Recognition of the importance of intraspecific variation in ecological processes has been growing, but empirical studies and models of global change have only begun to address this issue in detail. This review discusses sources and patterns of intraspecific trait variation and their consequences for understanding how ecological processes and patterns will respond to global change. We examine how current ecological models and theories incorporate intraspecific variation. review existing data sources that could help parameterize models that account for intraspecific variation in global change predictions, and discuss new data that may be needed. We provide guidelines on when it is most important to consider intraspecific variation, such as when trait variation is heritable or when nonlinear relationships are involved. We also highlight benefits and limitations of different model types, and argue that many common modeling approaches such as matrix population models or global dynamic vegetation models would allow a stronger consideration of intraspecific trait variation if the necessary data were available. We recommend that existing data needs to be made more accessible, and in some case new experiments are needed to disentangle causes of variation.

39

Introduction

- 40 Recently, many authors have stressed the importance of moving towards 41 more mechanistic models to be able to describe the response of species and 42 ecosystems to global change (Kearney & Porter, 2009; Chevin et al., 2010; 43 Pereira et al., 2010; Schurr et al., 2012). Current mechanistic and process-based 44 models are typically based on species-level traits and properties or even on 45 functional types, but some models are beginning to account for the fact that 46 species' traits are neither static nor homogenous in space or time (Bolnick et al., 2011; Violle et al., 2014). For instance, many species exhibit trait differences 47 48 between populations, frequently taking the form of geographic clines that 49 correspond to environmental gradients (Aitken & Whitlock, 2013), and 50 important phenotypic differences also exist between individuals within 51 populations, and even within sex, age, or size classes (Bolnick et al., 2011; 52 Richardson et al., 2014). Such intraspecific variation can strongly influence 53 ecological processes and the conclusions drawn from models thereof (Bovce, 54 1977; Kendall & Fox, 2002; Grear & Elderd, 2008; Kearney et al., 2009; Kramer et 55 al., 2010; Schindler et al., 2010; Oney et al., 2013). Understanding and 56 incorporating variation in traits is therefore important for basic science, for 57 making predictions about global change impacts, and for managing species 58 affected by global change. In this review, we address the following questions:
- 59
- 60 1. What are the sources and patterns of intraspecific trait variation?
- 61 2. When will intraspecific variation be crucial for ecological responses to 62 environmental change?

- 3. How do existing models attempt to address trait variation, and have theircapabilities to do so been fully utilized?
- 4. Are there useful data sources that have been overlooked, or new data thatmust be collected?

We will define "traits" broadly, as including phenotypic characters (e.g. coat color), behavioral or growth characteristics (e.g. fast vs. slow growth rate), or individual-level demographic rates (e.g. expected number of offspring).

Sources and patterns of trait variation

Sources

Intraspecific trait variation may be due to heritable differences

between individuals, or it may be due to phenotypic plasticity in trait values
across varying environmental conditions. Understanding which of these
sources is responsible for trait variability is crucial for predicting global change
responses. If differences in trait values within a population are due to genetic
differences they will be heritable, and therefore population-level means will be
subject to change through natural selection over generational timescales.

Plasticity, on the other hand, enables immediate adjustment of phenotypic traits,
which can buffer a population against rapid environmental change. Plasticity
tends to slow adaptive evolution in the short term by weakening selective
pressures, but by preserving population size and genetic diversity may provide
potential for evolutionary responses in the long run (Crispo, 2008). The degree
of plasticity exhibited in a trait is typically subject to genetic control and can
therefore also evolve. Stable conditions, for instance, can select against plasticity

if it is costly (Crispo, 2008). See also Gomez-Mestre & Jovani (2013), who developed a simple heuristic model to illustrate the potential interactions between plasticity and adaptation.

Epigenetic differences, which affect gene expression but not the underlying genetic code, can contribute to both categories. They contribute to plastic responses, but some can also be heritable over intermediate timespans $(\sim 1-5 \text{ generations})$. For instance, differential DNA methylation in plants can affect traits such as flowering-time or drought tolerance, and their heritability (Fieldes & Amyot, 1999; Zhang et al., 2013). Such heritable epigenetic variation may aid population adaptation to global change, but not all epigenetic effects are adaptive: Rats exposed to pesticides show negative fitness effects over at least 3 generations, likely due to methylation changes (Manikkam et al., 2012). Broadly speaking, any phenotypic effect not due to genetics might be said to be epigenetic. However, as discussed above, "plasticity" refers to non-heritable changes in phenotype due to environmental variation (Scheiner & Goodnight, 1984), while the epigenetic effects that have received the most research attention are heritable (Richards, 2011). As the molecular basis of phenotypic plasticity becomes better understood, we may need to develop new terms distinguishing epigenetic mechanism with short-term vs. long-term effects.

Disentangling these different sources of trait variation is often challenging (Gienapp *et al.*, 2008). Plasticity can lead to trait variation between populations even when they are genetically highly similar (Crispo, 2008). Common garden experiments or pedigree studies are needed to distinguish plastic and heritable variation (Wilson *et al.*, 2010; Aitken & Whitlock, 2013; Blanquart *et al.*, 2013),

though distinguishing heritable genetic and epigenetic effects presents further challenges (Richards, 2011).

