8

9  
10 **Abstract**

11 **Aim:** Several studies have suggested that lifetime cannabis consumption and childhood abuse  
12 synergistically contribute to the risk for psychotic disorders. This study aimed to extend existing  
13 findings regarding an additive interaction between childhood abuse and lifetime cannabis use, by  
14 investigating the moderating role of type and frequency of cannabis use.  
15  
16  
17  
18

19  
20 **Methods:** 231 individuals presenting for the first time to mental health services with psychotic  
21 disorders and 214 unaffected population controls from South London, United Kingdom, were  
22 recruited as part of the Genetics and Psychosis study. Information about history of cannabis use was  
23 collected using the Cannabis Experiences Questionnaire. Childhood physical and sexual abuse were  
24 assessed using the Childhood Experience of Care and Abuse Questionnaire.  
25  
26  
27  
28  
29

30  
31 **Results:** Neither lifetime cannabis use nor reported exposure to childhood abuse were associated  
32 with psychotic disorder when the other environmental variable was taken into account. Although  
33 the combination of the two risk factors raised the odds for psychosis by nearly three times (adjusted  
34 OR=2.94, 95% CI: 1.44-6.02, p=0.003), no evidence of interaction was found (adjusted OR=1.46,  
35 95% CI: -0.54-3.46, p=0.152). Furthermore, the association of high potency cannabis and daily  
36 consumption with psychosis was at least partially independent of the effect of childhood abuse.  
37  
38  
39  
40  
41  
42  
43  
44

45 **Conclusions:** The heavy use of high potency cannabis increases the risk of psychosis but, in  
46 addition, smoking of traditional resin (hash) and **less than daily** cannabis use may increase the risk  
47 for psychosis when combined with exposure to severe childhood abuse.  
48

## Introduction

Both childhood maltreatment and cannabis abuse are considered to play a role in the pathogenesis of psychosis.<sup>1,2</sup> Recent studies indicate that their effect on psychosis is neither fully confounded by other risk factors,<sup>3,4</sup> nor a simple effect of gene–environment correlation.<sup>5</sup> Moreover, there are suggestions that the risk for psychosis is greater in subjects exposed to both risk factors compared to those who experienced only either of them.<sup>6-8</sup> For instance, a preliminary investigation using the US National Comorbidity Survey found that when cannabis use and sexual molestation/rape before 16 years of age were entered into the same model neither of them was associated with psychosis, but it was only the combination of the two that increased the risk in a more than multiplicative way (OR=11.96, 95% CI 2.10-68.22).<sup>6</sup>

Subsequent studies have confirmed the interaction between cannabis and trauma, though at an additive level. In a small sample of adolescents aged 12-15 years, the odds of reporting psychotic symptoms was 20.9 among subjects exposed to both child abuse and lifetime cannabis use, compared to 1.9 among those exposed only to cannabis, and 2.6 in those exposed only to trauma.<sup>7</sup> Konings and colleagues replicated this additive interaction in a birth cohort study (the Greek National Perinatal Study) and a longitudinal population study (the Netherlands Mental Health Survey and Incidence Study, NEMESIS). It was found that the strength of interaction between lifetime cannabis use and childhood trauma increased with the frequency of maltreatment suggesting a dose-dependent, extra-linear relationship.<sup>8</sup> Contrasting with these promising findings, in another Dutch study (the Early Developmental Stage of Psychopathology, EDSP) there was no evidence that broadly defined traumatic experiences before 18 years of age (including, among others, wars, natural disasters, and serious accidents in addition to physical and sexual abuse) moderated the effect of smoking cannabis (five times or more) on psychotic symptoms.<sup>9</sup> One possible reason for the discrepancies in the findings is that previous studies used fairly crude measures of cannabis use, which often did not consider frequency of consumption, and may have

1  
2  
3 included participants using different strengths of cannabis – higher concentrations of delta9-  
4 tetrahydrocannabinol ( $\Delta$ 9-THC) have been associated with greater odds of developing psychosis.<sup>10</sup>  
5  
6

7 Therefore, the aim of the present study was to replicate existing findings regarding an  
8 additive interaction between childhood abuse and lifetime cannabis use in a sample of individuals  
9 presenting for the first time to mental health services with psychotic disorders and to extend these  
10 findings by investigating the moderating role of type and frequency of cannabis use on the  
11 association between childhood abuse and psychosis.

