was diagnosed by ultrasonography. CK-18, PTX3, PCSK9 and apo C3 levels were determined by ELISA, serum lipids enzymatically using Roche reagents, glycated hemoglobin A1c by HPLC.
Results: Mean (SD) age of patients was 59.1 (11.1) years, mean duration of diabetes 9.8 (5.9) years, mean values of HbA1c 8.63 (2.4%), and of BMI 32.8 (5.6) kg/m^2. Mean values of serum LDL-cholesterol were 2.6 (1.16), of triglyceride concentrations 1.8 (1.0) mmol/l, and of HDL-cholesterol 1.14 (0.29) mmol/l respectively. The mean (SD) values of serum PCSK9 were 255,44 (106,967) ng/ml, of PTX 3 4.53 (1,77) ng/ml and did not differ between patients with and without NAFLD or cad. In the whole group of patients circulating PCSK9 correlated negatively with age (r=-0.21, p<.05), HbA1c (r=-0.21, p<.05), and positively with BMI (r=0.21, p<.05) and, as expected, with total cholesterol (r=0.59), LDL-cholesterol (r=0.50), triglyceride (r=0.35) and po C3 (r=0.31) concentration (p<.001 for all). Interestingly, strong positive correlation between PTX3 and PCK9 was observed (r=0.47, p<.001). We did not found any associations between PCSK9 and CK-18 fragments nor liver enzymes.
Conclusion: The results of the study indicate that circulating PCSK9 is significantly associated with PTX3, marker of cardiovascular risk and NAFLD fibrosis. In our group of DMt2 patients PCSK9 is also significantly positively associated with BMI and atherogenic lipid levels and apo C3 concentrations. The association between circulating PCSK9 and PTX3 might be of value in understanding the processes of increased cvd risk in NAFLD patients.

Correlations between patatin-like phospholipase domain containing 3gene (PNPLA3) polymorphisms and nonalcoholic fatty liver disease in type 2 diabetes patients

R.S. Gavril, L. Mihalache, O. Nita, A.C. Oprescu, O.I. Ungureanu, A. Gherasim, L.I. Arhire;
UMF Iasi, Iasi, Romania.

Background and aims: Patatin-like phospholipase domain-containing protein 3 (PNPLA3) has been linked to the development and evolution of fatty liver, but not to insulin resistance. The aim of the study was to evaluate the relationship between PNPLA3 and fatty liver, metabolic syndrome and subclinical atherosclerosis.
Materials and methods: We evaluated a group of 130 subjects with type 2 diabetes treated with oral medication or diet, who were admitted to the Clinical Center of Diabetes, Nutrition and Metabolic Diseases. The subjects with hepatitis B, C and toxic hepatopathy were excluded. The study group was represented by 92 patients with a mean age of 60.38 ± 10.37 years, with 47.83 % men. We analysed the link between fatty liver and anthropometric indices, biochemical parameters, genetic marker and subclinical atherosclerosis assessed by measurement of carotid intima-media thickness (CIMT). Fatty liver and CIMT were assessed using ultrasonography. PNPLA3 rs738409 genotype determination was performed by high resolution melting analysis (HRM) with a Rotor-Gene 6000 instrument (Cornett Research), its software (Series Software 1.7.87) and uAnalyze web application that allowed three standards genotyping CC, CG and GG.
Results: More than 90% of the subjects showed various degrees of hepatic steatosis. Using the body mass index, 60% of the subjects were obese, but 90% of them had abdominal obesity (using abdominal circumference). Aspartate aminotransferase (AST) and alanine aminotransferase (ALT), serum triglycerides, insulin resistance (evaluated using the Homeostasis Model Assessment index - HOMA-IR), high sensitive C Reactive Protein, systolic blood pressure were correlated with fatty liver. A negative correlation was found between fatty liver, magnesemia and high density lipoprotein cholesterol (HDLc). The degree of liver fat accumulation increased significantly with the increasing number of the metabolic syndrome components. CIMT values were correlated with the degree of fatty liver. The frequency of cases with normal liver or mild steatosis was significantly higher in subjects with normal CIMT (54.29% versus 25% above normal values, p = 0.003), and the frequency of cases with moderate or severe steatosis was significantly higher in subjects with abnormal CIMT (75% versus 45.71% of normal values, p = 0.003). Genotyping PNPLA3 showed that the difference between subjects without steatosis and subjects with hepatic steatosis is given by the higher frequency of genotype GG. Triglycerides, cholesterol, HDLc, AST and ALT were similar among genotypes CC, CG, GG. PNPLA3 genotypes were not associated with the components of the metabolic syndrome, subclinical atherosclerosis or insulin resistance.
Conclusion: In our study, the GG genotype was associated with an increase regarding hepatic fat content. The results confirm that PNPLA3 polymorphism has a major role on the content of triglycerides in the liver. The lack of association with the components of metabolic syndrome (components) suggest that the presence of the G allele is not linked to metabolic disorders in subjects with type 2 diabetes. The data we have obtained confirm that the polymorphism PNPLA3 is closely associated with hepatic fat, but not with insulin resistance and metabolic syndrome. Cardiovascular risk in diabetic fatty liver is not shown to be directly dependent on the genotype.

Role of the gut in glucose-induced suppression of bone resorption in patients with non-alcoholic fatty liver disease and/or type 2 diabetes

H. Maagensen[1], A.E. Junker[1], N.R. Jørgensen[2,3], L.L. Gluud[4,5], F.K. Knop[1,5], T. Vilsbøll[1,6];
[1]Center for Diabetes Research, Gentofte Hospital, Hellerup, [2]Department of Clinical Biochemistry, Rigshospitalet, Glostrup, [3]OPEN, Odense Patient data Explorative Network, Odense University Hospital, Odense, [4]Gastrounit, Medical Division, Hvidovre Hospital, Hvidovre, [5]Department of Clinical Medicine, University of Copenhagen, Copenhagen, [6]Steno Diabetes Center Copenhagen, University of Copenhagen, Copenhagen, Denmark.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is associated with decreased bone mineral density (BMD), while type 2 diabetes (T2D) is associated with normal to high BMD. Both conditions are associated with increased fracture risk. The pathophysiology underlying bone abnormalities in NAFLD and T2D remains uncertain, but may involve the gut-bone axis. We investigated the influence of the gut on postprandial bone resorption in healthy individuals and patients with T2D and/or biopsy-verified NAFLD.
Materials and methods: NAFLD patients with normal glucose tolerance [n=8, HbA_{1c}: 33 (32, 37) mmol/mol (median with interquartile range in brackets); BMI: 30 (26, 35) kg/m^2], NAFLD patients with T2D [n=8, HbA_{1c}: 50 (41, 53) mmol/mol; BMI: 30 (28, 32) kg/m^2], T2D patients without liver disease [n=8, HbA_{1c}: 43 (39, 48) mmol/mol; BMI: 28 (26, 28) kg/m^2] and healthy controls [n=9, HbA_{1c}: 36 (34, 37) mmol/mol; BMI: 28 (28, 29) kg/m^2] underwent a 4-hour 50g oral glucose tolerance test (OGTT) and an isoglycaemic intravenous glucose infusion (IIGI) with repeated measurements of the bone resorption marker C-terminal type I collagen telopeptide (CTX).

Results: Plasma glucose levels achieved during OGTTs were successfully matched on corresponding IIGI days. Patients with NAFLD+T2D exhibited similar CTX suppression (as assessed by $AUC_{0\text{-}4h}$ for percent change from baseline) on OGTT vs. IIGI [-94 (-117, -70) vs. -114 (-129, -68) %×h, p=0.46], while remaining groups showed greater (p<0.05) CTX suppression during OGTT vs. IIGI (healthy subjects [-111 (-136, -93) vs. -66 (-102, -30) %×h], NAFLD [-145 (-162, -124) vs. -97 (-108, -44) %×h], and T2D [-79 (-96, -49) vs. -20 (-37, 32) %×h]).
Conclusion: OGTT-induced potentiation of CTX suppression seems to be abolished in patients with NAFLD+T2D, but preserved in patients with either NALFD *or* T2D. This suggests that coexistence of T2D *and* NAFLD may disturb the gut-bone axis.

Hypovitaminosis D is associated with insulin resistance in prediabetic individuals with nonalcoholic fatty liver disease

M.R. Shah[1], I.A. Hossain[2], L. Ali[2];
[1]Microbiology and Immunology, Bangabandhu Sheikh Mujib Medical University (BSMMU), [2]Biochemistry and Cell Biology, Bangladesh University of Health Sciences (BUHS), Dhaka, Bangladesh.

Background and aims: Vitamin D deficiency due to impaired insulin action enhances excessive accumulation of fat within the hepatocytes and is a leading cause of nonalcoholic fatty liver disease (NAFLD). A number of studies claim the association of hypovitaminosis D with features of insulin resistance such as obesity, type 2 diabetes, and other metabolic syndromes. However, data examining the association of vitamin D deficiency with insulin resistance among prediabetic subjects with NAFLD are limited. In this context, the present study was assessed to explore the association of vitamin D deficiency with insulin resistance in prediabetic individuals with NAFLD.
Materials and methods: We studied 151 prediabetic subjects (M/F, 85/66; age in years, 45±9; BMI in kg/m^2, 25.9±4.4; M±SD) after confirming their oral glucose tolerance test. NAFLD was confirmed by upper abdomen ultrasonography comprising into 84 non-NAFLD (47/37; 44±9; 25.3 ±4.6) and 67 NAFLD (38/29; 46±9; 26.6±4.0) groups. Serum glucose was measured by glucose-oxidase method. HbA_{1c} was measured by high performance liquid chromatography. Serum insulin and vitamin D levels reflecting 25-hydroxyvitamin D [25(OH)D] were measured by ELISA techniques. Insulin resistance (HOMA-IR) was calculated by homeostasis model assessment (HOMA). Data were analyzed by univariate, bivariate and multivariate as appropriate.
Results: Compared to the non-NAFLD counterparts, NAFLD subjects had significantly lower levels of [25(OH)D] (30.01±6.46 vs. 49.12±14.27 nmol/L, P<0.001) as well as significantly higher levels of HOMA-IR (3.72±1.12 vs. 1.69±0.39, P<0.001). Pearson's correlation analysis showed a significant negative correlation of [25(OH)D] with HOMA-IR (r=-0.275, P=0.024) in NAFLD subjects. Multiple linear regression analysis showed a significant negative association of HOMA-IR with [25(OH)D] (β=-0.309, P=0.025) in NAFLD subjects after adjusting the effects of potential cofounders of age, body mass index (BMI) and glycosylated hemoglobin (HbA_{1C}) respectively. In binary logistic regression analysis, HOMA-IR (odds ratio, OR = 1.393, 95% CI: 1.025-1.892, P=0.034) and [25(OH)D] (OR = 0.898, 95% CI: 0.858-0.940, P<0.001) were found to be significant determinants of NAFLD when adjusted the effects of major confounders of age, BMI, and HbA_{1c} respectively.
Conclusion: NAFLD subjects seem to have an association with low [25(OH)D] levels and this relationship is mediated by insulin resistance which also the pathophysiological determinant of prediabetes.