Moreover, which sources of variation are most important in real ecological systems is still poorly understood. In recent years, more researchers have begun to consider the consequences of genetic variation and evolutionary adaptation in studies of global change responses (Moran & Alexander, 2014), but epigenetic mechanisms and maternal effects are still rarely addressed (Bossdorf *et al.*, 2008). For most species, the cause of observed trait variation remains unknown.

When genetic and plastic effects on trait values are disentangled for current global change responses, the contribution of plasticity has been larger in many systems (Hoffmann & Sgro, 2011), but this likely reflects the relatively short timespans involved. Heritability for traits strongly related to fitness (eg. fecundity) is generally lower than for behavioral or morphological traits, but significant heritability (and therefore potential for responses to selection) often exists even in these traits (Mousseau & Roff, 1987). Where heritable changes have been observed in response to global change, it is generally in species with short generation times, high fecundity, and/or large population sizes – the types of species one would expect to exhibit more rapid evolutionary change (Moran & Alexander, 2014).

Patterns

Within a population or geographic area, trait variation can be **structured** (varying in a consistent or predictable way) or **unstructured** (random) with respect to space, time, or kinship. For instance, variation due to sex differences

in mammals and birds would usually be considered unstructured, because stochastic processes typically determine sex, as would variation due to annual fluctuations in an environmental variable around a stable mean. Persistent differences between individuals in space or time (in behavior, growth rate etc.) are structured variation. Such differences may either be due to heritable differences, or to persistent environmental differences that cause plastic responses. Natural history data can be useful in determining whether variation is likely to be structured (Kendall & Fox, 2002). This can be important – for example, misattributing structured variation to demographic stochasticity can lead to overestimation of extinction probabilities (Fox & Kendall, 2002).

Structured variation in traits across populations or large geographic areas can often be related to environmental gradients (Figure 1) or to geographic structure. If the variation is heritable and dispersal is very low, lack of genetic variation may inhibit adaptation to changing conditions; if dispersal is extremely high, the movement of alleles between heterogeneous environments may counteract local selective pressures (Aitken & Whitlock, 2013). If differences are due adaptive plasticity (trait changes that increase fitness in the new environment), it will facilitate gene flow by reducing the costs of dispersal, whereas maladaptive plasticity (eg. smaller size or lower fecundity when stressed) will do the opposite (Crispo, 2008).

Influences of intraspecific variation on ecological processes

One way that ecological processes can be affected by trait variation is due to non-linearity in the relationship between the variable trait and the response of interest, which is expressed by a mathematical relationship called **Jensen's**

inequality (Ruel & Ayres, 1999; Bolnick *et al.*, 2011). This states that when the relationship between a random variable x and a response variable y is nonlinear, the expectation for y differs depending on whether we use the mean of x, or the whole distribution. Specifically, if the relationship y = f(x) is concave-up, then E[y] > f(E[x]) and if it is concave-down (convex), then E[y] < f(E[x]). To give an example: seeds produced per unit pollen declines with increasing pollen deposition; when pollen deposition varies, the average seeds per flower is lower than predicted based on the average pollen deposited per flower (Richards *et al.*, 2009). Similarly, genetic variation in host insects that leads to variation in number of eggs per seed can stabilize host-parasitoid population dynamics via Jensen's inequality (Imura *et al.*, 2003).

Biology is rife with non-linear relationships (Benton *et al.*, 2006), and therefore there are many situations where using the trait mean in a process does not lead to the same result as using the whole trait distribution. This can be particularly important in predicting population growth and viability. For instance, unstructured variation in survival probabilities or offspring number between years typically reduces the long-term average growth rate in population models (Boyce, 1977), which increases the extinction probability in small populations (Kendall & Fox, 2002). The form of the non-linear relationship determines how variation affects the responses. If a matrix model is constructed with even age/size bins, survival for the individuals within the bin will be estimated well for a linear type II survival curve, but for a type III curve with high juvenile mortality the survival of the younger classes will be underestimated, and for a type I curve with late mortality the survival of older

classes will be overestimated. This, in turn, leads to under- or over-estimation of population growth, respectively (Grear & Elderd, 2008).

The type of variation most frequently included in population models is demographic stochasticity, which refers to variation in population growth rates resulting from random variation in survival or reproduction (Bolnick *et al.*, 2011). This process is most important in small populations, because as population size increases the mean survival or reproduction in a given year will approach the true population mean. Genetic drift resulting from demographic stochasticity can lead to random evolutionary changes in traits.

Intraspecific variation can also have positive effects on population growth or stability. The **portfolio effect**, for example, arises when intraspecific or interspecific variation reduce the variability of population growth or an ecosystem service in a temporally variable environment (Bolnick et al., 2011). For instance, Schindler et al. (2010) estimated that asynchrony between local populations and variation within cohorts of Bristol Bay salmon led to 2.2-fold lower variability in annual returns than if the population were homogeneous. Intraspecific variation (in the form of trait diversity) can also positively affect average productivity. This can be due to **sampling effects**, whereby the larger the number of species or genotypes included the more likely it is that one with high productivity will be present (similar to the portfolio effect, but in a spatial context), or to **complementarity effects**, whereby species or genotypes use resources differently and thus reduce competition. For example, ecological experiments (Crutsinger et al., 2006) and restoration studies (Bischoff et al., 2010) suggest that intraspecific genetic variation (more maternal families or clones) in plants will often increase primary productivity (eg. 50% increase in

NPP in 12-genotype vs. 1-genotype plantings of *Solidago altissima*) and reduce variation in establishment success. Genetic differences in environmental responses or resource use, cohort or microsite effects, and sub-population effects are all examples of structured variation, though unstructured variation could potentially contribute to these stabilizing or productivity-enhancing effects.