## 20 **Methods**

### 21 *Participants*

22  
23 Psychosis cases and unaffected controls were recruited as part of the Genetics and Psychosis Study  
24 (NIHR-BRC GAP), approved by the South London & Maudsley National Health Service (NHS)  
25 Trust and the Institute of Psychiatry ethical committees.<sup>10,11</sup> All the participants were informed  
26 about the study aims and provided written informed consent. Cases were individuals aged 18 to 65  
27 with a first episode of psychosis who presented to the Lambeth, Southwark and Croydon adult in-  
28 patient units of the South London and Maudsley Mental Health NHS Foundation Trust between  
29 December 2005 and October 2010. Cases had to fulfil International Classification of Diseases (ICD-  
30 10)<sup>12</sup> criteria for psychosis (codes F20-29 or F30-34); cases with a known organic cause for  
31 psychosis were excluded. Diagnoses were formulated by trained psychiatrists according to DSM-  
32 IV<sup>13</sup> and ICD 10<sup>12</sup> criteria using the Operational Criteria system, OPCRIT<sup>14</sup>, on the basis of clinical  
33 notes collected for each patient during the first month after admission. Controls were recruited from  
34 the same catchment area as cases through leaflet distributions and internet and newspaper  
35 advertisements. Potential controls were screened for current or past psychotic disorders using the  
36 Psychosis Screening Questionnaire (PSQ),<sup>15</sup> and those who met criteria for a psychotic disorder, or  
37 reported a previous diagnosis of psychosis, were excluded. Subjects with IQ<70 or poor English  
38 fluency were also excluded.

1  
2  
3 The data analysed in this paper was limited to the participants who provided full information  
4 about the two exposures of interest, by completing both the cannabis and the childhood abuse  
5 assessments. Therefore, it includes only 231/489 (47%) of the patients and 214/278 (77%) of the  
6 controls recruited into the study.<sup>11</sup> Reasons for dropout included the lack of interest in the research,  
7 the length of the assessment, and their view of their mental health.<sup>16,17</sup> There were no significant  
8 demographic differences between this subsample and the full GAP sample, except in the age of the  
9 control group ( $27.6 \pm 9.0$  vs.  $30.2 \pm 9.5$ ,  $t=3.120$ ,  $p=0.002$ ), though this only differed on average by  
10 3 years.

### 20 21 22 *Measures*

23 Socio-demographic information (age, gender, self-rated ethnicity, level of education achieved) and  
24 family history of psychiatric disorder (psychotic disorders, mood disorders, or substance/alcohol  
25 use disorders) were collected on both cases and controls using respectively the Medical Research  
26 Council Sociodemographic Schedule<sup>18</sup> and the Family Interview for Genetic Studies (FIGS).<sup>19</sup>  
27 Childhood physical and sexual abuse were assessed using the Childhood Experience of Care and  
28 Abuse Questionnaire (CECA.Q).<sup>20</sup> In order to reduce the possibility of recall bias and maximise  
29 likely effect on psychosis, analyses were limited to physical abuse resulting in injuries and to  
30 penetrative sexual abuse reported as occurring prior to 17 years of age. Reports of either of these  
31 forms of severe abuse were considered to indicate exposure to childhood abuse.  
32

43  
44

45 Lifetime cannabis use (i.e., having ever smoked cannabis, one time or more), type of  
46 cannabis most often used, and lifetime frequency of cannabis consumption (i.e., the frequency that  
47 characterized the subject's most consistent pattern of use) were investigated using the Cannabis  
48 Experiences Questionnaire modified version (CEQmv).<sup>10</sup> The types of cannabis used by the  
49 participants were classified as mainly resin (hash) vs. mainly sinsemilla (skunk), according to the  
50 different concentrations of delta9-tetrahydrocannabinol ( $\Delta 9$ -THC).  $\Delta 9$ -THC is the active principle  
51 component responsible for the psychogenic effect and cognitive impairments associated with  
52  
53  
54  
55  
56  
57

3 cannabis,<sup>21</sup> and is estimated as being 2–4% concentrated in cannabis resin but 12-18% in  
4 sinsemilla/skunk.<sup>22</sup> The lifetime frequency of cannabis consumption was classified as less than  
5  
6  
7 daily vs. daily.  
8  
9

