(Received 10 August 2011; accepted 5 January 2012; published online 30 January 2012)

The equilibrium conductance of LaAlO<sub>3</sub>/SrTiO<sub>3</sub> (LAO/STO)-heterointerfaces was investigated at high temperatures (950 K-1100 K) as a function of ambient oxygen partial pressure (pO<sub>2</sub>). Metallic LAO/STO-interfaces were obtained for LAO grown on STO single crystals as well as on STO-buffered (La,Sr)(Al,Ta)O<sub>3</sub> substrates. For both structures, the high temperature sheet carrier density  $n_{\rm S}$  of the LAO/STO-interface saturates at a value of about  $1 \times 10^{14}$  cm<sup>-2</sup> for reducing conditions, which indicates the presence of interfacial donor states. A significant decrease of  $n_{\rm S}$  is observed at high oxygen partial pressures. According to the defect chemistry model of donor-doped STO, this behavior for oxidizing conditions can be attributed to the formation of Sr-vacancies as charge compensating defects. © 2012 American Institute of Physics. [doi:10.1063/1.3679139]

The metallic conductivity of the heteroepitaxial interface between LaAlO<sub>3</sub> (LAO) and SrTiO<sub>3</sub> (STO) has generated enormous scientific interest.<sup>1</sup> The underlying physical mechanisms, however, are still under controversial debate.<sup>2–4</sup> In particular, the impact of crystal disorder and defects on the electrical properties of the LAO/STO-interface has become the central aspect of the ongoing discussion. In this context, lanthanum ions on strontium sites  $(La_{Sr}^{\bullet})^{5-10}$ and oxygen vacancies  $(V_0^{\bullet\bullet})$  within the STO substrate 11-15have been proposed as predominant defects at the LAO/ STO-interface since both types of defects can cause *n*-type conductivity in STO. High temperature equilibrium measurements show an oxygen partial pressure  $(pO_2)$  independent interface conductance in a certain pO<sub>2</sub> regime.<sup>6</sup> This supports the model of immobile donors and excludes mobile  $V_{\Omega}^{\bullet \bullet}$  as origin of the electronic charge carriers. However, the charge compensation mechanism in donor-doped STO is more complex than in conventional semiconductor materials. Intrinsic acceptor-like defects such as Sr-vacancies  $(V''_{Sr})$ can form in STO and act as electron traps (ionic compensation).<sup>16</sup> Thus, an increased amount of  $V_{Sr}''$  will result in a decrease of the electron density, and at the extreme, in a change from *n*-type metallic to insulating behavior. In previous studies, the conductivity of the LAO/STO-interface has been related to the formation of donor-type defects, i.e.,  $V_0^{\bullet\bullet}$ and Lasr. However, an additional, complementary influence of acceptor-type defects has not been considered so far.

This aspect will be addressed in the present study which investigates the high temperature equilibrium conductance (HTEC) of two types of LAO/STO-interfaces *insitu* as a function of ambient oxygen partial pressure  $(10^{-23} \text{ bar} < \text{pO}_2 < 10^{-2} \text{ bar})$  in the temperature range from 950 K to 1100 K (see Ref. 6 for experimental details). With this method, the pO<sub>2</sub>-dependent defect equilibria at the LAO/STO-interface can be studied in well-defined thermodynamical equilibrium conditions.

The LAO/STO-interface has been achieved by a standard pulsed laser deposition (PLD) of 8 unit cells (uc) LAO on a TiO<sub>2</sub> -terminated STO single crystal (sc) substrate  $pO_2 = 2 \times 10^{-3}$  mbar).<sup>11</sup>  $(T = 850 \degree C)$ Additionally, (La,Sr)(Al,Ta)O<sub>3</sub> (LSAT) has been used as an alternative substrate material for the epitaxial PLD-growth of 10 uc STO  $(T = 850 \degree C, pO_2 = 0.1 \text{ mbar})$  and 10 uc LAO  $(T = 850 \degree C \text{ and } pO_2 = 3 \times 10^{-5} \text{ mbar})^{17}$ . In the following, these two heterostructures will be denominated HS1 (LAO/ STO) and HS2 (LAO/STO/LSAT), respectively. A lower deposition pressure was used for the sample grown on LSAT in order to achieve a low temperature conductance and a room temperature sheet carrier density  $(n_{\rm S} \approx 1 \times 10^{14} \, {\rm cm}^{-2})$ similar to the ones measured in the HS1 sample.<sup>17</sup> For the HTEC measurements, a STO sc, a LSAT sc (both 0.5 mm thick), and a 10 uc thick STO film on LSAT (STO/LSAT) grown at similar conditions as for HS2 were investigated as reference samples. The HTEC characteristics of HS1 and HS2 are then discussed as the sum of the LAO/STOinterface contribution and the corresponding substrate contribution.