Besides having implications for population- or species-level responses to global change, intraspecific variation may also affect species interactions and community and ecosystem responses. There has been a renewed effort in recent years to link species traits to environmental responses and ecosystem processes (Lavorel & Garnier, 2002), and the need to understand the role of species interactions in global change responses has become increasingly well recognized (Gilman *et al.*, 2010). Variation between individuals in environmental responses, diet, etc. broadens the species niche for the species as a whole (though population- and individual-level tolerances may be narrow), and broadens the range of effects a species may have on its environment, including on other species. Through heritable or plastic effects, global change drivers have the potential to alter species trait means distributions in ways that affect species interactions.

The amount of heritable variation in traits may be particularly important for species interactions. Overall, intraspecific genetic diversity in parameters affecting species interactions (eg. prey choice) tends to increase the number of connections and decrease interaction strength, which in turn tends to increase the stability of the network by dampening population oscillations and reducing the probability of cascading extinctions when a member of the community is lost

(Fridley & Grime, 2010; Bolnick et al., 2011; Wolf & Weissing, 2012). Similarly, mathematical models have shown that heritable variation in prey preference within a predator population can alleviate apparent competition between prey species and affect the dynamics of predator and prey populations (Schreiber et al., 2011) and higher levels of heritable variation in both predator and prev can lead to more stable dynamics (Saloniemi, 1993). The emerging sub-field of community genetics has demonstrated that genetic variation in a "foundation species" (e.g. in phytochemistry of a common plant) can have cascading effects on the abundance and community composition of soil and leaf arthropods. nutrient cycling, and even higher trophic levels (Crutsinger et al., 2006; Whitham et al., 2008). For instance, *Populus* genotypes in a common garden experiment explained more than 70% of microbial community composition and 78% of the variation in microbial biomass (Schweitzer et al., 2008). The amount of variation in plastic responses to global change factors, including shifts in timing and body size, could also affect species interactions. For instance, if a plant and a pollinator shift their phenology different amounts in response to climate change. this could result in a mismatch in timing that may negatively affect one or both populations (Gilman et al., 2010) – but if either population exhibits variation in the extent of the shift, this mismatch would be alleviated. Evolutionary processes not only can alter trait means and variability (Figure 2D), but in some cases can affect population dynamics directly. In 'hard

(Figure 2D), but in some cases can affect population dynamics directly. In **'hard selection'**, there is a threshold that individuals must pass in order to survive or reproduce (e.g., surviving a minimum temperature) independent of population size. The removal of individuals that do not pass the threshold can have a strong impact on population size and persistence (Saccheri & Hanski, 2006). If a

population is exposed to altered environmental conditions, hard selection can reduce its maximum population growth rate below replacement levels. If the population evolves a higher intrinsic rate of population increase (r_{max}) in the new environment before it goes extinct, then it can increase again; this is called evolutionary rescue (Kinnison & Hairston Jr., 2007; Aitken & Whitlock, 2013). In 'soft selection', the strength of selection is frequency and/or density dependent (e.g. the largest 20% of individuals survive), and thus selection may not directly affect population size – though it can affect population cycles if, for example, the competing genotypes have reproductive rates that respond differently to their own density (Saccheri & Hanski, 2006). For colonizing populations, small evolutionary increases in r_{max} in the first few generations can increase the probability of establishment by enabling super-exponential population growth (Kinnison & Hairston Jr., 2007). This seems to have occurred in some invasive species. For instance, invasive populations of salmon in New Zealand accumulated changes in a variety of traits over 26 generations that more than doubled survival and fecundity relative to non-local genotypes (Kinnison & Hairston Jr., 2007). **Shifts in the mean trait value of a population** may change the selective

Shifts in the mean trait value of a population may change the selective environment experienced by co-occurring species, resulting in **eco-evolutionary** interactions (Post & Palkovacs, 2009). Such eco-evolutionary interactions can alter competitive and trophic dynamics. Several notable examples come from cases of introduced species or biological control. Lankau and Strauss (2007) found that genetic variation in *Brassica nigra's* production of sinigrin, an allelopathic chemical, promoted community diversity, and vice versa. Highsinigrin plants did well in heterospecific (newly-invaded) but not conspecific

neighborhoods, causing low-sinigrin plants to tend to increase in areas dominated by *B. nigra*, finally enabling other species to re-invade low-sinigrin patches of *B. nigra* where there was a 1.5 to 8-fold increase in seedling density compared to high-sinigrin patches. In communities invaded by the related *Allaria petiolata*, some resident species also exhibit evolution of increased tolerance to sinigrin, exhibiting up to a 2.8-fold difference in response to competition (Lankau, 2012).

Starting in the 1960's, many models have examined the effect of evolution on the dynamics of two-species systems and have found that evolution can either stabilize or destabilize interactions (Fussman *et al.*, 2007; Hartig *et al.*, 2014). However, the ecological assumptions in these models tend to be relatively simple and there has been limited work on multi-species systems (Fussman *et al.*, 2007). One of the best documented empirical examples is that of myxoma virus and rabbits in Australia: the virus was introduced as a biological control but, as has been observed in other host-parasite systems, evolution led to both reduced virulence of the virus and reduced susceptibility of the host (Fussman *et al.*, 2007), dampening oscillations and making population crashes less likely.