Non-alcoholic fatty liver disease and pancreatic beta cell function in non-diabetic patients

B. Pérez-Pevida[1], S. Romero[2], C. Silva[2], J. Salvador[2], G. Frühbeck[2], J. Escalada[2];
[1]Section of Investigative Medicine. Division of Diabetes, Endocrinology and Metabolism, Imperial College London, London, UK, [2]Department of Endocrinology and Nutrition/Metabolic Research Laboratory, Clínica Universidad de Navarra, Pamplona, Spain.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) represents a histological spectrum ranging from benign hepatic steatosis to non-alcoholic steatohepatitis. NAFLD is closely associated with metabolic syndrome and insulin resistance (IR), and although the role of IR in NAFLD has been previously investigated, there are limited data on pancreatic β-cell function (BCF) in non-diabetic subjects. We aim to evaluate the association between NAFLD and IR/BCF assessed by oral glucose tolerance test (OGTT) derived indexes and analyse the risk of NAFLD when IR or beta-cell dysfunction is present.
Materials and methods: We recruited 218 non-diabetic obese subjects, who carried out an OGTT and at least one hepatic imaging test (ultrasonography or computed tomography scanning). Subjects were divided in two groups according to the presence or not of NAFLD. Insulin resistance was assessed by homeostasis model assessment (HOMA-IR), Quantitative Insulin Sensitivity Check Index (QUICKI) and insulin sensitivity index (ISI). Pancreatic BCF was assessed by insulinogenic index (IGI) and disposition index (DI). Anthropometric measurements and body composition study were performed in all patients. Bioelectrical impedance analysis was used to determine visceral fat by the ViScan system (Tanita Corp).
Results: The mean age (SD) of participants was 39.5 (14.3) years and 36% of participants were men. The prevalence of NAFLD was 42.2% in our population. The subjects with NAFLD compared with control group had higher insulin resistance (HOMA-IR 3.25vs2.37; QUICKI 0.33vs0.36; ISI 3.37vs5.53 (p<0.001)) and strained pancreatic BCF (DI 4.28vs4.59 (p=0.008) despite no differences in visceral adipose tissue between groups. An association between ISI, IGI and DI and the presence of NAFLD was statistically significant, showing a 32%, 71% and 18% increase in the risk of NAFLD for a one unit increase in ISI, IGI and DI, respectively.
Conclusion: NAFLD is associated with insulin resistance and strained pancreatic β-cell function in non-diabetic subjects. Presenting impaired OGTT derived indexes was associated with an increased risk of NAFLD. Future studies are necessary to evaluate the temporal relationship between insulin resistance, β-cell dysfunction and NAFLD and the potential application of the OGTT in clinical practice as a risk predictive tool for this condition.
Disclosure: **B. Pérez-Pevida:** None.

PS 113 Non-alcoholic fatty liver disease: clinical studies

1242

Reduced plasma NT-proBNP levels are predictive of non-alcoholic fatty liver disease among patients with type 2 diabetes

M.L. Johansen[1], J. Rasmussen[1], M.R. Holm[1], J. Faber[1], E. Chabanova[2], M. Schou[3], P. Rossignol[4], C. Kistorp[1];
[1]Department of internal medicine, Herlev University Hospital, [2]Department of Radiology, Herlev University Hospital, [3]Department of Cardiology, Herlev University Hospital, Herlev, Denmark, [4]Inserm CIC Plurithémathique 1433, FCRIN INI-CRCT, CHRU Nancy, France.

Background and aims: Plasma NT-proBNP is a well-established biomarker in heart failure. Increased plasma levels are associated with an increased cardiovascular mortality in the general population and in patients with heart disease. Notably, reduced concentrations of natriuretic peptides (NPs) are often reported in patients with type 2 diabetes (T2D), which in experimental settings, has been demonstrated to exaggerate insulin resistance and adipocyte dysfunction. Thus, decreased plasma levels of NPs could play a role in the accumulation of ectopic fat and development of non-alcoholic fatty liver disease (NAFLD) in T2D. We hypothesized that reduced plasma NT-proBNP level is associated with NAFLD among patients with T2D.
Materials and methods: We included 110 T2D patients from a randomized double-blind, placebo-controlled trial (The MIRAD study), investigating the effect of the mineralocorticoid receptor antagonist eplerenone on biomarkers related to adipocyte function. The patients had T2D and high cardiovascular (CV) risk defined as ischemic heart disease, history of myocardial infarction, stroke, peripheral artery disease or albuminuria. At baseline the patients underwent MR spectroscopy measuring liver fat content quantitatively with high precision by determining the fat peak content relative to the water content and abdominal fat in 1cm slice in the middle of L3 using 3.0T MR imaging (Philips Medical Systems, Best, the Netherlands).
Results: The participants were predominantly male n=76 (69%), with a mean (±SD) age of 64 (±9) years. Mean duration of T2D was 12 (±7) years and mean HbA1c was 59 (±14) mmol/mol; BMI was 30.8 (±4.2) kg/m^2 with visceral fat volume of 269 (±98) cm^3. The median (IQR) level of NT-proBNP was 67 (37-128) ng/L. A total of n=52 (47%) had liver fat content ≥5.6 % which is the cut off value for (NAFLD). There was a clear association between low NT-proBNP level and increased risk of NAFLD OR 0.51 (95% CI 0.35; 0.76, p<0.001), in univariate logistics regression analysis. As expected high triglycerides and visceral fat volume increased the risk for NAFLD (p<0.0001, p=0.003 respectively). The predictive ability of NT-proBNP was assessed in a multivariate logistic regression analysis demonstrating that reduced concentrations were independently associated higher risk of NAFLD OR 0.48 (95 % CI 0.31; 0.76 p=0.001), adjusting for sex, HbA1c, BMI and visceral fat.
Conclusion: Decreased plasma NT-ProBNP concentration is independently associated with a high risk of NAFLD among T2D patients. Therefore, reduced levels of plasma NT-ProBNP, could be a marker of accumulation of ectopic fat in the liver and bear novel clinical implications regarding screening for NAFLD in T2D patients with high CV risk.

Increased liver fat content in totally pancreatectomised patients

J.I. Bagger[1], A.B. Lund[2,3], N.J. Wewer Albrechtsen[4], M. Christensen[1,3], M.F. Grøndahl[1], C.P. Hansen[5], J. Storkholm[6], J.J. Holst[4], T. Vilsbøll[1,7], F.K. Knop[1,3];
[1]Center for Diabetes Research, Copenhagen, [2]Center for Diabetes Research, Hellerup, [3]Department of Clinical Medicine, Copenhagen, [4]Novo Nordisk Foundation Center for Metabolic Research, Copenhagen, [5]Rigshospitalet, Department of Gastrointestinal Surgery, Copenhagen, Denmark, [6]Righshospitalet, Department of Gastrointestinal Surgery, Copenhagen, [7]Steno Diabetes Center Copenhagen, Copenhagen, Denmark.

Background and aims: Lack of glucagon signaling has been shown to increase hepatic fat content in animal studies. Furthermore, administration of glucagon receptor antagonists are associated with increases in hepatic transaminases and fat content in type 2 diabetes patients. Here we evaluated hepatic fat content and aspartate transaminase (AST) and alanine transaminase (ALT) in totally pancreatectomised patients without glucagon-secreting pancreatic alpha cells.
Materials and methods: Fasting blood samples and transient liver elastography (Fibroscan 501®, EchoSensTM, Paris, France), as a measure for hepatic fibrosis and steatosis, were performed in 10 totally pancreatectomised patients (age [mean ± SD]: 59.8±9.9 years; BMI: 21.5±4.3 kg/m2; HbA_{1c}: 67.3±11.0 mmol/mol; time since operation: 4.6±4.5 years), and 10 age, sex and BMI-matched healthy control subjects (age: 58.4±5.0 years; BMI: 22.9±2.4 kg/m2; HbA_{1c}: 34.6±6.2 mmol/mol).
Results: In both groups hepatic elasticity were within normal range (Fibrosis stage 0) with no difference in transmission speed of the ultrasonic waves between the pancreatectomised group and the control group (5.1±0.34 vs. 4.8±0.52 kPa, p=0.52). In the pancreatectomised group, two patients had steatosis grade 3 (67-100% of hepatocytes with fat accumulation), two patients had steatosis grade 2 (33-66% of hepatocytes with fat accumulation), one patient had steatosis grade 1 (11-33% of hepatocytes with fat accumulation) and five patients had steatosis grade 0 (<11% of hepatocytes with fat accumulation). In the control group, two subjects had steatosis grade 2, and eight subjects had steatosis grade 0. Fasting concentrations of AST were higher in the pancreatectomy group compared to the control group (54.2±4.5 vs 35.0±3.0 U/L, p=0.003) while no difference was observed for ALT (33.6±4.5 vs 25.6±2.2 U/L, p=0.13).
Conclusion: Totally pancreatectomised patients are characterised by increased hepatic fat content and higher fasting plasma concentrations of AST, which may relate to surgical removal of glucagon-secreting alpha cells.

Validity of hepatic steatosis indices for prediction of non-alcoholic hepatic steatosis in type 1 diabetic patients

J. Sokolovska[1], L. Sviklane[1], E. Olmane[2], Z. Dzerve[1], K. Kupcs[3]; [1]Laboratory for Personalized Medicine, University of Latvia, [2]Pauls Stradins University hospital, Magnetic resonance center DiaMed, [3], Pauls Stradins University hospital, Magnetic Resonance Center DiaMed, Riga, Latvia.