Fig. 1(a) shows the HTEC characteristic of the single crystalline substrates, STO and LSAT, plotted on double logarithmic scales. As a result of oxygen exchange, STO shows the characteristic V-shaped curve with enhanced *n*-type and *p*-type conductance in reducing and oxidizing atmospheres, respectively.<sup>6,16,18</sup> The LSAT sc shows a similar *p*-type behavior in oxidizing conditions, while a negligible increase of the conductance is observed in the reducing regime. In general, LSAT exhibits a significantly lower conductance than STO over the entire investigated pO<sub>2</sub>-range. Thus, LSAT is expected to substantially diminish the substrate contribution in the HTEC measurements compared to STO.

Fig. 1(b) shows the HTEC characteristic of HS1 ( $G_{\rm HS1}$ , filled symbols) in comparison to the STO sc ( $G_{\rm STO}$ , open symbols). Both characteristics deviate significantly for intermediate pO<sub>2</sub> due to the additional, temperature- and pO<sub>2</sub>-independent conductance contribution of the metallic LAO/

STO-interface  $(G_{\text{IF}})$ .<sup>6</sup> In the reducing regime as well as in the oxidizing regime,  $G_{\text{IF}}$  is concealed by the dominating substrate contribution  $G_{\text{STO}}$ .

The HTEC characteristics of HS2 ( $G_{HS2}$ , filled symbols) and the STO thin film on LSAT ( $G_{\text{STO/LSAT}}$ , open symbols) are illustrated in Fig. 1(c). Compared to the bare LSAT sc (Fig. 1(a)), the HTEC characteristic of the STO/LSAT-sample shows an additional conductance upturn due to the STOlayer in strongly reducing atmosphere. Accordingly, the STO/LSAT-data have to be taken as a reference for HS2. A clear impact of the metallic LAO/STO-interface is observed below 10<sup>-4</sup> bar where HS2 shows a significantly enhanced conductance compared to the STO/LSAT-stack. For reducing conditions, the LAO/STO-interface of HS2 exhibits a plateau-like conductance behavior with very weak dependence on temperature and  $pO_2$  which resembles the behavior of the standard LAO/STO-interface in HS1. Approaching oxidizing conditions ( $pO_2 > 10^{-12}$  bar), however, a deviation from the constant behavior is observed. This pO2-dependence of the interface conductance will be further discussed.

For the pO<sub>2</sub> -regions, in which the heterostructures exhibit a significantly higher conductance than the corresponding reference samples, the conductance contribution of the LAO/ STO-interface  $G_{\rm IF}$  can be calculated as  $(G_{\rm HS1} - G_{\rm STO})$  and  $(G_{\rm HS2} - G_{\rm STO/LSAT})$ , respectively. The corresponding sheet carrier density  $n_{\rm S} = G_{\rm IF}/e\mu_{\rm n}$  can then be determined by a proper estimation of the electron mobility  $\mu_n$ . For the investigated temperature range above 900 K,  $\mu_n$  is limited by phonon scattering resulting in a power law type temperature dependence. Reference data for  $\mu_n$ , obtained from a 5at. % La-doped STO sc, showed a good agreement with the temperature dependence reported in Ref. 16 ( $\mu_{\rm n} = 3.95 \times 10^4 \times T[{\rm K}]^{-1.62} \,{\rm cm}^2/{\rm Vs}$ ). Therefore, this value was applied to calculate the interfacial sheet carrier density of HS1 and HS2. These results are shown in Fig. 2.

In the pO<sub>2</sub>-independent plateau region,  $n_{\rm S}$  approaches a value of  $1 \times 10^{14}$  cm<sup>-2</sup> for both samples, which is consistent with the carrier densities obtained from Hall measurements<sup>17</sup> as well as from spectroscopic investigations.<sup>19</sup> For oxidizing conditions, HS2 shows a steep decrease of  $n_{\rm S}$  with a slope of approximately (-1/4) in the double logarithmic plot. In this region, the temperature dependence of  $n_{\rm S}$  follows an Arrhenius-type law with an activation energy ( $E_{\rm A}$ ) of about 1 eV (see inset of Fig. 2). HS1 shows a similar tendency of a decreasing  $n_{\rm S}$  with increasing pO<sub>2</sub> above  $10^{-8}$  bar. Due to

the large STO substrate contribution at oxidizing conditions, however, this tendency is concealed above  $10^{-4}$  bar.

The measured HTEC characteristics of the LAO/STOinterfaces resemble the HTEC behavior of donor-doped STO (Ref. 16) and can, therefore, be discussed within the corresponding defect chemistry model. Donor-doped STO shows a pO<sub>2</sub>-independent region in its HTEC characteristic for which the charge neutrality condition  $n = [D^{\bullet}]$  is valid (full electronic compensation). Here, *n* denotes the electron concentration and  $[D^{\bullet}]$  the concentration of ionized extrinsic donors. In this plateau region, the concentration of mobile oxygen vacancies  $[V_0^{\bullet\bullet}]$  is much smaller than  $[D^{\bullet}]$ , <sup>16</sup> so that *n* is unaffected by oxidation or reduction reactions. According to this model, the plateau-like region in the HTEC characteristics of HS1 and HS2, observed for reducing conditions, indicates the presence of donor dopants at the LAO/STOinterface provided for example by cation-intermixing.