Dispersal is a further crucial component for understanding the effects of trait variability on global change responses within species and communities, as it **affects both the probability of range shifts and population expansion as well as the potential for evolution** (Aitken *et al.*, 2008; Kubisch *et al.*, 2014). The interaction between dispersal and evolution, coupled with interspecific interactions, will likely determine the extent to which species respond to climate

change via either range shifts or local adaptation (Brooker *et al.*, 2007; Aitken *et al.*, 2008; Atkins & Travis, 2010; Bocedi *et al.*, 2013).

Dispersal ability is a trait that can evolve and exhibit plasticity itself (Ronce, 2007). Variation in dispersal affects population spread rates. Dispersers are likely to be a non-random subset of the population in terms of their behavior (Wolf & Weissing, 2012), size, or other traits (Nathan *et al.*, 2011). This may result in important structured variation between new and old populations, and can result in selection on dispersal traits (Shine *et al.*, 2011). Such increases in dispersal ability have been documented in the invasive cane toad and invasive plants, as well as in insects undergoing climate-linked range expansions, and can accelerate range shifts (Shine *et al.*, 2011). Conversely, if most dispersers have low survival due to unsuitability of the matrix between habitat patches, or if poor dispersers are left behind, selection or trait sorting can favor reduced dispersal ability (Shine *et al.*, 2011; Travis *et al.*, 2012; Moran & Alexander, 2014). However, these changes in dispersal traits may be transitory on a population scale, as dispersal ability can trade off with other traits (Travis *et al.*, 2012), such as competitive ability, that are more important in high-density populations.

Besides evolving itself, dispersal ability strongly affects the amount of local genetic variation in populations. This local variation tends to increase the speed of evolutionary responses because alleles advantageous in new environment may already be present at moderate frequencies (Barrett & Schluter, 2007; Wolf & Weissing, 2012). Because species that have small or highly fragmented populations and low genetic diversity may have limited potential for adaptation to changing future conditions, managers are increasingly considering "genetic restoration" or assisted movement to boost local genetic

diversity (Hoffmann & Sgro, 2011; Aitken & Whitlock, 2013). The direction of gene flow also matters: gene flow from historically warmer areas and between areas of similar historical climate may increase the probability that alleles advantageous under climate change will be present; gene flow from the range center toward the trailing edge, however, is likely to be unfavorable (Moran & Alexander, 2014).

Modeling approaches and current applications incorporating intraspecific

variation

Population models

Three common approaches for modeling trait variability in local populations are matrix models (MM), integral projection models (IPMs), and individual-based models (IBMs). All three can incorporate unstructured variation by adding stochastic effects to account for "random" environmental variation or demographic stochasticity. All can also include population-ecological relationships such as density dependence. They differ more strongly in their ability to include structured variation. All approaches can be incorporated into landscape- or range-wide models, as discussed in the next section.

Matrix models are an extension of classical population models – instead of modeling one population with uniform trait values they divide a population into several age or size classes, each of which is uniform in its trait values. A transition matrix represents fecundity, mortality and the transition between classes. The obvious limitation of these models is that they neglect variation in demographic rates within classes (Boyce, 1977). Particularly if there is size-

dependent growth or growth correlations within classes (2B), this can lead to errors in prediction (Pfister & Stevens, 2003). Careful use of natural history to define age or stage divisions (Figure 2A) will reduce, but may not eliminate, this problem (Grear & Elderd, 2008).

Matrix models can include structured variation in phenotypic traits, even heritable variation, but only if the traits are discrete, and the mode of inheritance simple. For instance, Kruger and Lindstrom (2001) divided buzzards into three color morphs which differed in reproductive success. In stage-based models, the distribution of ages within a stage or variation in the length of time an individual occupies a stage can affect dynamics, especially transient dynamics (de Valpine *et al.*, 2014).

Integral projection models (IPMs) can be viewed as an extension of matrix models, where differences within a population are modeled by continuous distributions instead of discrete classes (Ellner & Rees, 2007). Compared to matrix models, this makes it easier to incorporate multiple differences between individuals, such as differences within a size or age class (Zuidema *et al.*, 2010; de Valpine *et al.*, 2014).

Heritability can be included in more complex IPMs by introducing a distribution of trait values within an age class, and making this distribution in offspring traits dependent on parental traits (Coulson *et al.*, 2010). Changes in the environment (Hoffmann & Merila, 1999) and in the amount of genetic variation in a population due to immigration, selection, or bottlenecks (Bryant *et al.*, 1986; van Straalen & Timmermans, 2002; Lavergne & Molofsky, 2007) can affect heritability. Model projections based on a fixed heritability estimate should therefore only be applied over short time periods. While cumulative

effects (such as survival effects of past reproduction) are typically not included in an IPM, age-class models can identify differences in individual growth rates because fast growing individuals will be unusually large for their age. For instance, Jansen et al. (2012) found that in a tropical understory palm growth differences between individuals persisted over a lifetime and that fast growers had a 1.8-fold greater contribution to population growth. IPMs can also be used to explore trait evolution using an evolutionarily stable strategy (ESS) approach, though this does not account for transitory dynamics (Ellner & Rees, 2007).