### 10 11 *Statistical analyses*

12  
13  
14 Analyses were carried out using Stata version 12.0 (Stata Corporation, USA). Logistic regression  
15  
16 was used to assess the effect of the independent variables on the dependent variable (presence of  
17  
18 psychotic disorder). Analyses were repeated adjusting for the potentially confounding effects of  
19  
20 gender, self-rated ethnicity, current level of education, and family psychiatric history because in the  
21  
22 study sample these variables were associated either with psychotic disorders or with either of the  
23  
24 two exposures (lifetime cannabis use or childhood abuse). Statistical interaction is a model-  
25  
26 dependent estimation of biological synergism and refers to a situation in which the combined effect  
27  
28 of two or more exposures exceeds the sum (additive model) or the product (multiplicative model) of  
29  
30 their solitary effects.<sup>23,24</sup> Additive interaction between cannabis use and childhood abuse was  
31  
32 assessed using the Interaction Contrast Ratio (ICR), which estimates the relative excess due to  
33  
34 interaction using odds ratios (OR) derived from logistic regressions. In the presence of statistical  
35  
36 interaction, the ICR shows that the odds of being psychotic in those exposed to both risk factors is  
37  
38 greater than the sum of the odds conveyed by each risk factor (departure from additivity).<sup>25,26</sup>  
39  
40  
41  
42 Although the ICR was originally designed to assess additive interaction in cohort studies, it can be  
43  
44 used in the context of case-control studies under the rare-disease assumption that, when the  
45  
46 outcome is rare in the source population, odds ratios approximate risk ratios. Therefore, we  
47  
48 stratified our independent variable into four levels: those exposed to both cannabis and child abuse  
49  
50 (AB), those exposed only to cannabis (A), those exposed only to child abuse (B), and those exposed  
51  
52 to neither cannabis nor child abuse (reference category). The Stata nlcom command was used to  
53  
54 calculate the ICRs and the related 95% confidence intervals (CI) and p values.  
55  
56  
57  
58  
59  
60

1  
2  
3 One issue in interaction studies is that the “true” effect of the interaction may be confounded  
4 by correlation, meaning the extent to which one risk factor can drive the exposure to another risk  
5 factor.<sup>27</sup> In this study Environment by Environment correlation (rEE) refers to the probability that  
6 childhood trauma *per se* alters the probability that an individual will use cannabis. To test rEE we  
7 analysed the effect of childhood trauma on cannabis use in the control group using logistic  
8 regression. Because of a small percentage of missing data concerning family psychiatric history, a  
9 sensitivity analysis was carried out to investigate the effect of missingness on the interaction  
10 between cannabis use and childhood abuse, using an imputation method. *Post-hoc* power analysis  
11 was conducted using GPower 3.1.5.

23  
24

## 25 Results

26 Socio-demographic characteristics of the sample are reported in Table 1. There was some evidence  
27 of a difference between the psychosis cases and unaffected controls in terms of ethnicity, education  
28 level, and family psychiatric history. Furthermore, cases included a higher proportion of men  
29 although there was no strong evidence of a gender difference between the groups.  
30  
31  
32  
33  
34  
35

36 [Insert Table 1 here]  
37  
38  
39  
40

### 41 *Cannabis use by childhood abuse interaction*

42 There was no evidence of an association between childhood abuse and cannabis use in the control  
43 group (OR=0.98, 95% CI 0.46-2.08, p=0.963), suggesting no evidence of environment-environment  
44 correlation. Table 2 presents unadjusted and adjusted ORs for the four combinations of the  
45 environmental exposures and their associations with psychotic disorder.  
46  
47  
48  
49  
50

51 [Insert Table 2 here]  
52  
53

54 **While lifetime cannabis use alone (i.e., in those without exposure to childhood abuse) and**  
55 **childhood abuse alone (i.e., in those with no lifetime cannabis use) were not associated with**  
56 **psychotic disorders,** the combination of the two exposures raised the odds for the disease by nearly  
57  
58  
59  
60

1  
2  
3 three times (adj. OR=2.94, 95% CI 1.44-6.02, p=0.003). The ICR (2.18, 95% CI 0.01-4.36,  
4  
5 p=0.049) was greater than 0 and showed some evidence of an effect, suggesting that the joint effect  
6  
7 of cannabis use and childhood abuse on the additive scale was greater than the sum of their effects  
8  
9 alone. However, after adjusting for confounders, the interaction effect was attenuated and became  
10  
11 non-significant (ICR=1.46, 95% CI -0.54-3.46, p=0.152).  
12  
13

### 14 15 16 *Sensitivity analyses*

17  
18 Family psychiatric history was the only variable to account for a small percentage of missingness in  
19  
20 this sample (51/445, 11.5%). Missing data were equally distributed across levels of gender,  
21  
22 education level, ethnicity, cannabis use, and child abuse but were more frequent in cases than  
23  
24 controls (40 (17.3%) vs. 11 (5.1%),  $\chi^2=16.2$ , p<0.001). All missing values were replaced first by  
25  
26 positive family history and then by negative family history and analyses were repeated using these  
27  
28 new variables. There was no evidence of an interaction after imputation either of a positive  
29  
30 (ICR=1.23, 95% CI -0.35-2.81, p=0.127) or negative (ICR=1.53, 95% CI -0.33-3.39, p=0.107)  
31  
32 family history.  
33  
34  
35  
36  
37

