Abstract

31 The planetary boundary layer height (BLH) governs the vertical transport of mass,

32 momentum and moisture between the surface and the free atmosphere, and thus its

33 characterization is recognized as crucial for air quality, weather and climate. Although

34 reanalysis products can provide important insight into the global view of BLH in a

35 seamless way, the in situ observed BLH on a global scale remains poorly understood

36 due to the lack of high-resolution (1-s or 2-s) radiosonde measurements. The present

37 study attempts to establish a near-global BLH climatology at synoptic times (0000 and

38 1200 UTC) and in the daytime using high-resolution radiosonde measurements over

39 300 radiosonde sites worldwide for the period 2012 to 2019, which is then compared

40 against the BLHs obtained from four reanalysis datasets, including ERA-5, MERRA-2,

41 JRA-55, and NCEP-2. The variations of BLH exhibit large spatial and temporal

42 dependence, and as a result the BLH maxima are generally discerned over the regions

43 such as Western United States and Western China, in which the balloon launch times

44 mostly correspond to the afternoon. The diurnal variations of BLH are revealed with a

45 peak at 1700 Local Solar Time (LST). The most promising reanalysis product is ERA-

46 5, which underestimates BLH by around 130 m as compared to radiosondes. In addition,

47 MERRA-2 is a well-established product and has an underestimation of around 160 m.

48 JRA-55 and NCEP-2 might produce considerable additional uncertainties, with a much

49 larger underestimation of up to 400 m. The largest bias in the reanalysis data appears

50 over the Western United States and Western China and it might be attributed to the

51 maximal BLH in the afternoon when the boundary layer has grown up. Statistical

52 analyses further indicate that the biases of reanalysis BLH products are positively

53 associated with orographic complexity, as well as the occurrence of static instability.

54 To our best knowledge, this study presents the first near-global view of high-resolution

55 radiosonde derived BLH and provides a quantitative assessment of the four frequently

56 used reanalysis products.

57 **Keywords**. Radiosonde; boundary layer height; reanalysis; sensible heat flux

1. Introduction

The planetary boundary layer (PBL) and its evolution has a profound influence on research fields such as air quality (Stull, 1988; Li *et al.,* 2017), boundary layer cloud and fog (Liu and Liang, 2010), convective storm (Oliveira *et al*., 2020) and global warming (Davy and Esau, 2016), among others. It is well known to be influenced by radiative cooling at night and by downward solar radiation reaching the ground surface at daytime, respectively, forming a stable boundary layer (SBL) and convective boundary layer (CBL), with a typical boundary layer depth (BLH) of less than 500 m and 1–3 km (Zhang *et al.,* 2020a), respectively. For climate models, most of the PBL processes occur at sub-grid scales and thus are either underrepresented or not fully represented (von Engeln and Teixeira, 2013). Meanwhile, there are many problems in elucidating the PBL processes using numerical model simulations (Martins *et al.,* 2010), even over the relatively homogeneous ocean (Belmonte and Stoffelen, 2019), which is likely due to the scarcity of fine-scale vertical observations of the atmosphere.

Over the oceans Belmonte and Stoffelen (2019) performed a climatological comparison between state-of-the-art reanalysis and scatterometer surface winds in the PBL, revealing mean and transient PBL model errors. Houchi *et al.* (2010), based on high-resolution radiosondes, verified the climatological wind profiles and found in particular a factor of 2–3 lower wind shear simulated by the European Centre for Medium-Range Weather Forecasts (ECMWF) model. Wind shear is recognized to be able to significantly modulate turbulent mixing of atmospheric pollutants (Zhang *et al.,* 2020b), and thus the inabilities of the model in this regard may have repercussions for air quality prediction.

The temporal and spatial variations in BLH have been extensively assessed in previous studies at a regional or national scale, such as the contiguous United States (Seidel *et al.,* 2012; Zhang *et al.,* 2020a), Europe (Palarz *et al*., 2018), China (Guo *et al.,* 2016; Zhang *et al*., 2018, Su *et al*., 2018), Arctic and Antarctic (Zhang *et al*., 2011), which are mainly implemented by radiosonde measurements, reanalysis or both. And

86   notable diurnal and seasonal cycles have been revealed (e.g., Guo *et al.,* 2016; Short *et*

87   *al.,* 2019). Besides the regional results, several attempts have been made to provide

88   global-scale retrievals of BLH using the Global Positioning System radio occultation

89   (GPS RO) and Integrated Global Radiosonde Archive (IGRA) version 2 (Seidel *et al.,*

90   2010; Gu *et al.,* 2020; Ratnam and Basha, 2010), in which seasonal variations and

91   maritime-continental contrasts of BLHs have been achieved. The measurements of GPS

92   RO, at a vertical resolution of 100 m around the PBL top, are typically used to determine

93   BLH by searching for the altitude with a sharp gradient in the refractivity profile (Basha

94   *et al.,* 2018). However, such sharp gradient of refractivity might overestimate BLH

95   compared to other methods that the community usually used, such as the parcel method

96   (Seidel *et al.,* 2010). Compared with high-resolution soundings, IGRA is sparsely

97   sampled in the vertical, which could result in large uncertainties in estimating BLH.

98   Likewise, additional errors could be introduced in reanalysis products for their sparse

99   vertical resolutions, which are equivalent to or bigger than IGRA. A large spread

100   emerges in the explicit determination of BLH from a variety of instruments, in spite of

101   that the BLH detection based on radiosonde is the most accepted methodology for

102   deriving CBL and SBL (Seidel *et al.,* 2012; de Arruda Moreira *et al.,* 2018).

103   A wide range of reanalysis products, such as those from the fifth generation

104   ECMWF atmospheric reanalysis of the global climate (ERA-5), the National

105   Aeronautics and Space Administration (NASA) Modern-Era Retrospective-analysis for

106   Research and Applications version 2 (MERRA-2), Japanese 55-year Reanalysis (JRA-

107   55), and the NCEP climate forecast system version 2 (NCEP-2), provide a rich

108   ensemble of climate data products (Saha *et al.,* 2014; Hersbach *et al.,* 2020; Kobayashi

109   *et al.,* 2015; Gelaro *et al.,* 2017), but are sensitive to both empirical parameterizations

110   and the diagnostic method chosen, while verification by direct observations of BLH are

111   sparse (Seibert *et al.,* 2000). Some inter-comparisons between instruments, such as

112   radiosonde, LIDAR, and ERA-interim reanalysis have been previously conducted, and

113   a rough consistency has been yielded (e.g., Guo *et al.,* 2016; Korhonen *et al.,* 2017;

114   Zhang *et al.,* 2016). However, Basha *et al.* (2018) demonstrate that ERA-interim can

115   underestimate BLH by around 900 m compared to GPS RO. This underestimation may

116   be caused by different kinetic or thermodynamic assumptions use. For instance, ERA-

117   interim is implemented with a bulk Richardson number method (Palm *et al.,* 2005),

118   which is believed to be suitable for all atmospheric conditions (Anderson, 2009). It is

119   worth highlighting that the state-of-art reanalysis could be one of the most promising

120   data sources for obtaining the synoptic or climatological features of BLH.