In order to maintain charge neutrality, a decrease of *n* below the donor level  $[D^{\bullet}]$  requires the formation of additional compensating defects which carry a negative net charge. Predominately, Sr-vacancies  $(V_{Sr}'')$  are considered as acceptor-type cationic defects in STO. These can be reversibly created and annihilated<sup>16</sup> according to the reaction

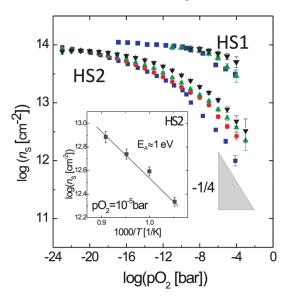

FIG. 2. (Color) The sheet carrier density  $n_{\rm S}$  at the LAO/STO-interface as a function of pO<sub>2</sub> at various temperatures (950 K ( $\blacksquare$ ), 1000 K ( $\bullet$ ), 1050 K ( $\blacktriangle$ ), and 1100 K ( $\blacktriangledown$ )). HS1 corresponds to LAO/STO, HS2 to LAO/STO/LSAT. Inset: Arrhenius-plot of  $n_{\rm S}$  at pO<sub>2</sub> = 10<sup>-5</sup> bar for HS2.

$$\mathbf{V}_{\mathrm{Sr}}'' + (\mathrm{SrO})_{sp} \rightleftharpoons \mathrm{Sr}_{\mathrm{Sr}}^{x} + 1/2 \,O_2 + 2\mathrm{e}'. \tag{1}$$

Here,  $(SrO)_{sp}$  denotes a Sr-rich secondary phase and e' a free electron. The corresponding law of mass action leads to the expression

$$\frac{pO_2^{1/2} \cdot n^2}{\left[\mathbf{V}_{Sr}''\right]} \propto \exp\left(-\frac{H_{\rm V}}{k_{\rm B}T}\right),\tag{2}$$

where  $H_{\rm V}$  is the reaction enthalpy. For a given temperature, it follows from Eq. (2), that  $[V_{Sr}'']$  increases with increasing pO<sub>2</sub>. Hence, an increasing fraction of donors is compensated by Sr-vacancies when the ambient  $pO_2$  is increased. In case of a full ionic compensation of the extrinsic donors  $([V_{Sr}''] = 1/2[D^{\bullet}] = \text{const.}), n \text{ becomes proportional to}$  $pO_2^{-1/4}$ . The characteristic slope of (-1/4), which results on double logarithmic scales, is also observed for HS2. This indicates that the decrease of  $n_{\rm S}$  at the LAO/STO-interface for oxidizing conditions originates from a self-compensation mechanism caused by Sr-vacancies. It follows for HS2, that  $[V_{Sr}'']$  has to reach a value of about  $1.3 \times 10^{20} \, \text{cm}^{-3}$  within the 10 uc thick STO-layer in order to compensate for an interfacial donor concentration of  $1 \times 10^{14} \text{ cm}^{-2}$ . The reaction enthalpy  $H_V$  can be calculated from  $E_A$ , which was determined for HS2 at oxidizing conditions, via  $H_{\rm V} = 2E_{\rm A} \approx 2 \, {\rm eV}$ . This value obtained for the LAO/STOinterface differs significantly from the value for bulk STO (3.6 eV).<sup>16</sup> Although a clear (-1/4)-behavior cannot be observed for HS1, the evolving decrease of  $n_{\rm S}$  above  $10^{-8}$  bar suggests that a similar charge compensation effect is present at the interface of the standard LAO/STO-heterostructure. Compared to sample HS2, however, the decrease of  $n_{\rm S}$  is shifted towards higher pO<sub>2</sub>-values indicating an effect of the particular STO-environment in a single crystal (HS1) and a (more defective)<sup>20</sup> thin film (HS2), respectively.

In conclusion, the *in-situ* study of the HTEC of LAO/ STO-heterostructures emphasizes the importance of crystal disorder for the electronic properties of the LAO/STO-interface. The observed  $pO_{2^-}$  and temperature-independence of the sheet electron density for reducing conditions supports the idea of a donor-type conduction mechanism at the LAO/ STO-interface such as provided by cation-intermixing. Furthermore, the decrease of  $n_s$  in oxidizing conditions indicates a complex charge compensation mechanism in the vicinity of the interface which involves the formation of Sr-vacancies at high oxygen partial pressures. This implies that oxygen annealing after the growth of LAO/STO-heterostructures, which is commonly thought to merely remove oxygen vacancies from the STO substrate, can also result in an increased cation vacancy concentration at the interface. These additional defects can reduce the electron density and, moreover, can act as scatter centers at low temperatures.

As pivotal result of this study, it has been shown that in the vicinity of the LAO/STO-interface exchange reactions in the cation sublattice, i.e., formation and annihilation of strontium vacancies take place at typical growth temperatures and have to be considered in the discussion of the LAO/STOinterface.