### 38 *Effect of type and frequency of cannabis use*

39  
40 Associations with psychotic disorders for potency of cannabis consumed (hash-like vs. skunk-like)  
41  
42 and frequency of cannabis use (daily vs. less than daily) in conjunction with reported exposure to  
43  
44 childhood abuse are presented in Tables 3 and 4, respectively. Looking at the effect of cannabis  
45  
46 alone or combined with childhood abuse (Tables 3 and 4), there is a suggestion that high-potency  
47  
48 and daily cannabis users might develop psychotic disorders at least partially independently of the  
49  
50 occurrence of severe childhood adversities. However, due to the small sample size, the interaction  
51  
52 between childhood abuse and specific patterns of cannabis use could not be formally tested.  
53  
54

55  
56 [Insert Tables 3 & 4 here]

## Discussions

### *Cannabis use by childhood abuse interaction*

This study found that neither lifetime cannabis use nor reported exposure to childhood abuse were associated with psychotic disorder when the other environmental variable was taken into account. By contrast, the combination of the two exposures appeared to exert a significantly greater effect than the sum of their individual effects suggesting an additive interaction. Nevertheless, after controlling for several covariates, this study found no evidence of interaction between lifetime cannabis use and childhood abuse. This result is consistent with the findings of Kuepper et al.,<sup>9</sup> who reported that the effect of smoking cannabis on psychotic symptoms was not affected by exposure to traumatic events in childhood or adolescence.

### *Effect of type and frequency of cannabis use*

To our knowledge, this is the first study to investigate the different effects of type and frequency of cannabis smoking in relation to the association between childhood abuse and psychosis. Our results suggest that hash-type cannabis and less than daily frequency of use are more likely to combine with childhood abuse in increasing the odds for psychosis. **It could be speculated that the interaction between cannabis use and childhood abuse in psychosis is mostly driven by low potency and less than daily cannabis use.** This might explain why our findings did not replicate the additive interaction described by Harley et al.<sup>7</sup> and Konings et al.<sup>8</sup>

On the other hand, high potency, skunk-like, cannabis and daily smoking seemed to influence the pathway to psychosis both alone as well as in association with childhood abuse in this sample. This confirms the existing literature demonstrating that individuals affected by psychotic disorders are over six times more likely to smoke cannabis every day and to use high-potency cannabis.<sup>10,28,29</sup> Furthermore, previous studies have suggested that the effect of cannabis on psychosis was not confounded by childhood trauma.<sup>28,29</sup> In fact, this is consistent with the view that in complex multifactorial disorders, such as psychotic disorders, individuals who are exposed to a

1  
2  
3 variety of risk factors might develop the disease either because of the specific effect of a particular  
4 risk factor (biological parallelism) or because of a combination of them (biological synergism).<sup>23,30</sup>  
5  
6  
7

### 8 9 10 *Potential mechanisms*

11 According to the sensitization hypothesis, genetically vulnerable individuals exposed early to  
12 environmental risk factors – including childhood adversities and certain illicit drugs – might show a  
13 progressive increase in the dopaminergic response to psycho-social stress that, in turn, might result  
14 in stable changes in dopaminergic reactivity and the development of psychotic symptoms.<sup>31,32</sup>  
15  
16  
17

18 While preliminary animal studies have suggested that housing stress moderates rats' response to  
19 delta-tetrahydrocannabinol (THC),<sup>33</sup> recent evidence suggests that the sensitization process was  
20 bidirectional, so that environmental stress may affect sensitivity to THC but also that THC  
21 administration alters the endo-cannabinoid transmission.<sup>34</sup> Despite these promising findings, the  
22 cross-sensitization between environmental stress and THC has not been fully supported by human  
23 studies.<sup>35-37</sup>  
24

35

### 36 37 *Limitations*

38 Compared with previous studies that reported an additive interaction between cannabis and  
39 trauma,<sup>7,8</sup> our findings are based on a smaller sample and might have been affected by inadequate  
40 power. In fact, *post-hoc* power analysis based on the results of the NEMESIS study<sup>8</sup> suggests that  
41 we had over 95% power to replicate the difference in the prevalence of psychosis amongst cannabis  
42 consumers who were also exposed to child abuse (62.5% vs. 26.5%), but only 44% power to  
43 replicate the analogous difference in the unexposed group (9.2% vs. 4.8%). This could explain why  
44 our study resulted in weaker findings. To our knowledge, the only other study reporting trauma by  
45 cannabis interaction with a similar sample size (N=211) is the one by Harley et al.<sup>7</sup>: the authors  
46 reported an ICR of 17.4 which was suggestive of additive interaction, but the lack of confidence  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 intervals did not allow evaluation of the significance of their results. Thus, further studies of the  
4  
5 interaction between cannabis and trauma are warranted.  
6