121   Despite much progress made in developing the BLH products, there are still some

122   unresolved issues in quantifying the variability of BLH from a global perspective.

123   These issues include: the worldwide variation of BLH by high-resolution vertical

124   soundings, the inter-comparisons among reanalysis datasets, and further evaluations

125   with radiosonde observations, especially in the daytime based on the same retrieval

126   algorithm. To this end, this study seeks to address the following scientific questions: (1)

127   a climatological distribution of near-global BLH by using high-resolution radiosonde

128   measurements; (2) inter-comparisons of ERA-5, MERRA-2, JRA-55, and NCEP-2 with

129   additional evaluation with radiosondes; and (3) investigate potential sources for the

130   biases of BLH between observation and reanalysis. The rest of the paper is organized

131   as follows. The descriptions of high-resolution radiosonde data, reanalysis products,

132   and the bulk Richardson number method are given in Section 2. Section 3 presents the

133   spatial distributions of BLH by radiosonde and reanalyses and their inter-comparisons.

134   A brief conclusion and remarks are finally outlined in Section 4.

135   **2. Data descriptions and BLH retrieval method**

136   *2.1 High-resolution radiosonde measurements*

137   Until January 2018, IGRA provided atmospheric soundings at around 445

138   radiosonde sites across the globe, including pressure, temperature, humidity and wind.

139   The number of pressure levels below 500 hPa is around 10. By comparison, for high-

140   resolution radiosondes, the sampling rate is 1-s or 2-s, corresponding to a vertical

141   resolution of approximately 5–10 meters throughout the atmosphere. The high-

142 resolution radiosonde measurements used in the present study are obtained from 342

143 sites around the world, which are provided by several organizations, including the

144 China Meteorological Administration (CMA), the National Oceanic and Atmospheric

145 Administration (NOAA) of United States, the German Deutscher Wetterdienst (Climate

146 Data Center), the Centre for Environmental Data Analysis (CEDA) of United Kingdom,

147 the Global Climate Observing System (GCOS) Reference Upper Air Network

148 (GRUAN), and University of Wyoming.

149   The CMA maintains the China Radiosonde Network (CRN), which contains 120

150 operational stations homogeneously distributed across mainland China with a vertical

151 sampling rate of 1 second (5–8 m resolution), since 2011 (Guo *et al.,* 2016; 2019; Zhang

152 *et al.,* 2016; 2018; Su *et al.,* 2020). The NOAA started the Radiosonde Replacement

153 System (RRS) program in 2005, which involved 89 sites with a vertical resolution of 5

154 m (Zhang *et al.,* 2019). The German Deutscher Wetterdienst (Climate Data Center) has

155 been sharing the radiosonde measurements at 14 sites with a sampling rate of 2 seconds

156 since 2010. Moreover, the 10 m resolution soundings at 12 sites was provided by the

157 CEDA, which began to share soundings since 1990, and 8 radiosonde sites were shared

158 by GRUAN with a vertical resolution smaller than 10 m. An additional 93 sites came

159 from the University of Wyoming, which started in 2018, with a sampling rate of 2-s or

160 1-s. In total, over 678,000 soundings at 342 stations are used here for the period of

161 January 2012 to December 2019 in total of eight years, including 633,000 soundings at

162 the regular release times of 0000 and 1200 UTC and 43,000 more irregular observations

163 during intensive observation period (IOP).

164   Radiosonde measurements are taken twice per day following the World

165 Meteorological Organisation (WMO) protocol for synoptic times at 0000 and 1200

166 UTC (Seibert *et al.,* 2000), except for special field campaign observations at specified

167 stations or time ranges during IOPs. The protocol implies that stations at different

168 longitudes sample the diurnal cycle differently. For instance, stations near 0°E (London)

169 and 180°E (Samoa) sample at midnight and midday, while stations near 90°E

170 (Bangladesh) and 90°W (Chicago) sample at dawn and dusk, with intermediate

171   longitudes at linearly varying intermediate local solar times (LSTs) of day. For

172   wintertime regions near 90°W and 90°E, the release times are insufficient for evaluating

173   the BLH during daytime. Hence, the BLH estimates from regular radiosondes will vary

174   with longitude and season (McGrath-Spangler and Denning, 2012). Generally, the

175   principal PBL mechanism at night is associated with an SBL, which gradually

176   transitions into CBL in the morning (Stull, 1988; Zhang *et al.,* 2018). The transition

177   from SBL to CBL is generally quick and occurs swiftly after sunrise, but the reverse

178   process can be slow in the late evening (Taylor *et al.,* 2014). Despite the dominance of

179   CBL during the daytime, an SBL still occurs, especially in the event of overcast sky

180   (Zhang *et al.,* 2018; 2020) and near strong divergence in moist convective downbursts

181   (King *et al.,* 2017). To illustrate the daytime variation of BLH, we only selected the

182   soundings that are launched 2 hours after sunrise and 2 hours before sunset. The sunrise

183   and sunset times are gauged in a longitude bin size of 15 degrees and based on the

184   latitude of station and the calendar day of the release. As a result, 190,013 profiles

185   which include soundings launched at both synoptic times and during IOP, spanning

186   from January 2012 to December 2019, to obtain the BLH in the daytime. The spatial

187   distribution of file number for each site is displayed in Figure S1, in which the sites

188   with less than 10 matches are excluded.