Individual-based models (IBMs), as the name suggests, model a population by describing each individual separately, using state variables such as age, size, location, genotype, and fecundity (Grimm & Railsback, 2005). This allows tracking cumulative changes over the lifecycle of each individual (e.g. increasing size or reproductive history), as well as any conceivable variation between individuals, including genetic variation in environmental responses.

Besides evolution, they can also incorporate spatial heterogeneity and individual movement (DeAngelis & Mooij, 2005; Dytham *et al.*, 2014).

There are a number of additional advantages associated with an individual-based approach. Like real populations, IBMs have a discrete number of individuals rather than a continuous value, making them naturally suitable for capturing effects of demographic stochasticity in small populations, as well as for simulating spatial dynamics within a population. Also, they allow one to explicitly model allelic frequency and diversity, avoiding the problem of assuming constant heritability. For instance, Kuparinen *et al.* (2010) simulated the evolution of growing-season timing in *Pinus* and *Betula*, using a simple multi-

locus model of bud-burst and bud-set date, over 100 years of climate change, and found that a higher adult mortality rate reduced evolutionary lags.

Due to these advantages, and supported by growing computing power which makes it possible to simulate large numbers of individuals, IBMs have become increasingly popular. A common application is individual-based forest gap models that project the influence of environmental factors on productivity and species composition (Smith *et al.*, 2001). Individual-based models are also used for fisheries models and for population viability analysis (DeAngelis & Mooij, 2005; Frank *et al.*, 2011). Comparing IBMs with different levels of detail to data from real systems can help to identify which types of variation are most important in these systems (DeAngelis & Mooij, 2005; Benton, 2012). IBM simulations can also be used to test when the simplifying assumptions of other model classes are likely to lead to problems (Pfister & Stevens, 2003).

Modelling landscape- or range-scale dynamics

In many global change applications, the focus is not so much on describing the change in local populations, but rather on capturing spatial structure and large-scale dynamics. For this purpose, two approaches exist that allow including trait variability. The first consists of using known spatial extensions of the above-described process-based population models. The second is to extend widely used statistical approaches such as correlative species-distribution models to include trait variability. We cover both options in this section, as well as the application of these concepts in dynamic vegetation models.

Metapopulation or metacommunity models are extensions of nonspatial population models that describe spatial structure through assuming a number of connected local populations (Ovaskainen & Hanski, 2004). Within each local population (patch), population dynamics may be modeled using any of the approaches previously described. For example, the CD FISH model, a simulator incorporating population genetics, demography, and stream connectivity, has shown how landscape-level connectivity in stream systems can constrain population vulnerability to environmental change in salmonid species (Landguth et al., 2014). Spatial Integral Projection Models (SIPMs) combine IPMs with models of dispersal to predict spread across a landscape (Jongejans et al., 2011), which can be useful in understanding the spread of invasive species or native species under climate change. In principle, this approach allows one to naturally scale-up the effects of intra-specific variation within and between populations to examine its impact on larger scales. In practice, the computational demands of this approach often limit the size of the landscape that can be simulated.

Species distribution models (SDMs) aim to predict the occurrence probability of a species given environmental variables and therefore the limits and size of its geographic range. The simplest and still most common approach is to correlate presences (and absences if available) with environmental variables. Various criticisms have been against correlative SDMs, mostly relating to the fact that the realized niche (where the species does occur) can differ from the fundamental niche (where it could occur) for a number of reasons, including disequilibrium with the environment, biotic interactions, and

dispersal and source-sink dynamics (Guisan & Thuiller, 2005). Still, correlative SDMs are widely used because they make use of the museum or herbarium records and climate data that are easily available (Moran & Alexander, 2014).

Due to the challenges of using correlative SDMs to predict range dynamics, particularly in the presence of biotic interactions, intraspecific variability and evolutionary potential, there has been a steady movement towards including more processes in these models (Dormann et al., 2012). For example, physiological SDMs make use of knowledge about physiological limits (Porter et al., 2002; Buckley, 2008; Rödder et al., 2009; Buckley et al., 2011) and behavior (Kearney et al., 2009). While most physiological SDMs to date have been applied to ectothermic organisms or plants, known relationships of body size to metabolic rate and/or heat exchange (Yarbrough, 1971) could be more widely applied to birds or mammals as well. **Hybrid SDMs** add a dispersal model on top of a classical SDM (De Cáceres & Brotons, 2012) (Marion et al., 2012), while **Dynamic Range Models** include both explicit population dynamics and dispersal (Schurr *et al.*, 2012). SDMs can also be "stacked" to examine effects of environmental changes on biodiversity, either assuming that species distributions are independent (Guisan & Rahbeck 2010) or interacting (Clark et al., 2013).

In all such extensions of classical SDMs, intraspecific differences can be included in principle, but such applications are still rare. When intraspecific differences are included, the most common approach is to describe **differences** in the environmental response of subpopulations by fitting separate SDMs to each subpopulation across a species' range. This has mainly been done in trees, for which good provenance (common garden) study data are often available

(Savolainen *et al.*, 2007). An example is the Phenofit model, which predicts tree presence based on the link between phenology and reproductive success, can allow different populations different responses (Chuine & Beaubien, 2001). Incorporating intraspecific population variation in that way can alter predictions of global change responses, making them either more (Valladares *et al.*, 2014) or less (Garzon *et al.*, 2011) severe. For instance, incorporating population-level differences in *Pinus contorta* yielded similar results to a species-level model for current distribution, but the models incorporating genetic diversity projected less than half as much range loss even without migration (Oney *et al.*, 2013). Ideally, such studies will be based on or complemented by data confirming genetic differences in environmental responses, as apparent differences between subpopulations could also be caused by biotic interactions or other non-genetic factors.