7  
8 This study relied on self-reported retrospective information and, thus, results might have  
9  
10 been affected by recall bias regarding traumatic experiences and use of illicit substances. Despite  
11  
12 the fact that the reliability of psychosis patients' reports of earlier abuse has been questioned in the  
13  
14 past, a recent study demonstrated that such reports are stable over time, consistent between  
15  
16 measures, and not affected by current symptomatology.<sup>38</sup> In our sample the prevalence of either  
17  
18 physical or sexual abuse among subjects affected by psychotic disorders was 28% which is higher  
19  
20 than rates estimated for the general population<sup>39</sup> but lower than those reported by literature reviews  
21  
22 of prevalence rates in psychosis patients (50%).<sup>40</sup> This might be related to the very conservative  
23  
24 definition of physical and sexual abuse used in this study, the difficulty in disclosure some  
25  
26 individuals experience during face-to-face interviews, or the tendency to under-report childhood  
27  
28 abuse, especially when involving family members. Reassuringly, though, another first-episode  
29  
30 psychosis sample obtained from an overlapping geographical area and using the same measurement  
31  
32 tool – **but a less conservative threshold** – found almost identical rates of physical and sexual  
33  
34 abuse (31%).<sup>41</sup> **Previous studies on cannabis by trauma interaction have used less conservative**  
35  
36 **definitions of child abuse but still found elevated rates of psychotic phenomena in those**  
37  
38 **reporting exposure to child abuse.**<sup>7,8</sup> **As pointed out by several reviews,**<sup>40,42</sup> **studies on**  
39  
40 **childhood adversities and psychosis have employed a wide range of measures and definitions**  
41  
42 **of early traumas, some of which did not account for severity. While broader definitions might**  
43  
44 **be more sensitive to minor events and contribute to greater generalizability of results, use of**  
45  
46 **narrow definitions of child abuse may be preferable as more severe events are postulated to**  
47  
48 **be more accurately remembered thus reducing recall bias.**<sup>43</sup> Similarly to childhood abuse,  
49  
50 cannabis use was assessed using a semi-structured interview, and was not supported by any  
51  
52 biological measure such as a urine or blood test. However, given that we were interested in lifetime  
53  
54 cannabis use and preferred type of cannabis used, these biological measures would not have  
55  
56  
57  
58  
59  
60

1  
2  
3 improved our study, because they are informative only about current consumption. Indeed, the  
4  
5 strength of the association between cannabis and psychosis was consistent with those reported by  
6  
7 existing literature reviews<sup>2,3</sup> and the prevalence of lifetime cannabis consumption among cases and  
8  
9 controls (69.7% vs. 57.9%) was fairly similar to the rates reported in a partially overlapping sample  
10  
11 (62.5% vs. 56.9%).<sup>10</sup>  
12

13  
14 Furthermore, it is possible that our findings were affected by selection bias, since our sample  
15  
16 included only 231/489 (47%) of the patients and 214/278 (77%) of the controls recruited into the  
17  
18 GAP study.<sup>11</sup> This is because we included only participants who provided exhaustive information  
19  
20 about both their frequency and type of cannabis use as well as the type and severity of childhood  
21  
22 abuse. In addition, there was a small proportion of missing data in one of the covariates (family  
23  
24 psychiatric history), an issue that was addressed by sensitivity analysis. However, our cases and  
25  
26 controls appear similar to those included by Di Forti et al.<sup>11</sup> in terms of the main demographic  
27  
28 variables suggesting their representativeness of the full study sample.  
29  
30  
31  
32

### 33 34 *Conclusions*

35  
36 This study did not replicate previous findings regarding the synergistic effect of cannabis  
37  
38 consumption and childhood abuse on the onset of psychotic disorders. Our findings suggest that,  
39  
40 besides the obvious risk conveyed by heavy use of high potency cannabis, smoking resin (hash) and  
41  
42 less than daily smoking are likely to increase the odds for psychosis when combined with severe  
43  
44 childhood abuse. For that reason, children and adolescents exposed to physical or sexual abuse  
45  
46 might benefit from psycho-social interventions aimed at promoting adaptive coping strategies and  
47  
48 informing them about the health-related risks of substance misuse. Clearly replication of these  
49  
50 results is required before clinical trials to test this proposition could be initiated.