189   *2.2 ERA-5, MERRA-2, JRA-55 and NCEP-2 reanalysis datasets*

190   ERA-5 is the successor of ERA-interim and undergo a variety of improvements,

191   including more recent parameterization schemes and data assimilation system, better

192   spatial resolution, both horizontally and vertically (137 levels), and improved

193   representation of evaporation balance, cyclones, soil moisture, and global precipitation

194   (Hersbach *et al.,* 2020). The BLH is composited in the ERA-5 product on a 1440×721

195   grids with 0.25° longitude and 0.25° latitude resolution. It is computed by the bulk

196   Richardson number method, with a temporal resolution of 1 hour.

197   MERRA-2 is the latest atmospheric reanalysis of the modern satellite era

198   produced by NASA's Global Modeling and Assimilation Office (GMAO). It includes

199   aerosol data assimilation, improvements on ozone, and cryospheric processes (Gelaro

200 *et al.,* 2017). The data is provided on a grid of 576×361 points with 0.625° longitude

201 and 0.5° latitude resolution and has 42 pressure levels (about 16 layers below 500 hPa),

202 with a temporal resolution of 3 h. In this product, the BLH is defined by identifying the

203 lowest level at which the heat diffusivity drops below a threshold value (McGrath-

204 Spangler and Denning, 2012). However, to preclude the uncertainty raised by different

205 methods adopted, the BLH by MERR-2 is extracted by bulk Richardson number

206 method, utilizing the parameters of horizontal wind, temperature, geopotential height,

207 relative humidity (RH), and surface pressure.

208   JRA-55 is the second Japanese global atmospheric reanalysis commissioned by

209 the Japan Meteorological Agency (JMA) (Kobayashi *et al.,* 2015). Data contains 37

210 pressure levels between 1 hPa and 1000 hPa (16 layers below 500 hPa), provided on a

211 grid of 288×145 points, with a horizontal spacing of 1.25°×1.25° and a temporal

212 resolution of 6 hours. The parameters, including geopotential height, temperature,

213 horizontal wind, surface pressure, and RH, are used to assess BLH as before. NCEP-2

214 has the coarsest model resolution than ERA-5 (Rinke *et al.,* 2019), with a spatial

215 resolution of 2.5° longitude and 2.5° latitude. The total level is 17 (6 layers below 500

216 hPa), which is substantially less than MERRA-2, JRA-55 or ERA-5, and the

217 temporal resolution is 6 hours. Similar parameters to JRA-55 are preserved to compute

218 BLH. It is noteworthy that all model times include 00 and 12 UTC and hence collocate

219 well with the synoptic radiosonde times.

2.3 Normalized sensible heat flux in the daytime

221   The sensible heat flux represents the level of energy that induces CBL growth (Wei

222 *et al.*, 2017), whereas the latent heat fluxes characterize the evaporation of moisture

223 from the soil to the CBL, which feedbacks on the development of CBL and the

224 formation of PBL cloud (Pal and Haeffelin, 2015) For a given amount of heat flux,

225 small latent heat fluxes usually mean more energy being available for PBL growth

226 (Chen *et al*., 2016). Moreover, the surface heat flux is closely associated with near-

227 surface meteorological variables. For instance, a lower RH usually indicates a larger

228 sensible heat flux and lower latent heat flux (Guo *et al*., 2019; Zhang *et al*., 2013).

229   Suppose that the heat supplied to the air at the radiosonde balloon launch time is the

230   area shaded under the heat flux curve (Fig.11.12 in Stull 1988), the normalized sensible

231   heat flux in the daytime is defined by

232

$$\overline{Q_H} \propto \int_{T_{sunrise}}^{T_{launch}} Q_H \rho^{-1} c_p^{-1} dt \qquad (1)$$

233   where $T_{sunrise}$ and T_{launch} are the sunrise time and radiosonde balloon launch

234   time, Q_H the sensible heat flux, ρ the near-surface density and c_p equals 1004

235   J°C$^{-1}kg^{-1}$. The similar principle is applied to the calculation of normalized latent

236   sensible heat flux as well.

237   *2.4 Bulk Richardson number method*

238   In the spirits of a like-for-like comparison, the BLHs derived from radiosonde and

239   reanalysis data (MERRA-2, JRA-55, and NCEP-2) are calculated using the bulk

240   Richardson number (BRN), which also serves as the built-in algorithm in ERA-5 for

241   BLH products. The BRN, an algorithm used to reflect how strongly buoyancy is

242   coupled to the vertical momentum (Scotti, 2015), has been widely used for the

243   climatological study of BLH from radiosonde measurements thanks to its applicability

244   and reliability for all PBL regimes (Anderson 2009; Seidel *et al.,* 2012; Guo *et al.,*

245   2019). It determines the BLH by identifying the level at which the bulk Richardson

246   number, represented by $Ri(z)$, reaches its critical value (Palm *et al.*, 2005) and is

247   formulated as

248

249

$$\text{Ri}(z) = \frac{\left(\frac{g}{\theta_{vs}}\right)(\theta_{vz} - \theta_{vs})z_{AG}}{(u_z - u_s)^2 + (v_z - v_s)^2 + (bu_*^2)} \qquad (2)$$

250   where g is the gravitational acceleration, z_{AG} the height above ground level (AGL),

251   θ_v the virtual potential temperature, u_* the surface friction velocity, and u and v

252   the horizontal wind components and b a constant, which is usually set to zero due to

253   the fact that friction velocity is much weaker compared with the horizontal wind (Seidel

254   *et al.*, 2012). The subscripts of z and s denote the parameters at z height above

255   ground and ground level, respectively.

Open Access
EGU

256   It is known that $Ri(z)$ increases with increasing free flow stability (Zilitinkevich

257   and Baklanov, 2002). Below a critical value of 0.25, the flow is dynamically unstable

258   and likely cause turbulent motion. Nevertheless, since turbulence can also occur away

259   from this critical value (Haack *et al.,* 2014), care must be taken in that the critical value

260   might not be well defined, leading to uncertainty in estimating BLH. Meanwhile, the

261   BLH estimates were found not to change very much by differing the input of critical

262   values ($Ri = 0.2; 0.25; 0.3$) (Guo *et al.,* 2016). Therefore, for a given discrete Ri

263   profile, here we identify the BLH as the interpolated height at which the $Ri(z)$ firstly

264   crosses the critical value of 0.25 starting upward from the ground surface.

265   *2.5 Collocation procedure and a case study*

266   In contrast to the reanalysis data, the longitude, and latitude distributions of high-

267   resolution radiosonde are irregular. A precise comparison between reanalysis data and

268   sounding is required for consistency in time, latitude, and longitude. The matching

269   procedures implemented in this present study go as follows. (1) A latitudinal and

270   longitudinal matching procedure is carried out by finding the geographical grid cell of

271   the reanalysis product that contains the radiosonde station. (2) Time matching for ERA-

272   5 is to find the exact UTC time (hour) of the weather balloon launch. (3) For MERRA-

273   2, NCEP-2, and JRA-55 datasets, the requirement is to limit the time difference with

274   the weather balloon launch time to 1 hour.