Background and aims: Non-alcoholic fatty liver disease in type 1 diabetes mellitus patients is associated with an increased risk of cardiovascular events and diabetic complications. Markers of hepatic steatosis, hepatic steatosis index (HSI) and fatty liver index (FLI) have demonstrated reasonable efficacy in several patient groups. The purpose of our work was screen the effectiveness of FLI and HSI in a observational pilot study of 40 type 1 diabetic patients.
Materials and methods: Data of 252 LatDiane study patients were analyzed. Patients with diabetes duration less than 5 years and with high-risk alcohol consumption were excluded. For remaining 201 patients, FLI and HSI indices were calculated. 40 patients with marginal FLI/HSI values were invited to take part in the liver magnetic resonance study. In-phase/opposed-phase technique of magnetic resonance imaging was used. Accuracy of FLI/HSI was assessed from the area under the receiver operating characteristic curve (AUROC).
Results: 12 (30.0%) patients had liver steatosis. These patients had higher body mass index, waist circumference, FLI, HSI, aspartate transaminase, gamma-glutamyl-transpeptidase, C-reactive protein, diastolic blood pressure, and metabolic syndrome was diagnosed more often in this group. For FLI, sensitivity was 90%, specificity was 74%, positive likelihood ratio was 3.46, negative likelihood ratio - 0.14, positive predictive value - 0.64; negative predictive value - 0.93. For HSI, sensitivity was 86%, specificity was 66%, positive likelihood ratio was 1.95, negative likelihood ratio - 0.21, positive predictive value - 0.50; negative predictive value - 0.92. AUROC for FLI was 0.86 (95% confidence interval [0.72; 0.99]); for HSI - 0.75 [0.58; 0.91]. Liver fat correlated with liver enzymes, waist circumference, triglycerides, C-reactive protein, but not with estimated glucose disposal rate or insulin dose/kg/24 h. In multiple regression model, only C-reactive protein (p=0.038), gamma-glutamyl-transpeptidase (p=0.047) and waist circumference (p=0.001) were independent determinants of microscopic fat content and taken together explained 45% of its variation (p=0.001). FLI correlated with C-reactive protein, alanine transaminase, aspartate transaminase, systolic and diastolic blood pressure. HSI correlated with waist circumference and C-reactive protein. Neither FLI, nor HSI correlated with estimated glucose disposal rate or total daily insulin dose. FLI exceeding 60 and HSI exceeding 36 were significantly associated with metabolic syndrome and nephropathy.
Conclusion: The tested indices can serve as surrogate markers for liver fat content and metabolic syndrome in type 1 diabetic patients. Parameters of insulin sensitivity were associated neither with indices, nor liver fat. C-reactive protein might be considered for development of novel biomarkers for liver steatosis assessment in type 1 diabetes.

Association and predictability of different non-invasive scores with nonalcoholic fatty liver disease diagnosis in patients with type 2 diabetes

A. Papazafiropoulou, A. Angelidi, K. Anagnostopoulou, E. Vagena, V. Velissaris, E. Markakis, K. Petropoulou, A. Kokolaki, V. Bampali, A. Melidonis; Diabetes Center, General Hospital of Piraeus "Tzaneio", Piraeus, Greece.

Background and aims: Non - alcoholic fatty liver disease (NAFLD) is the commonest cause of abnormal liver function tests and liver disease in the western countries. NAFLD is usually asymptomatic. As a result some non - invasive diagnostic models have been proposed for the diagnosis and staging of NAFLD. The objective of this study was to evaluate whether some of the most common and easily assessed models can also be used to screen for the presence of nonalcoholic fatty liver disease (NAFLD) in patients with type 2 diabetes (T2D) in clinical practice.
Materials and methods: The study population included 110 patients with T2D (58 men) [mean age (±SD) 60.1±9.5 years, HbA1c 6.4 ±1.0%, body - mass index 28.6±4.8 Kg/m2, duration of diabetes 8.5 ±4.0 years] attending the outpatient diabetic clinic of our hospital. Anthropometric, clinical, and laboratory data were analyzed during regular health checkups. NAFLD was diagnosed using ultrasound. NAFLD liver fat score, HAIR (Hypertension, ALT, Insulin Resistance), BARD, APRI (AST to Platelet Ratio Index), FIB - 4 and LAP (Lipid Accumulation Product) scores are were estimated. Discrimination capability was assessed based on the area under the receiver operating characteristic curve (AUC), sensitivity and specificity, positive (PPV) and negative (NPV) predictive values were calculated.
Results: NAFLD, using ultrasound, was diagnosed in 77 patients (70%). Receiver operating characteristic analysis showed that for the NAFLD liver fat score a cutoff of ≥ - 1.44 had a sensitivity of 93%, a specificity of 72%, with an AUC of 0.95 and a PPV of 89% and a NPV of 82%. For the HAIR score a cutoff of ≥0.50 had a sensitivity of 62%, a specificity of 44%, with an AUC of 0.58 and a PPV of 72% and a NPV of 33%. For the BARD score a cutoff of ≥2.50 had a sensitivity of 51%, a specificity of 64%, with an AUC of 0.59 and a PPV of 77% and a NPV of 36%. For the APRI a cutoff of ≥0.23 had a sensitivity of 49%, a specificity of 64%, with an AUC of 0.55 and a PPV of 76% and a NPV of 35%. For the FIB - 4 score a cutoff of ≥1.00 had a sensitivity of 53%, a specificity of 54%, with an AUC of 0.52 and a PPV of 73% and a NPV of 33%. For the LAP score a cutoff of ≥30.93 had a sensitivity of 94%, a specificity of 82%, with an AUC of 0.89 and a PPV of 92% and a NPV of 85%.
Conclusion: The results of the present study showed that NAFLD liver fat and LAP scores showed good sensitivity and specificity for the presence of NAFLD in patients with T2D. Both scores are two simple, accurate and non - invasive tools to predict NAFLD in patients with type 2 diabetes. On the contrary, HAIR, BARD, APRI and FIB - 4 scores showed poor sensitivity and specificity.

Application of the new EASL-EASD-EASO clinical practice guidelines for the management of non-alcoholic fatty liver disease (NAFLD) in people with type 2 diabetes

B. Bouillet[1], J. Petit[2], A. Sberna[2], R. Loffroy[2], A. Nguyen[2], L. Duvillard[2], D. Denimal[2], P. Hillon[2], B. Verges[2]; [1]Diabetology, CHU François Mitterand Dijon, [2]Diabetologie, CHU du Bocage, Dijon, France.

Background and aims: Recently, the European Association for the Study of the Liver (EASL)-European Association for the Study of Diabetes (EASD)-European Association for the Study of Obesity (EASO) propose recommendations for the diagnosis, treatment and follow-up of non-alcoholic fatty liver disease (NAFLD) patients. In this study we evaluate the application of these clinical practice guidelines for the management of NAFLD in people with type 2 diabetes. We also compare the performance of steatosis biomarkers (fatty liver index and steatotest) to 1H-magnetic resonance spectroscopy.
Materials and methods: A total of 179 type 2 diabetic patients were included in this study. Liver fat (1H-magnetic resonance spectroscopy),

Fatty liver index (FLI), NAFLD fibrosis score (NFS), Steatotest and fibrotest were measured.
Results: One hundred and twenty three (68.7%) patients had steatosis (hepatic triglyceride content greater than 5.6%) with 1H-magnetic resonance spectroscopy evaluation. With FLI biomarkers, 162 (90.5 %) patients had a diagnosis of steatosis (FLI>60). In comparison with 1H-magnetic resonance spectroscopy, FLI diagnosed 43 patients in excess, and did not diagnose correctly 5 patients (sensibility 73.4%, specificity 73.6%). With steatotest biomarkers, 141 (78.7%) patients had a diagnosis of steatosis (steatotest >0.57). In comparison with 1H-magnetic resonance spectroscopy, steatotest diagnosed 36 patients in excess, and did not diagnose correctly 16 patients (sensibility 74.8%, specificity 55.5%). Fifty-six patients were found to have abnormal liver transaminases or elevated serum gamma-glutamyltransferase. The application of the EASL-EASD-EASO guidelines using NFS in combination with FLI results to a referral to a liver clinic for 152 (84.9%) people with type 2 diabetes (NFS >-1.455). The application of the guidelines using Steatotest in combination with Fibrotest results to a referral for 62 (34.6%) people with type 2 diabetes to a liver clinic.
Conclusion: The SteatoTest and FLI biomarkers are not valid predictors of steatosis in type 2 diabetic patients. The application of these new recommendations for the diagnosis, treatment and follow-up of NAFLD would lead to an excessive number of people with type 2 patients that should be referred to a liver clinic. It seems very difficult to apply these new guidelines in clinical routine practice. We suggest that future clinical and/or biological biomarkers of steatosis and fibrosis be specifically validated in type-2 diabetic patients.

Improvement in liver histology with obeticholic acid in patients with nonalcoholic steatohepatitis and type 2 diabetes

A. Liberman[1], A. McCullough[2], B. Neuschwander-Tetri[3], A. Sanyal[4], M. Abdelmalek[5], R. Gogineni[1], B. Ferguson[1], R. Shringarpure[1], D. Shapiro[1];
[1]Intercept Pharmaceuticals, Inc., San Diego, [2]Cleveland Clinic, Cleveland, [3]Saint Louis University Health Sciences Center, St. Louis, [4]Virginia Commonwealth University, Richmond, [5]Duke University School of Medicine, Durham, USA.

Background and aims: Nonalcoholic steatohepatitis (NASH) is commonly associated with type 2 diabetes mellitus (T2DM) and the presence of both is associated with higher risk of poor clinical outcomes. Obeticholic acid is a potent farnesoid X receptor agonist that has been shown to improve liver histology in patients with NASH in the FLINT trial (N=283). 149 patients (61%) enrolled in FLINT had T2DM and within this population, 45% (67/149) were found to have the presence of advanced fibrosis (≥F3) which is further indicative of higher risk of poor outcomes. The purpose of this post-hoc analysis was to assess the efficacy of OCA in patients in the FLINT trial who had both NASH and T2DM.
Materials and methods: FLINT was a randomized, double-blind, placebo-controlled, 72-week study. This analysis included all patients who had a diagnosis of NASH and T2DM at Baseline, and were treated with OCA 25 mg (n=75) or PBO (n=74). The primary endpoint was ≥2-point improvement in NAFLD activity score (NAS) without worsening of fibrosis. Fibrosis improvement was defined as ≥1 stage improvement. Histologic changes were only evaluated in patients who had both Baseline and Week 72 liver biopsy (OCA 25 mg, n=54; PBO, n=53).
Results: A greater percentage of OCA-treated patients achieved the primary endpoint [OCA 25 mg: 31/54 (57%); PBO: 11/53 (21%); p<0.01] at Week 72. A larger percentage of OCA-treated patients achieved fibrosis improvement compared to PBO at Week 72 [OCA 25 mg: 22/54 (41%); PBO: 10/53 (19%); p<0.05]. OCA treatment also resulted in reduction in body weight from Baseline compared to PBO at Week 72 [LS Mean (95% CI); OCA 25 mg: -3.3 (-4.8, -1.8) kg; PBO: 0.3 (-1.1, 1.7) kg; p<0.01]. There were no statistical differences between OCA and PBO in glycemic parameters examined at Week 72.
Conclusion: In the FLINT trial, within the subgroup of patients with both NASH and T2DM, OCA treatment resulted in improvement in liver histology and reductions in body weight. Further prospective evaluation with OCA is necessary to confirm these findings.