There are multiple examples in the recent literature of metapopulation or SDM models being used to investigate the potential impact of evolution on global change responses. For instance, using sequentially updated SDMs, Urban *et al.* (2007) showed that the maximum annual temperature of areas occupied by the invasive cane toad (*Chaunus* [*Bufo*] *marinus*) had increased from 1975 to 2005, interpreted by the authors as niche expansion into increasingly extreme habitats. Models can also identify when such adaptation could alter dynamics. Kearney *et al.* (2009) developed a mechanistic niche model incorporating a quantitative genetic model to investigate whether evolution of egg desiccation resistance in the dengue mosquito *Aedes aegypti* might enable it to expand its range, and found that it would take 17.4% less time to reach Darwin under climate change

with a heritability 0.5 vs. 0.15. Similarly, a dynamic vegetation model developed by Kramer *et al.* (2010) to explore climate change responses in European beech incorporated a quantitative genetic submodel for budburst and stomatal conductance, and found that adaptive changes could occur at the leading and trailing edge over just 2-3 generations. Interactions between landscape features, the evolution of dispersal traits, and spread rates can also be investigated with IBMs (Travis *et al.*, 2012).

An important caveat is that most models that aim to project the effects of evolutions, with a few exceptions (Kramer *et al.*, 2010), have not been systematically validated, for example by reproducing the current pattern of local adaptation. We suggest that results should therefore not be interpreted as predictions, but rather as indicators that suggest a potential impact of evolution on environmental responses. It is also unclear how well the true genetic structure of ecologically important traits are approximated by the assumptions made in particular models (e.g. ten two-allele loci), and it is increasingly recognized that models of species presence or persistence need to take into account phenotypic plasticity (Chevin *et al.*, 2010; Valladares *et al.*, 2014).

Dynamic global vegetation models (DGVMs) are individual- or population-based population models that have a focus on predicting the composition and dynamics of the vegetation by describing physiological processes such as photosynthesis and water uptake, biotic interactions, and disturbances. In principle, the structure of these models is well suited to assess the effects of intraspecific variability in those processes. However, due to data limitations and computational constraints, most DGVMs currently still describe

vegetation dynamics and community interactions in terms of broad functional types that summarize a potentially large group of similar species. Hence, potential for improvement exists regarding the representation of interspecific as well as intraspecific trait differences (Hartig *et al.*, 2012).

In recent years, various studies have considered options to include trait variability in DGVMs. One approach is motivated by the observation that environmental drivers explain 52% of global variation in traits (van Bodegom et al., 2014). Allowing traits to vary within PFTs following observed trait-climate relationships can therefore improve the match of predicted to observed vegetation types (Verheijen et al., 2013). Similarly, Stahl (2014) demonstrated that a few easily-measured species-level traits could help predict environmental range limits in trees, which could impose useful constraints on a DGVM. Rödder et al. (2009) found that including physiological limits in an SDM for slider turtles enabled better prediction of their invasive range; including similar limits on vegetation types could provide similar benefits in DGVMs. Trait variation could also be assumed to arise from a large potential for plasticity (Nicotra et al., 2010) or genetic variation (Kramer et al., 2010; Valladares et al., 2014). Adaptive global dynamic vegetation models construct communities of trait combinations by filtering those traits that are most competitive and able to coexist in a given environment (Scheiter et al., 2013).

To conclude the review of the state-of-the-art in the field of modelling trait variability: all commonly used population model types could accommodate trait variability to a much greater degree than is the current practice. When trait variability is included, conclusions can be substantially altered. The inclusion of

trait variability has been limited by computational and data constraints. The former constraint is easing as computers become more powerful, the latter will be discussed in the next section. Finally, we emphasize that no one modeling approach is ideal for all situations, but that model choice rather depends on how the model will be used and whether there is sufficient data and/or understanding of process to parameterize and justify a more complex model.

Data and methods for parameterizing models that include trait variation and trait evolution

Recent advances in modeling techniques (see above) provide increasing flexibility to ecologists and evolutionary biologists to model and understand the consequences of trait variation. However, they also highlight the need for gathering new data that allows more direct estimates of structured and unstructured trait variation, and the need of making existing data better available to researchers.

Data sources

Especially at the local scale, useful data for estimating variation in important traits or demographic rates often already exist. For example, data on phenotype, growth, fecundity, and survival are typically collected at the individual level (Clark *et al.*, 2011), enabling one to construct trait distributions. If multiple measurements are available for each individual, structured variation (e.g. individuals that consistently grow faster or slower) can be distinguished from unstructured variation. Such longitudinal data can also be used to disentangle plastic versus evolutionary responses to global change, using approaches such as the 'animal model' (Gienapp *et al.*, 2008) – especially if family

relationships are also known. For instance, phenotypic plasticity in red squirrels accounted for 62% of an 18-day advance in average birth date, while 13% was attributable to evolutionary change (Berteaux *et al.*, 2004).