275   A case at 0600 UTC 06 Jun 2016, Chongqing (29.6°N, 106.4°E) is shown in Figure

276   1. In this case, BLH obtained by sounding is 1,337 m and is closest to that by ERA-5,

277   which underestimates the height by 72 m. Compared with the radiosonde profile,

278   MERRA-2 can capture the main vertical structures and the magnitude of wind speed

279   (WS), RH, and temperature, but not the fine-scale vertical variations (Figure 1b). It also

280   slightly undervalues the BLH by 125 m. By and large, the profiles from JRA-55 are not

281   as accurate as those from MERRA-2. More specifically, the wind speed at some heights,

282   prominently above 2 km, is underestimated (Figure 1d); the mean RH is 4% less than

283   that from the sounding. As a result, JRA-55 substantially underestimates BLH by 399

284   m. The basic parameters outlined by NCEP-2, for instance, RH (5% larger than

285   sounding), temperature (3°C less than sounding), and wind speed (4.5 m/s larger than

286   sounding), all have notable differences with the sounding (Figure 1c). The BLH is

287   considerably underestimated by 729 m. Based on this case, we can note that the

288   performances of ERA-5 and MERRA-2 are obviously better than those from JRA-55

289   and NCEP-2 in terms of the BLH, and that the remarkable underestimation by NCEP-

290   2 can be attributed to the large error in the prediction of basic parameters, such as wind,

291   temperature, and RH.

3. Results and discussion

3.1 Overview of BLHs at two synoptic times

294   The near-global mean BLHs at 0000 UTC from 2012 to 2019 by four reanalysis

295   products are shown in Figure 2, in which the results obtained from radiosonde are

296   overlaid by colored circles. The stations with sounding covering at least 2 continuous

297   years are kept. The four reanalysis products yield an analogous result with respect to

298   the spatial variation of BLHs, which are positively correlated with the sounding-derived

299   BLH, with correlation coefficients of 0.90, 0.47, 0.46, 0.81 for ERA-5, NCEP-2, JRA-

300   55, and MERRA-2, respectively. It is evident that the BLHs from NCEP-2 over the

301   continents of Africa, Asia, and South America are 300 m thicker than those of the other

302   three products (Figure 2b). Furthermore, the BLH in Antarctic by ERA-5 is notably 500

303   m lower than that by NCEP-2 and MERRA-2 (Figure 2a). Most of the mean BLHs by

304   radiosonde are consistent with the reanalysis products, except that the values from all

305   four reanalysis products over the Pacific Ocean and the contiguous U.S. are

306   underestimated by about 300 m. Moreover, it is worth to note here that the BLHs by

307   JRA-55 are considerably underestimated by around 1 km over these regimes. For 0000

308   UTC, the regions nearly from the east coast to the west coast of Pacific Ocean (UTC+8

309   to UTC+12, and UTC–12 to UTC–8) are covered by sunshine, and thus are filled with

310   deeper PBL.

311   Comparable results at 1200 UTC are presented in Figure S2. Africa, the Middle

312   East, and the west of India and China, corresponding to local noon and afternoon, have

313   maximal BLHs of around 1.8 km. Moreover, it is noteworthy that the values from

314   NCEP-2 and JRA-55 over these areas are visibly lower than those from ERA-5 and

315   MERRA-2, particularly over Africa and the Middle East, whereas these low values can

316   barely be validated with soundings due to their sparse distribution. Over these areas,

317   the BLHs are underestimated by reanalysis by about 200 m relative to the sounding

318   results. Notably, BLHs from NCEP-2 over the continents of Africa are 1 km lower than

319   those from ERA-5 and MERRA-2. According to the results at 0000 and 1200 UTC, the

320   comparisons between reanalysis products and soundings demonstrate that the BLHs are

321   well resolved in the nighttime but are underestimated at daytime by reanalysis datasets.

322   For the near-global variation of BLH at a certain synoptic time, daytime and

323   nighttime appear on the map simultaneously, but as a function of longitude, which is

324   displayed in Figure 2. Thus, the variations at a fixed synoptic time on the map create a

325   picture of the diurnal BLH variation. Given the dominance of CBL in the daytime,

326   investigating the BLHs in the daytime is thus favorable for unravelling the underlying

327   causes for the discrepancies existed in the BLHs from both radiosonde and reanalysis.

328   Therefore, the following results show the variations of daytime BLH only, unless

329   otherwise noted.

330   *3.2 Variations over the day and comparisons with reanalysis products*

331   The climatological mean variations in the daytime BLH from the soundings and

332   four reanalysis products are drawn in Figure 3. The period spans from January 2012 to

333   December 2019 for most of the stations provided by China, the U.S., Germany, and the

334   U.K. As implied by the results from soundings (Figure 3e), the deepest PBL is observed

335   over the Tibetan Plateau (TP) and the northwest of China, the south of Africa, and the

336   west of U.S, with values as high as 1.7 km. The possible reason for this phenomenon is

337   that the weather balloons over these regions are basically launched in the early

338   afternoon of boreal summer (June–July–August) when the maximal BLH is usually

339   observed (Collaud Coen *et al.,* 2014; Guo *et al.,* 2016). The BLHs over the Pacific

340 Ocean are noticeably large, with values of 1.3 km. The longitudinal variation of BLH

341 is evident, likely due to LST variations of the soundings. Additionally, BLHs in the

342 middle and low latitudes are larger than high latitudes, which is consistent with the

343 findings in Gu *et al.* (2020).

344   By and large, the climatological results of BLH by radiosonde and four model

345 products are comparable, indicating that both capture the diurnal and seasonal

346 variations implied by the sounding LST times sampled. Among the model products,

347 ERA-5 shows the best prediction of BLH contrasted with radiosonde, with a correlation

348 coefficient of 0.88 (Figure 3a). Furthermore, the results from MERRA-2 are positively

349 correlated with those from the soundings, with a correlation coefficient of 0.66 (Figure

350 3b). The performances of JRA-55 and NCEP-2 are significantly poorer than those of

351 ERA-5 and MERRA-2, with correlation coefficients of 0.4 and 0.41, respectively

352 (Figure 3c, d). The values of BLH over the west of U.S and the west of China are

353 seriously underestimated by NCEP-2 and JRA-55 by around 800 m. Thus, we note that

354 ERA-5 and MERRA-2 are more robust in deriving the BLH, purely based on the

355 climatological distribution of BLHs.