1248

Dulaglutide decreases liver enzymes in people with type 2 diabetes: a post-hoc analysis of the AWARD programme

A. Haupt[1], K. Cusi[2], N. Sattar[3], L.-E. García-Pérez[1], I. Pavo[4], M. Yu[5], K.E. Robertson[1];
[1]Eli Lilly and Company, Indianapolis, [2]Division of Endocrinology, Diabetes, and Metabolism, Department of Medicine, University of Florida, Gainesville, USA, [3]Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, UK, [4]Eli Lilly and Company, Vienna, Austria, [5]Eli Lilly and Company, Toronto, Canada.

Background and aims: GLP-1 receptor agonists may reduce hepatic steatosis and steatohepatitic liver histology in people with NAFLD/NASH. Higher plasma alanine transaminase (ALT) levels correlate with hepatic steatosis and regress in response to treatment. This post-hoc analysis evaluated the effects of once weekly dulaglutide 1.5 mg (DU) on plasma ALT, aspartate transaminase (AST) and gamma-glutamyl transpeptidase (GGT) in patients with type 2 diabetes (T2D) and compared the effect of DU vs placebo (PL) on several metabolic measures in all patients, as well as in a subset predicted to have higher prevalence of non-alcoholic fatty liver disease and non-alcoholic steatohepatitis (enriched by baseline ALT thresholds: male, ≥30 IU/L; female, ≥19 IU/L) from 4 PL-controlled studies in the AWARD program (AWARD-1, AWARD-5, AWARD-8 and AWARD-9).
Materials and methods: Patients receiving DU or PL were included in this post-hoc analysis. The objectives were to assess: 1) changes from baseline in ALT, AST and GGT between patients treated with DU vs PL at 6 months and, 2) changes from baseline in ALT, AST, GGT, HbA_{1c}, fasting serum glucose (FSG), lipid profile and weight between DU vs PL after 6 months of treatment in a NAFLD/NASH enriched population.
Results: At baseline, the clinical characteristics of DU and PL groups were similar. At 6 months, changes from baseline in ALT, AST and GGT were: (LSM [SE]) -4.7 (0.6), -1.9 (0.5), -5.0 (2.8) on DU vs -3.0 (0.6), -0.8 (0.6), 1.6 (3.3) on PL, respectively. Treatment differences were significant for ALT, AST and GGT (-1.7 [0.6] p=0.003, -1.1 [0.5] p=0.037 and -6.6 [3.0] p=0.025, respectively). The NAFLD/NASH enriched population had more males, shorter duration of diabetes, higher AST and triglycerides at baseline. At 6 months, a more pronounced change in ALT was observed in patients with baseline ALT ≥ULN treated with DU vs PL (p=0.022) (table). Overall, DU-treated patients with baseline ALT ≥ULN demonstrated significantly greater change from baseline in HbA_{1c}, FSG, weight, and triglycerides vs PL (p≤0.014 all parameters; table). Similar differences between DU vs PL were observed in patients with ALT <ULN.
Conclusion: Results from this post-hoc analysis suggest that once weekly DU 1.5 mg improves hepatic enzymes compared to placebo, with greater reduction seen in ALT and GGT than AST, consistent with reduced liver fat in both the overall and NAFLD/NASH enriched population. The glycaemic and metabolic response of DU in the enriched population was consistent with the results observed in the overall population.

Table. Change from baseline in efficacy and safety parameters and select hepatic enzymes by ALT ≥ULN in AWARD-1, AWARD-5, AWARD-8 and AWARD-9

Parameter	Dulaglutide 1.5 mg N=939	Placebo N=488	Treatment Difference[a]
ALT (IU/L)	-8.8 (0.7)*	-6.7 (0.9)*	-2.1 (0.9)#
AST (IU/L)	-4.3 (0.6)*	-3.8 (0.8)*	-0.5 (0.8)
GGT (IU/L)	-7.4 (3.3)*	-3.6 (4.1)	-3.8 (4.1)
HbA_{1c}, mmol/mol	-16.1 (0.7)*	-3.6 (0.9)*	-12.4 (0.9)#

Body weight lowering agents and their comparative metabolic and hepatic effects in obese mouse models of nonalcoholic fatty liver disease

J. Jelsing, M. Feigh, K.S. Tølbøl, S.S. Veidal, N. Vrang;
Gubra, Hørsholm, Denmark.

Background and aims: The GLP-1 analogue liraglutide is an established treatment for obesity and type 2 diabetes. Here we aimed to compare the body weight lowering effects of liraglutide and the peroxisome proliferator activated receptor (PPAR) α/δ agonist, elafibranor, in diet-induced obese (DIO) and genetically obese mouse models of nonalcoholic fatty liver disease (NAFLD) and steatohepatitis (NASH).
Materials and methods: Male wildtype C57BL/6J and leptin-deficient $Lep^{ob/ob}$ mice (5 weeks of age) were fed a diet high in trans-fat, fructose and cholesterol for a total of 26 weeks and 12 weeks, respectively, for induction of NASH. Only biopsy-confirmed steatotic and fibrotic animals were included and stratified into DIO-NASH and ob/ob-NASH treatment groups and treated for 8 weeks with vehicle (PO, QD), liraglutide (0.2 mg/kg, SC, BID) or elafibranor (30 mg/kg, PO, QD). At termination, blood samples were collected for plasma liver enzymes (alanine/aspartate aminotransferases; ALT/AST) and lipids (total cholesterol; TC, triglycerides; TG). Furthermore, liver post-biopsies and tissue samples were obtained for histological and biochemical analysis. Finally, a blinded histological evaluation of NAFLD Activity Score (NAS) (steatosis, inflammation, ballooning degeneration) including Fibrosis Stage was performed.
Results: Liraglutide and elafibranor treatment induced a weight loss of approximately 10% in both DIO-NASH and ob/ob-NASH mice, albeit with differential effect on hepatomegaly, plasma ALT/AST/TG/TC and liver lipids. Based on histopathological analysis, liraglutide reduced composite NAS in DIO-NASH (7/10 animals), but not in ob/ob-NASH (2/10 animals), mainly by reducing steatosis component. In contrast, Elafibranor induced resolution of NAS in both DIO-NASH and ob/ob-NASH (10/10 animals) by improving all three dimensions (steatosis, inflammation and hepatocyte ballooning). Furthermore, only elafibranor reduced liver fibrosis stage in DIO-NASH (6/10 animals) and ob/ob-NASH (10/10).
Conclusion: Pharmacological intervention with liraglutide and elafibranor induced a diverse metabolic and hepatic profile, irrespectively of similar weight-loss inducing effect in wildtype diet-induced and genetically obese mouse models of NASH. Notably, both treatments exerted an anti-steatotic action and improved liver histopathology by reducing NAFLD Activity Score in DIO-NASH mice. In addition, elafibranor improved steatohepatitis in ob/ob-NASH mice and exerted anti-fibrotic effects in DIO-NASH and ob/ob-NASH mice.These finding suggest that weight-loss inducing agents with a direct liver target effect exerts superiority in alleviating NASH.

Pirfenidone prevents and reverses hepatic insulin resistance and steatohepatitis by polarising M2 macrophages in mice

T. Ota, G. Chen, Y. Ni, N. Nagata, M. Nagashimada;
Brain/Liver Interface Medicine Research Center, Kanazawa University, Kanazawa, Japan.

Background and aims: Excessive hepatic lipid accumulation promotes the activation of macrophage/Kupffer cells, resulting in exacerbation of insulin resistance and nonalcoholic steatohepatitis (NASH). In our previous study, we developed a cholesterol- and saturated fatty acid-induced model of lipotoxic NASH and revealed that hepatic oxidative stress and

insulin resistance promotes hepatic inflammation and fibrosis. Pirfenidone is an antifibrotic agent used in the treatment of pulmonary fibrosis. In addition, pirfenidone suppresses bleomycin-induced increases in the pulmonary influx of T cells and macrophages. However, less attention has been focused on its anti-inflammatory effects. In the present study, we investigated the effect of pirfenidone in a lipotoxicity-induced NASH model.

Materials and methods: Eight-week-old C57BL/6 mice were fed a high-cholesterol, high-fat (CL) diet or CL diet with 0.2% pirfenidone (CL + PFD), for a total of 12 weeks. The liver histology, insulin sensitivity, and inflammatory/stress signal were examined. Next, we quantified intrahepatic immune cells by flow cytometry.

Results: After 12 weeks of feeding, histological examination revealed hepatic steatosis, inflammation and fibrosis in mice fed CL diet. They showed hyperinsulinemia even though weight and adiposity were similar. Pirfenidone administration reduced hepatic TG, TC, and NEFA levels by 24%, 23%, and 50%, respectively (all $p < 0.05$), as well as lipid peroxidation, which was assessed by TBARS. Pirfenidone improved glucose intolerance and hyperinsulinemia in the CL group and enhanced the insulin signal, assessed by IRβ and Akt phosphorylation, in the liver, which is associated with the attenuation of MAPK (ERK/p38MAPK) and NF-kB activation. To assess the effect of pirfenidone on hepatic inflammation further, intrahepatic leukocytes were quantified using flow cytometry. Hepatic macrophages identified as $CD45^+CD11b^+F4/80^+$ cells were markedly decreased in the CL + PFD group by 67% compared with mice fed the CL diet. In addition to a reduction of the total macrophage content in the liver, mice fed CL + PFD had 81% fewer $CD11c^+CD206^-$ (M1)-type macrophages, but 33% more $CD11c^-CD206^+$ (M2)-type macrophages than mice fed the CL diet, resulting in a predominance of M2 over the M1 macrophage population. Pirfenidone also reduced $CD4^+$ and $CD8^+$ T-cell contents by 55% and 41% respectively, which contributed to the improvement of insulin resistance and steatohepatitis. Moreover, pirfenidone downregulated LPS-induced M1 marker (*Tnfa, Il1b* and *Mcp-1*) mRNA expression in RAW264.7 macrophages but augmented IL-4-induced M2 marker (*Mrc2, Cd206* and *Mgl1*) mRNA expression in a dose-dependent manner. Additionally, pirfenidone reduced the activation of hepatic stellate cells and inhibited fibrosis, lowering hydroxyproline content by 40% ($p < 0.05$). Importantly, pirfenidone reversed insulin resistance, as well as hepatic inflammation and fibrosis, in pre-existing advanced NASH.

Conclusion: Pirfenidone prevents and reverses hepatic insulin resistance and steatohepatitis by polarizing M2 macrophages in mice. Pirfenidone might be a novel and promising treatment for NASH.

Allopurinol reduces hepatic fat accumulation through regulating lipid oxidation and ER stress signalling in high fructose-fed OLETF rats

I.-J. Cho, K. Choi, D.-H. Oh, J. Yoo, Y.-C. Hwang, K. Ahn, H.-Y. Chung, I.-K. Jeong;
Department of Endocrinology and Metabolism, Kyung Hee University Hospital at Gangdong, Seoul, Republic of Korea.