However, data are rarely synthesized in this manner, and instead are usually aggregated for analysis – for instance, into species-level means and variances (Clark et al., 2011). Unless the original data are included as an appendix, it is usually impossible to obtain the individual-level measurements from the published literature, which greatly complicates meta-analysis and means that information can easily be lost. Fortunately, journals and funding agencies have been encouraging or, more recently, requiring researchers to archive data in a more accessible format. Trait databases are currently being constructed for many taxa. Plants seem to be better represented than animals (but see the linked trait databases at http://scales.ckff.si/scaletool/). The TRY database, for instance, contains 5.6 million trait entries for 100,000 plant species around the world, and preliminary analyses showed that up to 40% of overall variation in a trait can be intraspecific (Kattge et al., 2011). Such data can be used to better define plant functional types, and to give an idea of the range of values a trait may take within a species, though for many species it is as yet too patchy to, for example, compare trait distributions between multiple populations of a species.

Large-scale observational networks can also provide useful data. Again, this kind of data tends to be more abundant for plants than for animals. For instance, Forest Inventory and Analysis (FIA) censuses have tracked tree sizes and identities in plots across the United States for decades, and such data can be used to examine variation in global change responses between life stages, species

types, or regions, or to parameterize individual-based forest models (Canham *et al.*, 2006; Bell *et al.*, 2014). The new National Ecological Observatory Network (NEON), now coming online, while not explicitly geared to investigate intraspecific variation, will be collecting data such as size and reproductive status for select species, phenology, soil microbial metagenomes, as well as detailed measurements of the physical environment (Keller, 2010). Data on plants' plastic phenological responses to climate can be obtained from both observation networks (eg. https://www.usanpn.org/) and meta-databases.

However, to fully investigate the role of intraspecific variation in species' environmental responses, new data specifically collected for this purpose are needed. In addition to the need for accessible trait-variation data for a broader range of species, some research questions, such as those relating to the role of evolution in global change responses, require specialized experiments or observations. For instance, while provenance study data can be useful for understanding tree responses to climate, these studies rarely included very long-distance transfers, or populations from or test sites at the environmental limits (Leites *et al.*, 2012). Another important consideration is that covariation in traits can be important for population and eco-evolutionary dynamics, so sampling schemes should be designed to make calculation of covariances possible - long-term demographic data are particularly valuable (Saether & Bakke, 2000).

Theoretical models can suggest where it is important to consider variation, and therefore where more data is required. For instance, key factors affecting the potential rate of evolutionary change, and therefore the probability of extinction or persistence in a population facing environmental change, include demographic properties of populations (e.g. generation time and maximum

population growth rate), the strength of selection, and the available genetic and environmental variance in the key traits (Chevin *et al.*, 2010). They can also suggest when the costs of selection might lead to extinction (Burger & Lynch, 1995). Gienapp et al. (2013) provide a good example of applying such models to real populations. Another key area in which more data is needed to understand global change responses is range shifts, as it is unknown in most cases whether species ranges are currently limited by abiotic factors, biotic interactions, dispersal, or lack of genetic variation (Sexton *et al.*, 2009).

Distinguishing genetic (or epigenetic) variation from plastic responses to the environment tends to require either detailed, long-term observational data that enables one to build a pedigree (Wilson *et al.*, 2010) or common-garden experiments in which different genotypes are reared in one or more common environments (Blanquart *et al.*, 2013). Unlike the incidental individual-level data discussed above, which may be able to generally distinguish structured vs. unstructured variation, these types of studies are usually specifically designed to investigate the genetic components of intraspecific variation. They are thus extremely valuable for understanding how and when to include genetic variation in models of environmental responses. However, because of high cost in time and money, these studies are rarer than short-term observational trait measurements, and have similar issues of accessibility if the data have not been archived.

If we could better identify the genetic basis of the trait(s) of interest, extrapolating heritabilities outside of tested environments would become more feasible. Genome-wide association studies (GWAS), usually making use of single-nucleotide polymorphisms (SNPs) are becoming more widely used as a means of

identifying candidate genes for particular traits of interest. SNP variation can be correlated either with variation in phenotype (e.g. water use efficiency), or with variation in environment (e.g. climatic water deficit) (Neale & Kremer, 2011). Results are usually qualitatively consistent with other approaches. However, the amount of variation explained is typically lower than the total heritability because rare variants unique to local families are often missed, multiple functional alleles may exist, and linkage disequilibrium and epistasis may interfere with the analysis (Brachi *et al.*, 2011). Some of the missing heritability may also be attributable to epigenetic variation (Bossdorf *et al.*, 2008). A rangewide sample will have low power to detect significant associations with phenotype if adaptive alleles are locally common but globally rare, so sampling must be structured to account for this (Brachi *et al.*, 2011). Methods for incorporating realistic functional genetic submodels into models of species' responses to global change are still in the early stages of development.

Neutral genetic variation (e.g. microsatellites), while not always closely correlated with functional variation (Holderegger *et al.*, 2006), is useful for estimating the degree of gene flow between populations, hybridization, or dispersal ability (Aldrich *et al.*, 2003; Ashley, 2010; Moran & Clark, 2012). Dispersal ability and population connectivity can also be estimated based on physical traits in systems for which there are good mechanistic models, such as wind dispersal of seeds (Kuparinen, 2006), via inverse modeling of observations of dispersed individuals (Jones & Muller-Landau, 2008), or through tracking of tagged individuals. Regardless of the method, it is advisable to take into account intraspecific variation – for instance, considering that adult trees may vary in seed production.