356   Figure 4 illustrates the diurnal variations in BLH at 0000 and 1200 UTC and

357 during daytime. A notable diurnal variation can be noticed, with a minimum of 343 m

358 at 04 LST and a maximum of 1224 m at 17 LST (Figure 4a). The magnitude in BLH

359 during daytime are essentially larger than that at 0000 and 1200 UTC and has a maximal

360 value of 1926 m at 1700 LST (Figure 4b). It follows that some soundings that are

361 released at 0000 and 1200 UTC are excluded by the collocation procedure designed for

362 collecting samples in the daytime.

363   The radiosonde stations are mainly dispersed over the U.S, China, Austria, Europe,

364 the Pacifica Ocean, and the polar region, and only a few stations contribute over the

365 rest of the world. The polar region contains a station with a longitude larger/lower than

366 67.7°N/°W. Therefore, six regions are specifically examined in terms of the bias

367 between radiosonde and model product.

368   The BLH differences between radiosonde and ERA-5 are shown in Figure 5, in

369   which we specify the differences over the six above-mentioned regions. As observed in

370   Figure 5e, the BLH over most of the stations is underestimated to a slight extent, with

371   a near-global mean of 130.44 m. As expected, the most underestimated regions cover

372   the west of U.S, and southern China (Figure 5e), with a difference of around 200 m. In

373   addition, it is worth mentioning that the BLHs over the Pacific Ocean are overestimated

374   in four seasons, with a bias of around 400 m (Figure 5h). Among the six classified

375   regions, BLHs in Europe, East Asia, and polar are reliably determined by ERA-5, with

376   an average bias of around 50 m (Figure 5b, c, i). The bias seems to exhibit a seasonal

377   dependence, and it is larger in the warm seasons and smaller in the cool seasons.

378   Regardless of the small bias, the newest model product, ERA-5, properly estimates the

379   BLH, especially above the regions of Europe, the eastern U.S, East Asia, and polar.

380   Similarly, the BLHs by MERRA-2 are underestimated, with a near-global mean

381   bias of 159.72 m (Figure 6), which is slightly larger than that of ERA-5 (130.44 m).

382   This could indicate that the MERR-2-derived BLH is more dispersed than ERA-5. The

383   spatial distribution of bias value is broadly identical to that of ERA-5, except that the

384   BLHs over Europe, Austria, and polar region are well estimated by MERR-2, due to

385   much smaller mean biases at 42.10 m, 39.70/. m, and 52.27 m, respectively (Figure 6b,

386   g, i).

387   By comparison, the mean bias produced by JRA-55 is larger than those from ERA-

388   5 and MERRA-2, with a mean value of 352.59 m, as shown in Figure 7. The BLHs

389   above most stations are underestimated by JRA-55, particularly for the sites over

390   western China and western U.S, and the Pacific Ocean, with an underestimation of

391   about 800 m. The most underestimated stations cluster at the latitude range of 40–45°N,

392   with a mean difference of around 1 km (Figure 7f). Although the ensemble mean of

393   bias is significantly larger than ERA-5 and MERRA-2, the estimations over Europe and

394   the Polar regions seem to be acceptable, with mean values of 177.0 m and 99.2 m,

395   respectively (Figure 7b, i).

396   The mean bias by NCEP-2 is larger than that by JRA-55, with a mean value of

397   420.87 m, as illustrated by Figure 8. The distribution results are similar to JRA-55,

398   except for Europe and Austria, where the bias is about twice that of JRA-55.

399   In general, the comparison analysis of the daytime BLH results between soundings

400   and four reanalysis datasets indicates that ERA-5 reanalysis produces the BLH that is

401   closest to the high-resolution soundings. Interestingly, MERRA-2 can provide a good

402   spatial distribution of BLH. JRA-55 and NCEP-2 can only give a good prediction over

403   some regions, most of which tends to produce a much larger BLH estimates compared

404   to those from ERA-5 and MERRA-2.

405   *3.3 Correlations with near-surface meteorological variables and surface heat flux*

406   The PBL is the lowest part of the troposphere and evolves diurnally due to near-

407   surface thermodynamic variables through turbulent exchanges of momentum, heat, and

408   moisture (Pithan *et al*., 2015). Thus, the surface meteorological variables depend on the

409   underlying land surface and its coupling with the PBL, and they could act as a good

410   proxy for BLH under some specific circumstances (Zhang *et al*., 2013; Zhang *et al*.,

411   2018). An analysis of the correlation between the BLHs by radiosondes and near-

412   surface meteorological variables is presented in Figure 9. The variables include near-

413   surface air temperature at 2 m AGL (T_{2m}), pressure (Ps), RH, and WD, which are

414   extracted from the first level in sounding. The first level is assumed to be associated

415   with the near-surface variables (Serreze *et al*., 1992; Wang and Wang 2016). We note

416   that BLH, T_{2m}, RH and WD all have substantial diurnal and seasonal variability as

417   partly expressed in Eq. (2).

418   Relatively high positive (negative) correlation coefficients can be noticed between

419   BLH and T_{2m} (RH), with mean values of 0.39/-0.51 (Figure 9a, c), implying that both

420   T_{2m} and RH could be an adequate indicator for the temporal variation of BLH.

421   Moreover, the correlations between BLH and WD are also positively notable, with a

422   mean value of 0.24 (Figure 9d). By contrast, the correlation between Ps and BLH can

423   be ignored above most of the regions (Figure 9b).

15

424   The correlation analyses between BLH and normalized heat fluxes, which are

425   assessed by EAR-5 reanalysis products, are displayed in Figure 10. It is notable that

426   positive/negative correlation coefficients usually exist in normalized sensible/latent

427   heat flux, with a global mean of 0.29 and -0.31. This correlation is not high because

428   BLH also depends on the radiative heating/cooling and the temperature profile in

429   different stations (Yang *et al.*, 2004).

430   For the climatological variation of BLH, the near surface variables such as T_{2m},

431   RH and WS, and the normalized sensible/latent heat flux could be a good indicator.

432   Conversely, the development of BLH could also limit the magnitude of RH (McGrath-

433   Spanglerm, 2016).

3.4 Potential sources for the bias between radiosonde and reanalysis products

435   The possible sources for the difference between radiosonde and reanalysis could

436   be rather complicated. From the spatial pattern of BLH discrepancy results between

437   radiosonde and reanalysis (Figures 5–8), we can notice that the regions with large

438   differences tend to be observed over regions with high elevation, such as the TP in

439   China and Rocky mountain in the U.S. These regions generally have much more

440   complex orography. Coincidently, the soundings over the above-mentioned two regions

441   are all obtained from afternoon, in which the PBL develops to the maximum (Figure 4).