Background and aims: Excess fructose consumption is associated with development of metabolic syndrome, type 2 diabetes, and nonalcoholic fatty liver disease (NAFLD). Uric acid generation is a unique feature of fructose metabolism and may have a direct role in the development of NAFLD. However, its mechanism is unclear. Therefore, we examined the effects of uric acid lowering treatment on fatty liver using a high fructose-fed OLETF rats for evaluating the contributions of fructose and uric acid on NAFLD development.

Materials and methods: 30-week-old OLETF rats were randomly divided into three groups as follows: (1) normal chow-diet OLETF rats (NC group); (2) high fructose-diet OLETF rats (HFrD group); and (3) high fructose-diet OLETF rats with allopurinol treatment (HFrDAL group). After 16 weeks of treatment, body weight was measured and intraperitoneal glucose tolerance test was conducted. Liver tissue was collected at sacrifice and processed to assess histological characteristics. Real-time polymerase chain reaction (PCR) was performed to evaluate hepatic expression of genes involved in lipid metabolism and inflammation. Hepatic endoplasmic reticulum (ER) stress pathway was evaluated by Western blot. All animal experiments were conducted according to the institutional animal research regulations of our center.

Results: The HFrD group had significantly elevated body weight, as well as higher serum uric acid and triglyceride concentrations compared to the NC group ($P<0.05$). Blood glucose concentrations at 2 hours after glucose load were significantly increased in the HFrD and HFrDAL groups compared with the NC group ($P<0.05$). Hepatic lipid accumulation was significantly increased in the HFrD group versus the NC group. Allopurinol treatment significantly reduced body weight, decreased serum uric acid concentrations, and ameliorated hepatic steatosis in the HFrDAL group compared with the HFrD group ($P<0.05$). High fructose diet significantly suppressed hepatic expression of fat oxidation genes and elevated hepatic expression of proinflammatory cytokine genes, whereas allopurinol treatment restored it ($P<0.05$). Furthermore, high fructose diet significantly increased protein expression of immunoglobulin heavy chain-binding protein and phosphorylated inositol-requiring enzyme 1. And x-box binding protein 1, which is the downstream effector, was spliced by high fructose diet in PCR. However, allopurinol treatment attenuated these changes induced by high fructose diet.

Conclusion: Allopurinol ameliorates high fructose diet-induced hepatic steatosis via modulating not only hepatic lipid metabolism and proinflammatory cytokines expression but also ER stress signaling.

Disclosure: **I. Cho:** None.

Protective effects of the TAZ modulator TM-25659 against palmitate-induced lipogenesis in HepG2 cells and fatty livers from DIO and MCD-diet fed mice

T. Kim[1], J. Jung[2], S.-E. Choi[3], J. Jeon[3], Y. Kang[3], M. Bae[4], J. Ahn[5], H. Jeong[6], E. Hwang[7], S. Han[2], H. Kim[2], D. Kim[2], K.-W. Lee[2];
[1]Endocrinology and Metabolism, Seoul Medical Center, Seoul, [2]Endocrinology and metabolism, Ajou University Hospital, Suwon, [3]Physiology, Ajou University Hospital, Suwon, [4]Korea Research Institute of Chemical Technology, University of Science & Technology, Daejeon, [5]Chemistry, Gwangju Institute of Science and Technology (GIST), Gwangju, [6]College of Pharmacy, Ewha Womans University, Seoul, [7]6College of Pharmacy, Ewha Womans University, Seoul, Republic of Korea.

Background and aims: The transcriptional co-activator with PDZ-binding motif (TAZ) binds various transcription factors to control many physiological processes including cell differentiation, organ development, and inflammation. The TAZ modulator 2-butyl-5-methyl-6-(pyridine-3-yl)-3-[2'-(1H-tetrazole-5-yl)-biphenyl-4-ylmethyl]-3H-imidazo[4,5-b]pyridine] (TM-25659) inhibits adipocyte differentiation by interacting with peroxisome proliferator-activated receptor gamma (PPARgamma). TM-25659 has anti-obesity and anti-diabetic effects in high fat (HF) diet-induced obese (DIO) mice. However, the effects of TM-25659 in non-alcoholic fatty liver disease (NAFLD) have not been well studied. In this study, we investigated the beneficial effects of TM-25659 and the molecular mechanism of palmitate-induced lipogenesis in HepG2 cells and in the fatty liver of DIO and mice fed a HF completely devoid of methionine and choline diet (MCD).

Materials and methods: To clarify the molecular mechanism of TM-25659 in palmitate-induced HepG2 cells and in the fatty liver of mice, we treated the cells and mice with TM-25659 and used mRNA sequencing to evaluate the expression of transcription factor,s such as PPARgamma, retinoid X receptor, and nuclear receptor corepressor 1 (NCOR1), as well

as gene expression-related lipogenesis and inflammation. To investigate the protective effects of TM-25659 on fatty liver, C57BL/6J mice were randomly divided into five groups: low-fat diet control group (LFD), 60% HF group, HF plus TM-25659 diet group, MCD diet group, and MCD plus TM-25659 group. Glucose homeostasis and insulin sensitivity were evaluated after 16 weeks of treatment in the HF diet mice and after 4 weeks in the MCD mice. Fasting insulin and serum lipid levels were measured at the end of the study. Genes involved in inflammation and lipid metabolism were analyzed by real-time polymerase chain reaction and immunoblotting. Body weight, fasting insulin, and plasma glucose were maintained in the TM-25659-treated animal group.
Results: We demonstrated that TM-25659 was significantly effective for ameliorating HF diet-induced glucose intolerance, insulin resistance, and fatty liver. In addition, TM-25659 significantly reduced hepatic steatosis and immune cell infiltration. TM-25659 also reduced fatty liver in MCD mice as well as the expression of several inflammation-related genes. TM-25659 led to TAZ nuclear localization and binding with transcription factors, such as PPARgamma and NCOR1, in HepG2 cells. Finally, TM-25659 inhibited palmitate-induced inflammatory cytokine and lipogenic gene expression in HepG2 cells.
Conclusion: This is the first report demonstrating that TM-25659 has protective effects on NAFLD through the enhanced interaction between TAZ and PPARgamma. Therefore, TM-25659 may be useful for preventing NAFLD.

Curcumin8, a novel curcumin analog, prevent liver steatosis in high fat diet-induced obese mice

C.H. Chung[1], M.H. Kwon[1], H.M. Kim[1], E.S. Lee[1], W. Sangartit[1], E.Y. Lee[2];
[1]Department of Internal Medicine, Wonju College of Medicine, Yonsei University, Wonju, [2]Department of Internal Medicine, College of Medicine, SoonCheonHyang University, Cheonan, Republic of Korea.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) occurs when excess fat is stored in the liver. NAFLD is highly prevalent in type 2 diabetes mellitus (T2DM), likely reflecting the frequent occurrence of obesity and insulin resistance in T2DM. Curcumin8 (CUR8) is a synthetic derivative of natural active curcumin (CUR), which has antioxidant and anti-inflammatory properties. Here, we investigated the effects of CUR8, a novel CUR analog, on liver steatosis in high fat diet (HFD)-induced obese mice.
Materials and methods: We categorized six groups such as regular diet mice (RD, n=10), RD fed with curcumin (RD+CUR, 100mg/kg/day, n=10), RD fed with curcumin8 (RD+CUR8, 100mg/kg/day, n=10), high fat diet-induced obese mice (HFD, n=10) and HFD fed with curcumin (HFD+CUR, 100mg/kg/day, n=10), HFD fed with curcumin8 (HFD+CUR8, 100mg/kg/day, n=10) for 12 weeks. Liver steatosis was detected in hematoxylin and eosin (H&E) stained sections.
Results: CUR8 prevented the increase of body and liver weights in HFD-induced obese mice. In addition, insulin resistance was significantly improved in HFD+CUR8 group than HFD group. Serum ALT level, an indicator of liver damage, also reduced after CUR8 treatment. Moreover, H&E stain revealed that CUR8 decreased liver steatosis in HFD-induced obese mice. Interestingly, the increase of liver TG resulting from HFD also decreased after the administration of CUR8 but not CUR.
Conclusion: Our data demonstrates that CUR8 ameliorated insulin resistance and reduced liver steatosis in HFD-induced obese mice

1254

E2F1 participates in liver cholesterol metabolism and protects against liver fibrosis development

P.-D. Denechaud[1], L. Qiuwen[2], A. Giralt[1], C. Le MAy[3], Z. Lianjun[2], B. Cariou[4], L. Fajas[1];
[1]Center for Integrative Genomics, University of Lausanne, [2]University of Lausanne, Lausanne, Switzerland, [3]L'institut du Thorax, INSERM UMR 1087/CNRS UMR 6291, Nantes, [4]L'institut du Thorax, INSERM, UMR 1087, CNRS UMR 6291, Nantes, France.

Background and aims: Over the past 30 years, non-alcoholic fatty liver disease (NAFLD) has become the most common chronic liver disorder in the world. The liver is a central organ for the metabolism of cholesterol whose hepatic accumulation is an early even of NAFLD. In our laboratory, we work on the metabolic roles of the transcription factor E2F1 mainly known for its roles in cell cycle control. We found that E2F1 plays a crucial role in maintaining cellular cholesterol homeostasis and the development of hepatic fibrosis, via the regulation of PCSK9.
Materials and methods: The importance of E2F1 on cholesterol metabolism was assessed by studying the mice invalidated for E2F1. Analysis of the E2F1 ChIP-seq in hepatocytes allowed us to determine its direct targets, which were validated by promoter's studies. The cellular models of mouse hepatocytes and HepG2 cell lines, invalidated for E2F1, allowed us to determine the mechanisms involved. The influence of cholesterol overload was determined by subjecting these mice to an atherogenic diet, rich in cholesterol. The importance of PCSK9 in the liver phenotype observed was determined by re-expressing PCSK9 in the liver of E2F1 -/- mice (by adenoviral strategy). We also studied PCSK9 -/- mice under high cholesterol diet.
Results: E2F1-/- mice display reduced total plasma cholesterol levels and increased cholesterol content in the liver. We show that E2F1 deletion in cellular and mouse models leads to a marked decrease in PCSK9 expression and increase in LDLR expression. In addition to the up regulation of LDLR, we report that E2F1-/- hepatocytes exhibit increased LDL uptake. ChIP-Seq and PCSK9 promoter reporter experiments confirmed that E2F1 binds to and transactivates the PCSK9 promoter. Interestingly, E2F1-/- mice fed a high cholesterol diet (HCD) display a fatty liver phenotype and early liver fibrosis, which is reversed by re-expression of PCSK9 in the liver.
Conclusion: Collectively, these data indicate that E2F1 regulates cholesterol uptake and that the loss of E2F1 leads to abnormal cholesterol accumulation in the liver and the development of fibrosis in response to a high cholesterol diet. In our study, we not only describe a new regulator of PCSK9, whose inhibitors have recently been developed for the treatment of hypercholesterolemia in humans, but we also highlight for the first time potential liver problems that could result from this inhibition.