A further challenge connected to data on trait variability is statistical analysis and the connection of these data to models. Many of the data types we have discussed above should probably be treated with hierarchical statistical models that allow including underlying dependencies between traits as well as spatial, taxonomic and phylogenetic structure in the data. Such multilevel models describe how individual responses vary according to the context, help avoid over-fitting because they don't use independent "individual" parameters, and enable the proper propagation of uncertainty from parameters to predictions (Clark, 2003). If vital rate calculations are based on capture-recapture methods, it may also be important to account for size- or stage-effects on capture or detection probabilities (Punt *et al.*, 2006).

For process-based models such as IPMs, DRMs (Dynamic Range Models), or DGVMs, data can be used in two ways: one can use statistical approaches to infer individual parameters or subsets of the model parameters first, and then use the process-based model to calculate the consequences of those parameter estimates. An alternative is to infer model parameters inversely for the entire model simultaneously, using the raw observations. For DRMs and SDMs, for example, this is often still possible in a hierarchical Bayesian approach (Bykova et al., 2012; Marion et al., 2012). For more complex models such as DGVMs, it may become necessary to resort to simulation-based inference methods to calibrate model parameters (Hartig et al., 2011). Bayesian approaches allow mixing parameter estimates from independent analysis and from calibration, which allows a flexible mix of both approaches (Hartig et al., 2012).

When variation matters

Generally, intraspecific variation is likely to be important for understanding responses to global change a) for phenotypic traits that affect demography, b) when the relationship of interest is a non-linear function of the trait (Jensen's inequality), c) in small populations, where demographic stochasticity can cause mean demographic rates or phenotypic traits to fluctuate. d) when variation in the trait of interest is structured (because structured variation cannot be accounted for merely by adding stochasticity to a model). and e) if the timescale of interest spans multiple generations, and the trait is likely to be under directional selection (e.g. drought tolerance in a warming environment). Mechanistic models can be helpful in identifying which traits or demographic rates have the largest effect on a process of interest, and where variation might be most important. For instance, Nathan et al. (2011) found that for wind-dispersed trees, the plant traits most important for migration rate tended to be 1) age at maturity, 2) post-dispersal survival, 3) seed terminal velocity, 4) fecundity, 5) tree height, and 6) time between seed crops. Conversely, natural history data can suggest what traits should be allowed to vary in models: in *Pinus sylvestris*, for instance, there is little variation in seed wing loading because seed mass and wing size are correlated, but isolated trees have more seeds than those in dense populations (Debain *et al.*, 2003). *Incorporating variation in global change models* Although models differ in their ability to include trait variation, it seems from our analysis that the opportunity for including and analyzing trait

variability hasn't been fully explored or exploited in any of the modeling approaches we considered. The main reason seems the lack of data and computational restrictions. As both limitations should ease in the coming years, we hope that these capabilities will become more widely used.

Data needs for the future

Computational limits can be expected to improve without active effort of the ecological community, but the limits on data will not. Existing data collected at the individual level should be more frequently used to investigate intraspecific variation. The growing availability of databases and data archives mean that future meta-analyses and models will be able to rely less heavily on published trait statistics and therefore will be able to address variation more accurately. However, for distinguishing causes of structured variation that may have different effects (e.g. genetic vs. environmental) more specialized experiments are required. Data from these variation-focused studies also needs to be made more widely available.

Summary

Intraspecific variation has been gaining attention in ecological theory. Empirical studies quantify and classify variation in real populations, while developments in modeling techniques enable the effects of variation to be assessed in more sophisticated ways. Successfully integrating theoretical insights with these new data and modeling techniques will be crucial for making robust predictions of species responses to global change.

1118	Figure Captions
1119	Figure 1: At the landscape scale (top), trait variation is shaped by large-scale
1120	environmental gradients. Within local sites (bottom), phenotypic variation in
1121	each species is shaped by genetic variation and by plastic responses to the local
1122	biotic and abiotic environment. This variation affects species interactions with
1123	one another and with the environment, ultimately impacting individual fitness.

Differences in fitness feed back to affect genetic variation. Local genetic variation is also affected by dispersal between populations (white arrows at top).

Figure 2: A) Variation in a trait deriving from developmental processes (e.g. changes in offspring number with size or age) can be accounted for – for example, by defining age/size classes to minimize intra-class variation (dashed lines). However, variation in natural populations is not so simple. B) If growth rate and offspring number both depend on current size, then small differences in initial size can cause the relationship between age and fecundity to vary between individuals. In this example, larger individuals grow faster. C) Even without such growth correlations, individuals can differ in the relationship between the predictor and response variables, affecting the shape of the function. D) If such differences are heritable, then trait distributions and the population processes that depend on them may change over time.

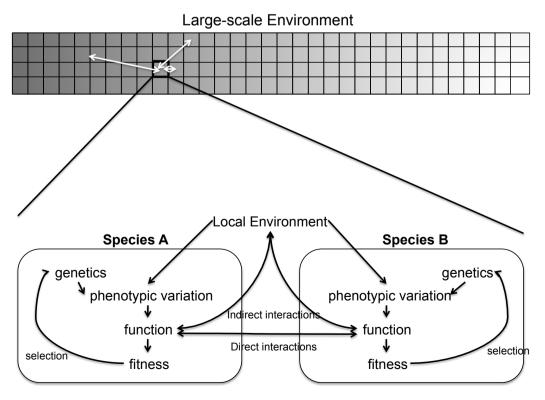

Figure 1