442   As expected, highest biases generally are accompanied with peak BLHs, which has also

443   been confirmed in our previous studies (cf. Figure 2c in Li *et al.*, 2017). Therefore, the

444   biases depend on the LST when the weather balloon is launched, which at least could

445   not be ruled out.

446   In addition, the large differences primarily appear in the low and middle latitudes,

447   where thermal convection frequently occurs. Therefore, it is reasonable to infer that

448   static stability could exert an influence on the comparison results. Then, we will analyze

449   the probable influences from terrain and static stability on BLH differences.

450   We evaluate the influence from the orographic complexity around the sounding

451   station and calculate the standard derivation (STD) of elevation within 1°x1° grid, with

452   the help of 30 arc second digital elevation model (DEM) dataset. The analysis of the

453   correlation between the bias of the BLH and the standard derivation of the DEM is

454   shown in Figure 11. It follows that the influence from the orography appears

455   instrumental, given the correlation coefficient varying from 0.31 to 0.81. Furthermore,

456   the errors or uncertainties in ERA-5 are less easily impacted by the orographic

457   complexity due to the relatively lower correlation coefficient of 0.31 (Figure 11a).

458   Based on the correlation between orographic complexity (manifested by the STD

459   of the DEM) and the bias of a reanalysis relative to radiosonde measurements, it is

460   likely that the performances of MERR-2, JRA-55, and NCEP-2 might be restricted by

461   the complex underlying terrains. One of the reasons could be because global reanalysis

462   with coarse resolution that cannot resolve the sub-grid processes due to topography.

463   However, ERA-5 appears to be less dependent on terrain. In other words, the models

464   used in ERA-5 show sufficient capability and excellent performance in reproducing the

465   atmospheres, particularly in the PBL over complex terrains.

466   Lower tropospheric stability (LTS) is an indicator to describe the thermodynamic

467   state of the lower atmosphere and is defined by the differences in potential temperature

468   at 700 hPa and 1000 hPa (Guo *et al*., 2016). Typically, the smaller the LTS, the more

469   unstable the low troposphere. The mean LTS over each station is defined by the

470   ensemble mean by four reanalysis datasets, and its spatial distribution is depicted in

471   Figure 12. The lower troposphere over the western United States and western China is

472   more unstable compared to the rest of the world, with LTS of around 6K (Figure 11a),

473   which is likely associated with afternoon launch time of weather balloons. According

474   to the correlation between the bias of BLH and the mean LTS, it is clear that the

475   underestimation in BLH by JRA-55 and NCEP-2 products are negatively correlated

476   with LTS, with correlation coefficients of -0.32 and -0.36 (Figure 12b).

477   Besides the LTS, the role of lifted index could be another influential factor. The

478   lifted index is a predictor of latent instability (Galway, 1956), and it is defined as the

479   temperature difference between the environment temperature and an air parcel lifted

480   adiabatically at 500 hPa. The index is computed by the air temperature, RH, and

481   pressure profiles from radiosondes. We calculate the percentage of negative lifted index

482   above each station, which represents the occurrence rate of latent instability that exists

483   in the daytime (Figure 12c). The stations with high probability of strong instability,

484   denoted by P(lifted index < 0), are predominantly dispersed over the west U.S, the

485   west and south of China, and the Pacific Ocean, reaching a percentage as high as around

486   70%. These stations are regularly overlapped with great biases in the reanalysis

487   products as shown in Figures 5-8. According to the analysis, it is clear that all four

488   reanalysis products are positively associated with P (lifted index < 0), with

489   correlation coefficients ranging from 0.34 to 0.47 (Figure 12d). The positive (negative)

490   correlation coefficients in lifted index suggests that the underestimation by reanalysis

491   might be associated with the instability activity in the lower troposphere that has not

492   been adequately represented or simulated by the models used in reanalyses. In light of

493   the surface heating during the day and the growth of the PBL due to air ascent, it is also

494   inferred that afternoon BLHs suffer the greatest errors if this is caused by inadequate

495   air mixing within the free troposphere in models.

496   **4. Conclusions and summary**

497   A climatology of near-global BLH from high-resolution radiosonde measurements

498   has been yielded for the daytime BLH. The high-resolution radiosonde data has a much

499   finer spatial resolution of 5 m or 10 m, compared to that by IGRA, and can establish a

500   finer and more precise structure of the PBL. In addition, direct comparisons among four

501   well-established reanalysis model products have been conducted. The present study

502   adopts over 300 sounding stations with high-resolution, spanning from 2012 to 2019,

503   to investigate the climatological variation of near-global BLH in the daytime and

504   evaluates four model products at the radiosonde sampling.

505   Notable spatial variation can be observed in the climatological mean of BLH at

506   0000 and 1200 UTC. In the afternoon, the regions over the Western United States and

507   Western China have the largest BLHs with values as high as 1.7 km, whereas 0000 and

508 1200 UTC compare generally to earlier times of day (LST) in the rest of the world with

509 hence lower BLH. In addition, BLHs in the middle and low latitudes are larger than

510 those in high latitudes. The T_{2m} and RH, and the normalized sensible/latent heat flux

511 are a good predictor for the spatio-temporal evolution of BLH. The most important

512 result is we found that all the four reanalysis products generally underestimate the

513 daytime BLH, with a near-global mean varying from around 130 m to 420 m. The

514 largest bias in reanalysis appears over the Western United States and Western China,

515 where the boundary layers grow vigorously in the afternoon. ERA-5 and MERRA-2

516 definitely have better performance than JRA-55 and NCEP-2 in terms of the magnitude

517 of BLH and a higher correlation coefficient with the soundings. The newest version of

518 reanalysis, ERA-5, has the smallest bias and the highest positive correlation relative to

519 radiosondes. The underestimation by NCEP-2 and JRA-55 is robust over some regions,

520 for instance, western China and western U.S, with differences even exceeding 800 m.

521 However, all products can obtain a precise estimate over some regions, for instance,

522 Europe, the eastern U.S, and polar, probably due to morning LST soundings and smaller

523 daytime PBL development. The BLH over the Pacific Ocean is underestimated in all

524 seasons and by all products. The underestimation tends to have a seasonal dependence,

525 i.e., the warm season has a larger underestimation.

526   We investigated two possible sources contributing to the biases, including

527 topography and static stability. The analysis shows that the DEM spread does have a

528 positive correlation with the bias, suggesting that the reanalysis data cannot provide a

529 reliable simulation result under complex terrain conditions. In addition, reanalysis BLH

530 errors tends to be positively correlated with the occurrence rate of unstable air,

531 suggesting that the reanalyses do not accurately determine BLH when the lower

532 troposphere is unstable.