A novel mouse model of maternal overnutrition-induced non-alcoholic steatohepatitis (NASH)/hepatocellular carcinoma

Y. Takiyama[1], M. Nakamura[2], T. Sera[3], K. Uesugi[4], M. Hoshino[4], N. Yagi[4], M. Haneda[1];
[1]Department of Medicine, Asahikawa Medical University, Asahikawa, [2]Department of Mechanical Engineering, Saitama University, Saitama, [3]Department of Mechanical Engineering, Kyushu University, Fukuoka, [4]Research & Utilization Division, Japan Synchrotron Radiation Research Institute, Hyogo, Japan.

Background and aims: Non-alcoholic steatohepatitis (NASH) is associated with hepatocellular carcinoma, which is the leading cause of cancer-related mortalities in Japanese patients with type 2 diabetes mellitus. NASH is believed to develop after two-hit process, and the first 'hit' may lie in early intrauterine exposures. To examine the impact of intrauterine nutrition on the pathophysiology of NASH, we have generated a novel mouse model.
Materials and methods: Female C57BL6J mice were fed either high-fat diet (H) or a control diet (C) during gestation. During lactation, all mice were fed the control chow. After weaning, the male offspring were fed the

control chow (C), generating two groups: H/C (n=7), C/C (n=7). At 15 weeks of age, offspring body weight, fasting blood glucose (FBS), HbA1c, nonesterified fatty acid (NEFA), alanine transaminase (ALT), systolic blood pressure (SBP) were measured. Following sacrifice, liver was dissected and assessed using histology and CT imaging using the beam line at the SPring-8 synchrotron radiation research facility in Japan. To address the underlying the epigenetic mechanisms, we performed a microarray experiment using formalin-fixed paraffin-embedded (FFPE) liver tissue. The target genes of microRNAs were predicted by TargetScan.

Results: Compared with C/C offspring, H/C offspring showed lower FBS (74.00±16.95 *vs*. 52.86±8.71 mg/dL, $p<0.05$), HbA1c (3.57±0.44 *vs*. 2.94±0.34 %, $p<0.05$) despite of more food intake (2.33±0.97 *vs*. 3.45 ±0.54 g/day, $p<0.05$). Body weight (21.98±0.90 *vs*. 22.55±1.82 g) and SBP (100±11.54 *vs*. 98.19±7.7 mmHg) were not different between both groups. Remarkably, plasma NEFA (608.0±66.61 *vs*. 911.0±242.4 microEq/L, $p<0.01$) and ALT (17.00±4.2 *vs*. 27.71±5.95 IU/L, $p<0.01$) were elevated in H/C. Consistent with metabolic changes, H/C had severe form of NASH, presenting the fibrosis evaluated by masson trichrome stain. Synchrotron micro-CT imaging at SPring-8 showed the architectural remodeling of the parenchyma in 6 out of 7 the H/C, not in the C/C. Intriguingly, melanocortin 4 receptor (MC4R), which plays a pivotal role in regulating the energy homeostasis, was over-expressed in the cytoplasm of hepatocellular carcinoma cells of H/C. Microarray analysis revealed that 140 of 1,900 miRNAs analyzed were differentially expressed in FFPE liver samples of H/C in comparison to C/C, i.e. 27 up-regulated and 120 down-regulated miRNAs. Of those miRNAs, miR-29c-3p, which targets MC4R, was down-regulated (ratio 0.52) in H/C.

Conclusion: This study suggests that the early exposure to an overnutrition in utero ("first-hit"), and subsequent neonatal nutritional alternation ("second hit"), which results in dynamic metabolic changes, could develop NASH in adult offspring. In addition, the epigenetic mechanism by miRNA which targets MC4R might be involved in NASH-based hepatocaricinogenesis. These results suggest that the intervention in the maternal nutrition should be important for preventing the future NASH/hepatocellular carcinoma in the next generation.

Hepatocyte-specific sirtuin 6 deletion predisposes to nonalcoholic steatohepatitis by upregulation of Bach1, an Nrf2 repressor

B.-H. Park[1], S.-O. Ka[1], I. Bang[1], E. Bae[2];
[1]Chonbuk National University Medical School, Jeonju, [2]Woosuk University, College of Pharmacy, Wanju, Republic of Korea.

Background and aims: Nonalcoholic steatohepatitis (NASH), ranging from liver steatosis, inflammation, and fibrosis is associated with insulin resistance and is a worldwide epidemic. Sirtuin 6 (Sirt6), a chromatin associated deacetylase has been implicated in negative regulation of inflammation and lipid metabolism, although its function in the progression from NASH to fibrosis remains to be defined.

Materials and methods: To explore the role of hepatocyte Sirt6 in diet-induced insulin resistance and NASH development, we generated hepatocyte-specific Sirt6 knockout (KO) mice that were fed a high-fat and high-fructose (HFHF) diet for 16 weeks.

Results: HFHF-fed KO mice had increased hepatic steatosis and inflammation and aggravated glucose intolerance and insulin resistance compared to wild type. Notably, HFHF-induced liver fibrosis and oxidative stress, as determined by Sirius-red staining, dihydroethidium fluorescence, and related gene expression analyses, were significantly elevated in KO mice. In the livers of KO mice, nuclear factor erythroid 2-related factor 2 (Nrf2) was downregulated and conversely BTB and CNC homolog 1 (Bach1), a nuclear repressor of Nrf2, were upregulated. We discovered that Sirt6, which interacts with Bach1 under basal condition, induces its detachment from the antioxidant response element (ARE) region of heme oxygenase 1 promoter. Furthermore, we found that Sirt6 promotes Nrf2 binding to ARE in response to oxidative stimuli, which leads to the expression of phase II/antioxidant enzymes. We also showed that HFHF-induced steatosis, inflammation, and fibrosis were ameliorated by adenoviral Sirt6 overexpression.

Conclusion: Sirt6 may be a useful therapeutic target for amelioration of NASH and liver fibrosis.

PS 115 Diabetes and cognitive dysfunction

1257

Neuroprotective effects of HM15211, a novel long-acting GLP-1/Glucagon/GIP tri-agonist in the MPTP Parkinson's disease mouse model

Y. Lee, S.-H. Lee, J. Kim, I. Choi, Y. Kim, S. Kwon;
Hanmi Pharm. Co., Ltd., Hwaseong-si, Republic of Korea.

Background and aims: HM15211 is a novel long-acting GLP-1/glucagon/GIP tri-agonist that is being developed for the treatment of obesity and related complications. Recent studies have shown that obesity, type 2 diabetes, and non-alcoholic fatty liver disease increase the risk of developing progressive neurodegenerative disease such as Parkinson's disease (PD) and Alzheimer's disease (AD). The dysregulated metabolic pathways are shared in the metabolic syndrome (MetS). To date, no disease modifying drug has been developed for PD or AD. Therefore, it is hypothesized that a treatment improving MetS may be useful for PD and AD patients. It was reported that both GLP-1 and GIP analogs show neuroprotective properties in PD and AD mouse models. In this study, we demonstrated the neuroprotective effect of HM15211 treatment in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) induced PD mouse model. MPTP is a neurotoxin, which can selectively destroy nigrostriatal dopaminergic neurons and cause parkinsonism in humans, nonhuman primates and mice, therefore it is used to induce PD in mice.
Materials and methods: MPTP 30 mg/kg was intraperitoneally injected once-daily for 7 days. HM15211 (2.5 nmol/kg, 5 nmol/kg) was subcutaneously administrated once at the first day and liraglutide (30 nmol/kg), as comparative control, was subcutaneously treated once-daily for 7 days. HM15211 and liraglutide were dosed 30 min after the MPTP administration. For motor function evaluation, the traction test, pole test and rotarod test were conducted before sacrifice. To assess the histological changes, hemi brain of all mice were sectioned with cryotome and stained. And for the molecular changes, striata were dissected from the other hemi brain and lysed with RIPA buffer and assayed with ELISAs.
Results: HM15211 significantly improved the MPTP induced motor impairments in three behavior tests in a dose-dependent manner. Histologically, the tyrosine hydroxylase positive neurons in substantia nigra and the staining density in striatum were reduced by MPTP. However, they were protected by HM15211 and liraglutide. In addition, HM15211 showed an anti-inflammatory effect over MPTP and decreased lipid peroxidation in the MPTP PD model. These neuroprotective effects of HM15211 were similar to the liraglutide-treated groups while only a single injection of HM15211 was used.
Conclusion: Based on these results, the novel long-acting GLP-1/glucagon/GIP tri-agonist HM15211 could have therapeutic potential for PD.

Alterations of brain energy metabolism in insulin-resistant Goto-Kakizaki rats measured in vivo by ^{13}C magnetic resonance spectroscopy

J.M.N. Duarte, F.-M. Girault, S. Sonnay;
Laboratoire d'imagerie fonctionnelle et métabolique, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland.

Background and aims: Type 2 diabetes is associated with deterioration of brain structure and function, leading to cognitive impairments. We hypothesized that diabetes induces a reorganization of the brain metabolic networks that support brain function. In this work, we investigated alterations of neuronal and glial energy metabolism in the living brain of a model of type 2 diabetes, the insulin-resistant Goto-Kakizaki (GK) rat.
Materials and methods: ^{13}C magnetic resonance spectroscopy *in vivo* at 14.1 T was used to detect labeling incorporation in to aliphatic carbons of glutamate, glutamine and aspartate in the brain of GK (n=7) and control Wistar (n=13) rats during [1,6-^{13}C]glucose administration. Labeling of brain glucose and amino acids over time was analyzed with a two-compartment mathematical model of brain energy metabolism to determine the rates of metabolic pathways in neurons and glia.
Results: Insulin resistance in GK rats caused mitochondrial oxidation rate to be reduced in neurons (-9±6%, P=0.002) but increased in astrocytes (+90±45%, P<0.001), when compared to the fluxes in the brain of control Wistar rats. Additionally, GK rats displayed lower rates of brain glutamine synthesis (-24±8%, P<0.001) and glutamate-glutamine cycle (-32 ±11%, P<0.001) than controls. Rates of global brain glucose transport and consumption were similar in GK and control rats.
Conclusion: Insulin resistance alters brain energy metabolism and impairs the glutamate-glutamine cycle between neurons and astrocytes, in line with diabetes-induced neurodegeneration and astrogliosis underlying brain dysfunction.

GLUT1 and VEGF are highly heritable, regulated by fat intake and affect memory performance

R. Schüler[1], N. Küffel[1], M.A. Osterhoff[1,2], V. Witte[3,4], A. Flöel[3,5], A. Busjahn[6], S. Kabisch[1,7], O. Pivovarova[1,2], S. Hornemann[1], M. Kruse[1,2], A.F.H. Pfeiffer[1,2];
[1]Clinical Nutrition, German Institute of Human Nutrition Potsdam-Rehbrücke (DIfE), Nuthetal, [2]Endocrinology, Diabetes and Nutrition, Charité-Universitätsmedizin Berlin, Campus Benjamin Franklin, Berlin, [3]Department of Neurology, Charité-Universitätsmedizin Berlin, Berlin, [4]Department of Neurology, Max Planck Institute of Human Cognitive and Brain Sciences and SFB 1052 Obesity Mechanism subproject A1, University of Leipzig, Leipzig, [5]Department of Neurology, University Medicine Greifswald, Greifswald, [6]HealthTwiSt GmbH, Berlin, [7]German Center for Diabetes Research (DZD), München-Neuherberg, Germany.

Background and aims: VEGF is required to restore and maintain brain glucose uptake across the blood brain barrier via GLUT1, which was shown to be acutely diminished in response to a high fat diet (HFD) in mice. We aimed to investigate the genetic and HFD-related regulation and association of GLUT1 and VEGF in humans in our NUtriGenomic Analysis in Twins (NUGAT) study.
Materials and methods: 92 healthy and non-obese twins were included. After they were standardized to a high-carbohydrate low-fat diet for 6 weeks they switched to a 6-week HFD under isocaloric conditions. Three clinical investigation days were conducted, after 6 weeks of low-fat diet (LF6) and after 1 and 6 weeks of HFD (HF1 and HF6). Serum VEGF and other cytokine levels were measured using ELISA. Gene expression in subcutaneous adipose tissue (SAT) was assessed by quantitative Real-Time PCR. Genotyping was performed on HumanOmniExpressExome BeadChips. Auditory verbal learning task was conducted to measure cognitive performance.
Results: In response to the HFD serum VEGF levels increased significantly (P=0.002) while GLUT1 (*SLC2A1*) mRNA expression in adipose tissue significantly decreased (P=0.001). Both, serum VEGF and GLUT1 gene expression showed very high heritability (>90%) and correlated negatively (HF1 ρ=-0.428, P=5.4x10^{-5}). The rs9472159 polymorphism explained up to 39% of the variation in circulating VEGF concentrations (P=1.4x10^{-11}). Homozygous carriers (AA-genotypes) showed significantly reduced serum VEGF levels (HF6 P=6.4x10^{-11}) but higher GLUT1 expression in SAT (HF6 P=0.009) compared to CC or CA-genotypes. AA-genotypes showed impaired consolidated memory scores after 6 weeks of HFD compared to CC and CA-genotypes (P=0.001).

Conclusion: The environmental regulation of GLUT1 expression and serum VEGF by high fat diet is inversely correlated and both factors show very strong heritability. The rs9472159 polymorphism affected both VEGF and GLUT1 levels and homozygous carriers showed declined memory performance in response to the HFD. High fat diet induces a genetically determined and correlated decrease of GLUT1 and increase of VEGF which may affect memory performance.

Apolipoprotein E ε4 affects cognition, but not brain structure and functioning in patients with longstanding type 1 diabetes

E. van Duinkerken[1,2], M. Klein[3], D.C. Mograbi[4,5], F. Barkhof[6], A.C. Moll[7], M. Diamant[1], F.J. Snoek[3], F.J. Snoek[3], R.G. IJzerman[1];
[1]Amsterdam Diabetes Centre / Department of Internal Medicine, VU University Medical Centre, Amsterdam, Netherlands, [2]Department of Functional Neuroimaging, Instituto Estadual do Cérebro Paulo Niemeyer Rio de Janeiro, Rio de Janeiro, Brazil, [3]Department of Medical Psychology, VU University Medical Centre, Amsterdam, Netherlands, [4]Department of Psychology, Pontifícia Universidade Católica Rio de Janeiro, Rio de Janeiro, Brazil, [5]Department of Psychiatry, King's College London, London, UK, [6]Department of Radiology and Nuclear Medicine, VU University Medical Centre, Amsterdam, [7]Department of Ophthalmology, VU University Medical Centre, Amsterdam, Netherlands.

Background and aims: Apolipoprotein E (APOE) ε4 is a genetic risk factor for cognitive decline, brain alterations, and dementia, especially in older age. In type 1 diabetes (T1DM), the DCCT/EDIC study showed no effect of APOE ε4 on cognitive decline, whereas a cross-sectional study found a negative association between APOE ε4 and decrements in cognition, but only in T1DM women. Brain structure or functioning have not been examined in relation to APOE ε4 in T1DM.
Materials and methods: We therefore determined the APOE genotype in 104 T1DM patients and 51 controls. Interaction terms were used to determine the differential effect of APOE ε4 genotype in patients and controls for cognition, cortical thickness, default mode network (DMN) functional connectivity, and white matter integrity. Analyses were corrected for age, sex, and systolic blood pressure.
Results: Genotyping was not possible in 3 patients due to insufficient material. The prevalence of APOE ε4 was similar between patients (n=33; 32.7%) and controls (n=15; 31.4%; $P>0.05$). Corrected for confounding, there were significant interactions between APOE ε4 and group for general cognitive ability (GCA), information processing speed (IPS), attention (ATT), cortical thickness and DMN functional connectivity (all $P<0.05$), but not for white matter integrity ($P>0.05$). Performance on these cognitive domains was lower in T1DM patients with APOE ε4 compared to without (GCA: β=-0.267; IPS: β=-0.264; ATT: β=-0.218; all $P<0.03$), without differences in controls. Contrary, in controls but not T1DM, right superior frontal and temporal cortical thickness and left lateral occipital DMN functional connectivity were lower in APOE ε4 carriers relative to non-carriers (all $P<0.05$).
Conclusion: To conclude, in T1DM APOE ε4 affected cognition, but not brain structure and functioning, which is similar to results found in type 2 diabetes. In controls, brain structure and functioning, but not cognition, were affected by APOE ε4, suggesting a distinct difference in the effect of APOE ε4 on the brain in T1DM and controls, with behavioural performance being most vulnerable to the effects APOE ε4 in patients.

The interaction with insulin receptor substrate 1 and cognition for patients with type 2 diabetes: in vivo evidence from gene association analysis

J. Huang;
Southeast University, Nanjing, China.

Background and aims: The dysregulations of insulin receptor substrate 1 (IRS-1) have been demonstrated to play vital roles in the interactions with brain insulin resistance and Alzheimer's disease by series of cellular and molecular investigations. However, little is known concerning its in vivo neurobiology underlying cognitive impairment. The present study aimed to clarify the associations between IRS-1 and brain functional network via genetic-imaging approach.
Materials and methods: 80 subjects with mild cognitive impairment (MCI) and 80 healthy controls (HCs) were employed. Every participants are patients with type 2 diabetes, and they went through the evaluation of cognition, scan of functional magnetic resonance imaging (MRI) and sequencing of the whole exome of IRS-1 gene. Haplotypes of IRS-1 were constructed to evaluate the integrations of multi-single nucleotide polymorphisms (SNPs). We explored the cognitive significance of IRS-1 haplotypes and corresponding influences on brain functional network.
Results: Two blocks of IRS-1 were detected. None of the haplotypes showed significantly different distributions between HCs and MCIs ($P > 0.05$), but the cognitive significance of block 1 was highlighted by the haplotype-based analyses (β = 0.39, raw P = 0.001, corrected P = 0.015). The further genetic-imaging analysis was performed to explore the effects of block 1 on brain default mode network. Regions related to the interactive effects of block 1 and disease statues were in frontal and temporal cortex. The behavioral relevance of the network was further indicated, as the functional connectivity within superior temporal cortex partially determine the cognitive performance for MCIs (β = 0.54, P = 0.005) .
Conclusion: The haplotype-based genetic-imaging analysis expanded our understanding for the mechanisms underlying the diabetes-related cognitive impairments, and relieving the dysfunctions of IRS-1 may be an effective method to alleviate the injuries of cognition related to both Alzheimer's disease and type 2 diabetes.

Serum ghrelin levels in elderly, diabetic patients with mild cognitive impairment

M. Gorska-Ciebiada[1], K. Cypryk[2], M. Saryusz-Wolska[3], A. Borkowska[3], M. Loba[1], K. Lokieć[1], M. Ciebiada[4];
[1]Department of Propaedeutics of Lifestyle Diseases, Medical University of Lodz, [2]Department of Diabetology and Metabolic Diseases, Medical University of Lodz, [3]Department of Internal Medicine and Diabetology, Medical University of Lodz, [4]Department of General and Oncological Pneumology, Medical University of Lodz, Lodz, Poland.

Background and aims: Recent evidence has indicated that type 2 diabetes mellitus (T2DM) in the elderly is a risk factor for mild cognitive impairment (MCI) or dementia. The etiology of cognitive impairment in diabetes is unknown, but probably associated with many factors. One of the recent hypotheses suggests that ghrelin could be involved in cognitive impairment in diabetic patients. It has been reported that ghrelin signaling occurs in the hippocampus and improves memory and spatial learning. The aim of the study was to evaluate serum levels of ghrelin in elderly, diabetic patients with and without MCI and to determine the predictors (including ghrelin levels) of having MCI in elderly patients with T2DM.
Materials and methods: A survey was conduct among 276 elderly subjects with T2DM. 87 patients with MCI and 189 controls were selected according to the criteria proposed by the MCI Working Group of the European Consortium on Alzheimer's Disease (using the Montreal Cognitive Assessment: MoCA score). Data of biochemical parameters and biomarkers were collected. The serum levels of ghrelin were assessed using ELISA kit. The approval was obtained from the independent Local Ethics Committee.
Results: Serum levels of ghrelin were significantly lower in patients with MCI (239.03 ± 47.09 pg/ml) compared to controls (297.83 ± 39.18 pg/ml, p<0.001). In group of subjects with MCI serum ghrelin levels were positively correlated with MoCA score (r=0.555; p<0.001) and negatively correlated with HbA1c (r=-0.318; p<0.001) and BMI (r=-0.395, p<0.001). The univariate logistic regression models revealed that variables which increased the likelihood of diagnosis of MCI in elderly patients with T2DM were: lower levels of ghrelin and HDL cholesterol, higher levels of HbA1c, triglicerydes, previous cardiovascular disease (CVD), hypertension (HA) or use of antihypertensive drugs, hiperlipidaemia, retinopathy, nephropathy, increased number of co-morbidities, older age and less years of formal education. Lower levels of ghrelin (OR 0.97, 95% CI: 0.95-0.98, p<0.001), higher levels of HbA1c (OR 2.42, 95% CI: 1.17-5.01, P-0.017), HA or use of anti-HA drugs (OR 6.26, 95% CI: 1.28-30.7, p=0.024), previous CVD (OR 8.76, 95% CI: 3.42-22.4, p<0.001), increased number of co-morbidities (OR 1.23, 95% CI: 1.05-1.44, P-0.01), and less years of formal education (OR 0.62, 95% CI: 0.48-0.8, P<0.001) are the factors increasing the likelihood of having MCI in elderly patients with T2DM in multivariable analysis.
Conclusion: In summary, serum levels of ghrelin were decreased in MCI elderly diabetic patients compared to controls and associated with poor MoCA score. The results indicated that lower ghrelin levels may be a risk factor for a cognitive impairment in diabetic, elderly patients. Further prospective larger studies are needed to confirm the role of this marker in the progression to dementia.
Disclosure: **M. Gorska-Ciebiada:** None.