533   Although this study suffers from the inhomogeneous distribution of the radiosonde

534 sites, the climatological BLHs at the near-global scale can help us understand the

535 variation characteristics of BLH in different regions and for different LST. For the first

536 time, we present near-global BLH estimates from high-resolution radiosondes, and

537 further conduct a comprehensive comparison of BLH products for four widely used

538 reanalysis datasets using the BLHs derived from the soundings. The findings provide

539 insights into the limitations of reanalysis data and, more importantly, are expected to

540 greatly benefit future research works related to applications of different kinds of

541 reanalysis data in the future.

758

759   **Figures:**

760
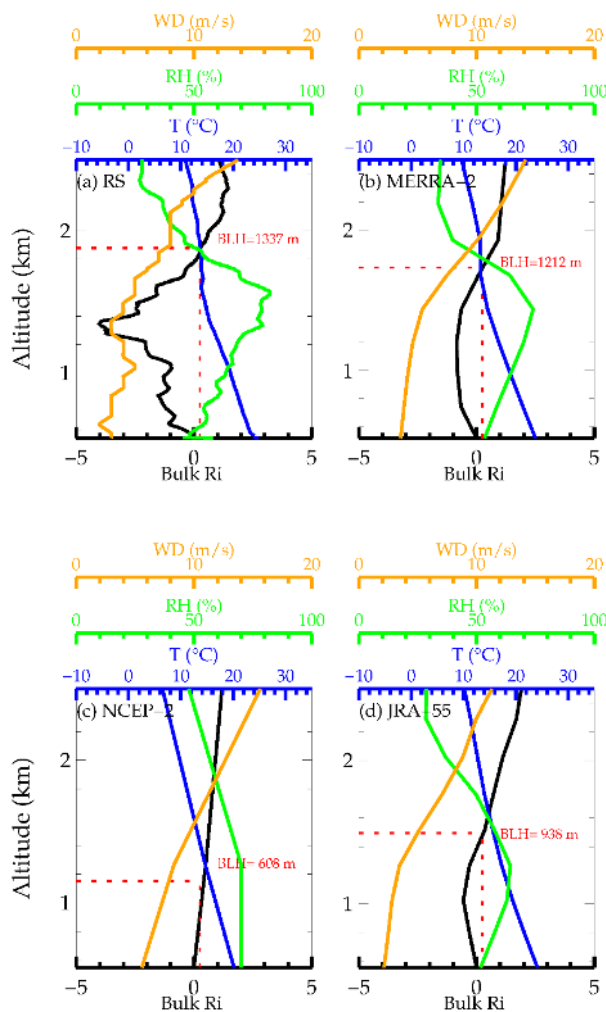

761

762   **Figure 1**. Profiles of basic atmomospheric parameters from the ground up to 2.5 km

763   AGL, including wind speed (orange), bulk Ri (black), temperature (blue), and RH

764   (green) at 0500 UTC (13 LST) 06 Jun 2016 at Chongqing (29.6°N, 106.4°E) from

765   radiosonde (a), MERRA-2 (b), NCEP-2 (c), and JRA-55 (d) reanalysis datasets. Note

766   that the boundary layer height in each subplot is marked by red dash lines and red texts,

767   and the BLH for ERA-5 is 1265m in this case.

768

769

770
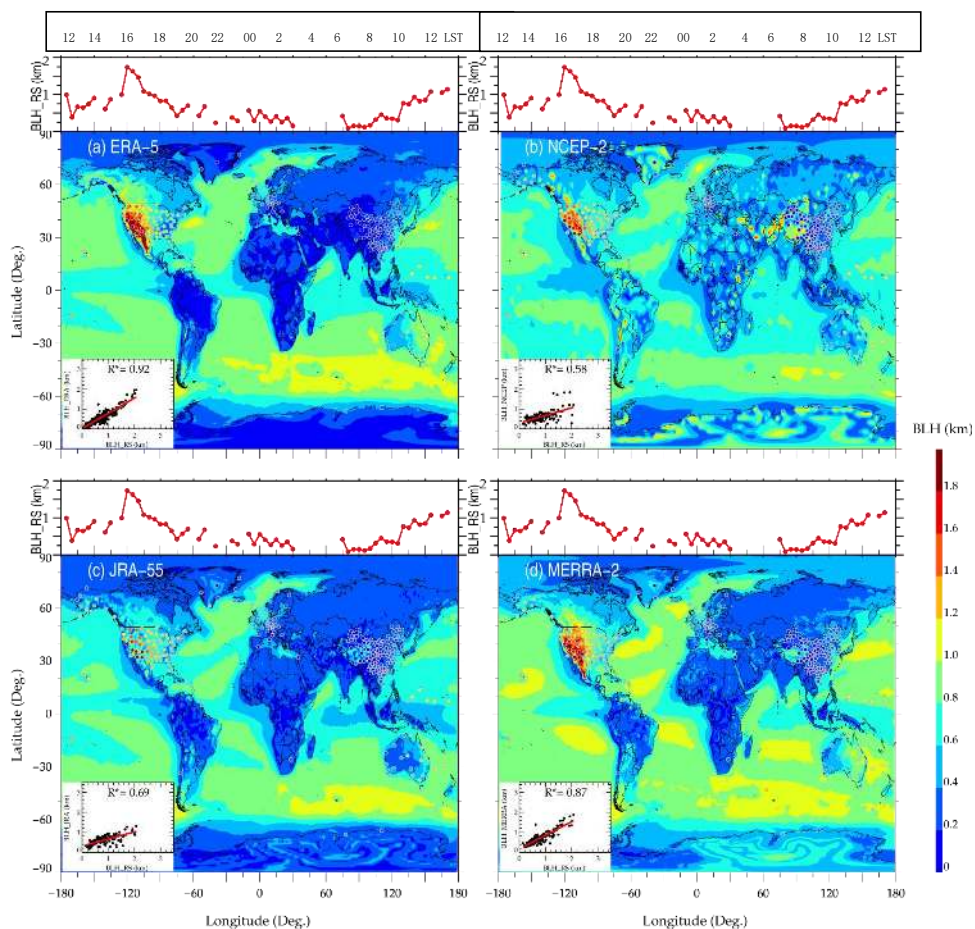

Figure 2. The ensemble mean BLH estimated from ERA-5 (a), NCEP-2 (b), JRA-55

(c), and MERRA-2 (d) reanalysis data at 0000 UTC during years 2012 − 2019. The dots

with gray marginal lines in each map denote the mean BLH derived by sondes at 0000

UTC, and the red dotted lines present the mean BLH derived by radiosonde on a grid

with 5° longitude. Stations with less than 10 profiles are not included in the analysis.