Neuropsychological scores are correlated with the retinal sensitivity in type 2 diabetic patients with mild cognitive impairment and Alzheimer´s disease

A. Ciudin[1], O. Simo-Servat[1], G. Arcos[2], I. Hernandez[3], M. Boada[3], J. Mesa[1], C. Hernandez[1], R. Simo[1];
[1]Endocrinology and Nutrition, Vall d´Hebron University Hospital, [2]Ophthalmology Department, Vall d´Hebron University Hospital, [3]Neurology, Fundació ACE. Barcelona Alzheimer Treatment & Research Center, Barcelona, Spain, Barcelona, Spain.

Background and aims: Epidemiological studies have demonstrated that type 2 diabetic (T2D) patients have a significantly higher risk of developing mild cognitive impairment (MCI) and Alzheimer's disease (AD) in comparison with age-matched non-diabetic subjects. The annual conversion rate from MCI to dementia ranges between 10-30%. The diagnosis of MCI is based on complex neuropsychological tests which makes unfeasible their incorporation in the daily practice. The retina is ontogenically a brain-derived tissue and it has been suggested that it may provide an easily accessible and non-invasive way of examining the pathology of the brain. Therefore, it seems reasonable to propose that the evaluation of retinal parameters related to neurodegeneration such as retinal function would be useful for identifying those T2D patients at a higher risk of developing AD. Fundus-driven microperimetry has emerged as a simple, non-invasive and rapid test that can be used in the clinical practice to evaluate the retinal function.On these bases, the aim of the present study was to determine whether retinal sensitivity assessed by microperimetry correlates with the neuropsychological tests in T2D patients MCI and AD.
Materials and methods: We have designed a prospective nested case-control study including 35 T2D patients with MCI matched by age (±4 years), diabetes duration (±4 years) and classic cardiovascular risk factors with 35 T2D patients with AD. All patients were functionally literate, without clinical evidence of diabetic retinopathy and cerebrovascular disease. Mini-mental state evaluation test (MMSE) and The Alzheimer's disease assessment scale (ADAS-cog) were performed for the neuropsychological evaluation. Retinal function was assessed by standard microperimetry (MAIA microperimeter 3rd generation).
Results: No differences were found between the two groups regarding the HbA1c levels, BMI, gender, family history of AD, and the APOEe4 allele genotype. Retinal sensitivity was lower in the T2D patients with AD in comparison with the MCI group (17.11±6.3dB versus 21.68±4,06, p<0.001). We found a significant correlation between retinal sensitivity and the MMSE and ADAS-cog tests (r=0,427, p<0,001 and r= -0.523, p<0,001 respectively).
Conclusion: Our findings suggest that retinal sensitivity may be a useful biomarker for cognitive changes in T2D patients, strongly correlated with actual neuropsychological scales used in the clinical practice. Retinal microperimetry is an effective, rapid and reliable tool for discriminating patients with AD from those with MCI.

Metformin therapy improves cognitive function in women with Polycystic Ovary Syndrome (PCOS)

A. Alzaid, A. Tourkmani, A. Alsahaby, A. Robert, A. Bin Rsheed, A. Alabood, A. Alrasheed, M. Aldawish, M. Al-Eithan;
Prince Sultan Military Medical City, Riyadh, Saudi Arabia.

Background and aims: Data is limited on the status of cognitive function in women with PCOS and whether or not this is affected by treatment with metformin. Therefore, we decided to investigate prospectively cognitive function in women with PCOS at diagnosis and after the administration of metformin.
Materials and methods: Sixty eight (68) women with PCOS and 27 healthy women serving as control subjects (mean ±SD: age 26.8±5.7 vs 29.3 ± 4.6, p=0.038; BMI 31.2 ±7.0 vs 27.9 ± 5.2, p=0.022; educational status p=0.568 respectively) underwent cognitive function testing using the Montreal Cognitive Assessment test (MoCA). MoCA test was done in PCOS patients at diagnosis (baseline) and repeated 3 months after treatment with metformin. In the control group, MoCA tests were also done on two occasions, 3 months apart to ensure lack of familiarity of the test. All MoCA tests were conducted by a trained nurse supervised by a neuropsychologist. Fifteen (15) patients were excluded (3 incomplete data, 2

intolerance to metformin, 1 undiagnosed diabetes, 9 successful pregnancy) leaving 53 patients with valid data for analysis.
Results: MoCA test score was found to be significantly lower in the patients with PCOS compared to the control subjects (23.7±3.2; 25.6 ±2.4, p=0.001). MoCA score however, improved significantly from baseline with metformin treatment (23.7±3.2, 25.9±2.4; p=0.0001) to levels comparable to those observed in the control group (25.6±2.3; 25.2±2.4, p=0.569). MoCA score did not change over time in the control group (25.8±2.6, 25.1±2.4, p=0.236).
Conclusion: Women with PCOS demonstrate impaired cognitive function at diagnosis but this is restored to normal level after 3-months treatment with metformin. Metformin may therefore have beneficial effect on cognitive function in women with PCOS, in addition to its well established metabolic effects.

Increased plasma homocysteine level is associated with executive dysfunction in type 2 diabetic patients with mild cognitive impairment

S. Tian, R. Huang, J. Han, J. Sun, R. Cai, Y. Shen, S. Wang;
Endocrinology, Affiliated Zhongda Hospital of Southeast University, Nanjing, China.

Background and aims: Homocysteine (Hcy) is involved in the pathogenesis of type 2 diabetes mellitus (T2DM) and Alzheimer's disease. We aimed to investigate the role of Hcy in T2DM patients with mild cognitive impairment (MCI), and to determine whether methylene tetrahydrofolate reductase (MTHFR) C677T or cystathionine beta-synthase (CBS) 844ins68 polymorphism is related to T2DM-associated MCI.
Materials and methods: We recruited 285 T2DM patients and divided them into two groups, 140 patients with MCI and 145 healthy-cognition controls, on the basis of Montreal Cognitive Assessment (MoCA) scores. Demographic characteristics, clinical parameters and neuropsychological tests were assessed. MTHFR C677T and CBS 844ins68 polymorphisms were also analyzed.
Results: The MCI group exhibited a significantly higher plasma total Hcy (tHcy) level than the control group ($p < 0.001$). After adjusting some confounding factors, plasma tHcy level was negatively correlated with MoCA scores ($p = 0.002$), but positively associated with Trail Making Test A and B scores ($p = 0.044$; $p = 0.005$, respectively), which evaluated executive function. Multivariable logistic regression model showed that high tHcy level was an independent factor for MCI in T2DM patients. No significant difference was observed in the genotype or allele distributions of MTHFR and CBS between MCI and control groups. Increased MCI risk was found in MTHFR T allele compared with C allele, and in CBS I allele compared with D allele (OR = 1.361, $p = 0.067$; OR = 1.048, $p = 0.909$, respectively).
Conclusion: Increased plasma tHcy level was significantly related to T2DM-associated MCI, especially executive dysfunction. Further investigation with a large population size should be conducted to confirm these observed findings.

Table 1 Assessment results of the risk of having MCI in a multivariable logistic regression model in T2DM patients.

Variables analyzed	β	SE of β	P	OR	95%CI
Education Levels (years)	-0.062	0.078	0.426	0.939	0.806-1.095
Diabetes duration (years)	0.002	0.040	0.952	1.002	0.927-1.084
HbA1c (%)*	-0.571	0.112	<0.001*	0.565	0.453-0.704
FCP(nmol/L)	-0.353	0.204	0.083	0.703	0.471-1.048
HOMA-IR	1.394	0.988	0.158	4.033	0.582-27.945
tHcy (nmol/L)*	1.207	0.174	<0.001*	3.343	2.379-4.698
Vitamin B12 (pmol/L)*	0.042	0.013	0.001*	1.043	1.016-1.071
Folate (nmol/L)*	-0.439	0.142	0.002*	0.644	0.488-0.851

*Significance, $p < 0.05$. Abbreviations: β, regression coefficient; SE, standard error; OR, odds ratio; CI, confidence interval for odds ratio; MCI, mild cognitive impairment; HbAlc, glycosylated hemoglobin; FCP, Fasting c-peptide; HOMA-IR, the homeostasis model assessment of insulin resistance; tHcy, total homocysteine.

High fat diet-induced mild insulin resistance accelerates memory dysfunction via Tau phosphorylation in an Alzheimer mouse model

J.-H. Park[1], J.-H. Jang[2], H. Kim[3], N. Cho[3], E. Han[3], H. Cho[3];

Background and aims: Type 2 diabetes mellitus (T2DM) and Alzheimer's disease (AD) are both more prevalent with aging, but it has generally been assumed that this is coincidental, not a reflection of comorbidity. However, evidence suggests that patients with T2DM that were hyperinsulinemic or insulin resistant as hallmarks of T2DM are at an increased risk of getting AD. In the present study, we investigate the effect of high-fat diet (HFD)-induced mild insulin resistance on memory function in a mouse model of genetically induced AD-like neuropathology (3xTg-AD).
Materials and methods: To induce mild insulin resistance in 3xTg-AD mice, mice received a HFD (60% kcal fat) for only a 8-week period starting at the age of 4 months. Food intake and body weight gain were followed up every 4 days. After 8-week HFD, we investigated cognitive dysfunction with water maze test. Cerebral amyloid-beta and Tau phosphorylation levels were determined by Western blotting. Plasma 50 cytokines were analyzed using a cytokine antibody array.
Results: HFD enhanced memory impairment and Tau phosphorylation levels compared to the normal diet (ND) in 3xTg-AD mice. However, the expression of cerebral amyloid-beta did not differ between ND and HFD in 3xTg-AD mice. 3xTg-AD mice with HFD showed significantly elevated plasma levels of L-selection, sTNF RII, IGFBP-2, MMP-3, resistin and osteopontin compared with 3xTg-AD mice with ND.
Conclusion: aken together, these findings suggest that HFD-induced mild obesity and insulin resistance may play an important role in the development of Alzheimer's disease via Tau phosphorylation. In addition, elevated cytokines in 3xTg-AD mice with HFD might be correlated with the development of Alzheimer's disease or may prove to be useful biomarkers in Alzheimer's disease.