The 2D scatter plot in the left bottom corner of each panel illustrates the correlations

between reanalysis-derived and sonde-derived BLHs at 0000 UTC, where the asterisk

(*) superscripts indicate that the correlation coefficients are statistically significant

(p<0.05) and the red lines denote the least-squares regression line.

780

781

782
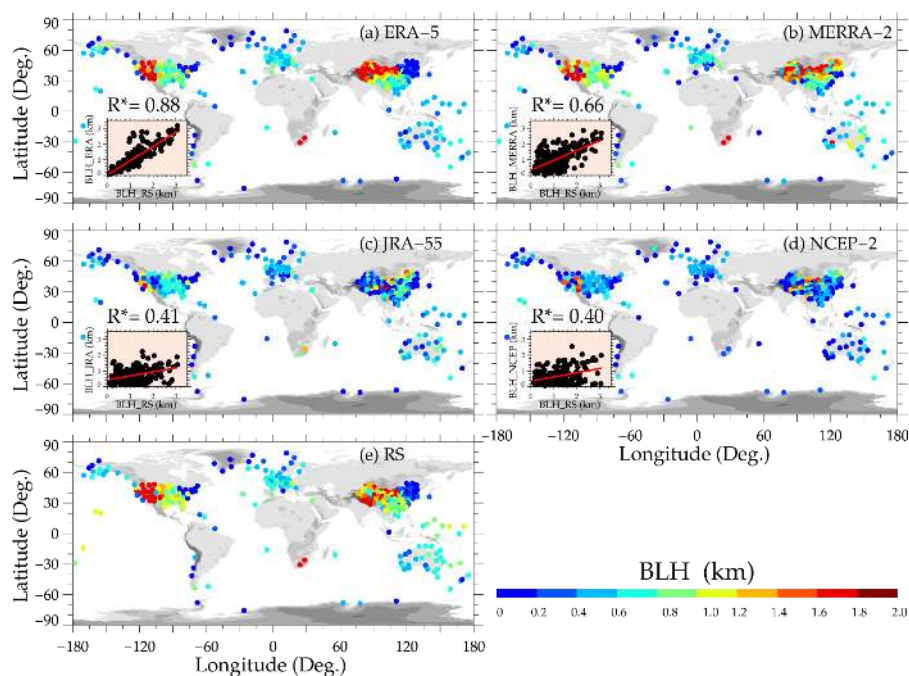

Figure 3. Spatial distributions of the mean BLHs determined at the near-global high-resolution radiosonde observational network locations during the daytime for the period 2012 to 2019, which is extracted from ERA-5 (a), MERRA-2 (b), JRA-55 (c), NCEP-2 (d), and radiosonde measurements (e), respectively. Similar to Figure 2, the scatter plot illustrates the correlations between reanalysis-derived and sonde-determined BLHs in the daytime.

789

790

791
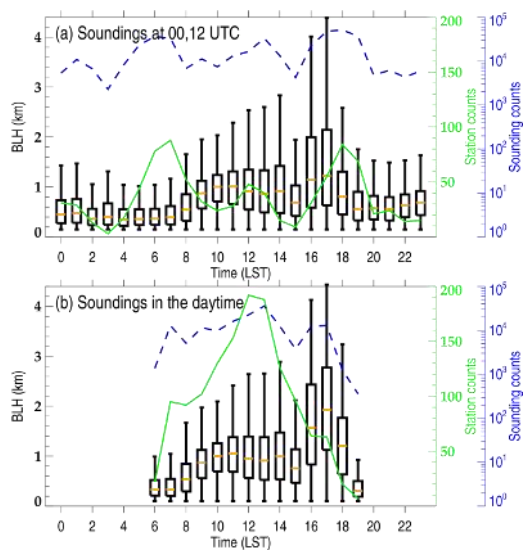

Figure 4. Box and whisker plots of diurnal variation (in LST, 24 hours) of BLH determined by all soundings operationally launched at 0000 and 1200 UTC (a) and by the soundings launched at both synoptic times and intensive observation times that are limited to the daytime alone (b). Solid green line and dotted blue line highlight the number of sonde station and total sounding for each hour of day, respectively.
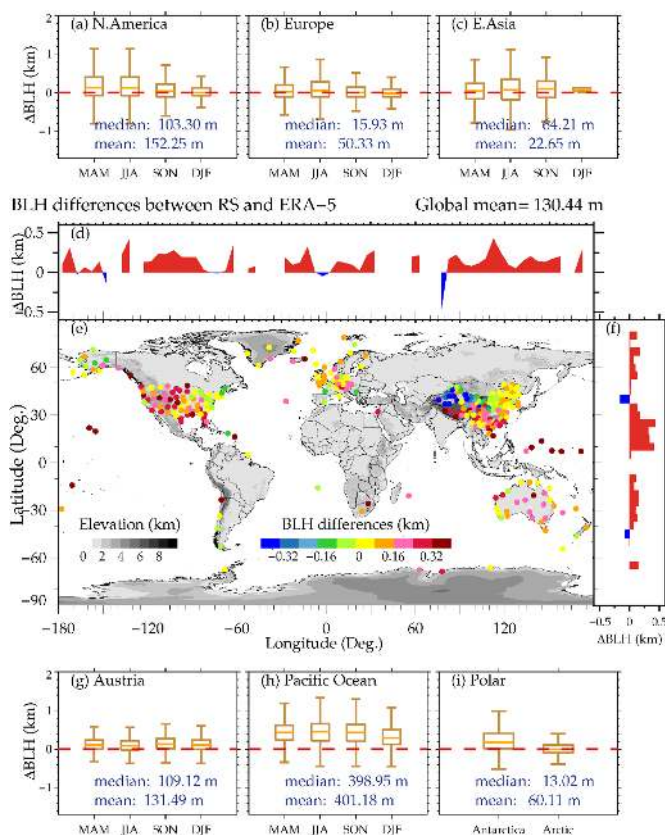

Figure 5. Statstical results of BLH differences between radiosonde and ERA-5. The spatial distribution of mean differences is highlighted in (e). Also shown are the distributions of mean BLH differences as a function of longitude (d) and latitude (f). The box and whisker plot of BLH differences over the six regions of interest (i.e., North America, Europe, East Asia, Austria, Pacific Ocean, Polar) over four seasons are displayed in (a-c), (g-i). The seasons are defined as follows: MAM, March–April–May; JJA, June–July–August; SON, September–October–November; DJF, December–January–February.

812
