Investigation of temperature and residual stresses field of submerged arc welding by finite element method and experiments

M. R. Nezamdost[1] · M. R. Nekouie Esfahani[2] · S. H. Hashemi[1] · S. A. Mirbozorgi[1]

Abstract This article reports on a numerical and experimental investigation to understand and improve computer methods in application of the Goldak model for predicting thermal distribution in submerged arc welding (SAW) of APIX65 pipeline steel. Accurate prediction of the thermal cycle and residual stresses will enable control of the fusion zone geometry, microstructure, and mechanical properties of the SAW joint. In this study, a new Goldak heat source distribution model for SAW is presented first. Both 2D and 3D finite element models are developed using the solution of heat transfer equations in ABAQUS Standard implicit. The obtained results proved that the 2D axi-symmetric model can be effectively employed to simulate the thermal cycles and the welding residual stresses for the test steel. As compared to the 3D analysis, the 2D model significantly reduced the time and cost of the FE computation. The numerical accuracy of the predicted fusion zone geometry is compared to the experimentally obtained values for bead-on-plate welds. The predictions given by the present model were found to be in good agreement with experimental measurements.

1 Introduction

Because of its high quality and reliability, submerged arc welding (SAW) is employed extensively in industry to join metals for the manufacture of energy transportation pipes applied for different applications [1–3]. The service performance of SAW joints is dependent on the fusion zone microstructure, which itself is dependent on the weld thermal cycle and alloying elements [4]. However, it is challenging and costly to quantify the thermal cycles and temperature fields by pure experimental studies. In addition, the results of experimental works are often limited to welding technology, work-piece geometry, and welding set-up and cannot be used if the test parameters are varied. Therefore, FEA analysis can be employed to effectively predict the welding temperature field, cooling rate, microstructure and residual stresses.

A schematic diagram of a SAW welding is given in Fig. 1. A moving arc of sufficient energy input is incident upon the work-piece surface at a constant welding speed. A fraction of the incident energy is absorbed by the work-piece leading to the formation of a fusion zone. As the electrode passes over the work-piece, the melt pool extends along the scanning direction and solidifies soon after the electrode and contact tip moves away.

Several numerical [5–17] and experimental investigations [1, 2, 18–22] of arc welding have been reported by various researchers. Rosenthal [23] first proposed a mathematical model of a moving heat source under the assumption of quasi-steady state; however, as many researchers have discussed, Rosenthal's analysis (that assumes either a point, line, or plane source of heat) has major error for temperatures in or near the fusion and heat-affected zones [24]. After his work, various studies have been carried out on submerged arc welding to investigate the whole SAW process using numerical simulations. Goldak et al. [24] established a

Fig. 1 Schematic diagram of submerged arc welding process
mathematical double ellipsoid model for the welding heat source with versatility to be used for analysing the thermal history in both shallow and high penetration welds. His model provided an effective and reliable solution for calculation of the thermal history in weld. Andersson [25] developed a 2D FE approach to study the distributions of residual stress in the top and bottom surfaces of the parent plate near the weld during a butt SAW process. The phase transformation during cooling was taken into account employing a volumetric dilatation technique, which was proposed to be of primary importance to the residual stress analysis of weldment. FE results were compared to experimental measurements and are showed that despite of good agreement for thermal history, there are differences in calculated and measured values of residual stresses in the weldment. Marimuthu et al. [26] used ANSYS package to predict surface topology of weld bead and subsequent structural performance. A sequentially coupled thermal–mechanical analysis approach was adopted in which the weld bead surface profile and thermal history were calculated using a 3D CFD model. This model then applied into a finite element method (FEM) scheme for further structural analysis. They discussed that the main driving force for weld bead surface geometry formation is the Marangoni effect. Increasingly, commercial software packages such as ABAQUS [27] have been applied to study various welding processes [14, 28–30]. Michaleris and DeBiccari [30] employed ABAQUS to calculate welding-induced distortion and to study the structural integrity of large and complex structures. A decoupled thermal–mechanical analysis approach was developed where the welding-induced residual stresses were calculated based on a 2D FE model and then applied to a 3D FE model for structural analysis. Sharma et al. [16] suggested and validated a volumetric heat source model of twin-wire SAW by using different electrode diameters and polarities. It has been found that the heat source model parameters

for twin-wire welding are substantially different from the single-wire welding. Moreover, they showed that the heat source model parameters also depend upon welding parameters. Heat transfer and cooling rate of the fusion zone for SAW-T welding process were investigated using finite element methods by Kiran et al. [17]. They showed that welding cooling rates decreases with higher welding current. Wen et al. [14] developed the 2D and 3D FE models to predict welding-induced residual stresses and strains using FE package ABAQUS [27]. The heat transfer in the fusion and heat affect zones were investigated and linked to their structural analysis. Kim et al. [31] obtained the fluid dynamics and temperature distribution for different driving forces during tungsten arc welding (GTAW). Recently, Esfahani et al. [4, 32] carried out a research on microstructure and mechanical properties of dissimilar laser welding. They reported that the alloying concentration and consequent microstructure of the fusion zone is highly dependent on the fluid flow driven by thermal gradient, and hence accurate prediction of thermal gradient in fusion zone is of great importance. Until now, however, the significance of using two Goldak's double ellipsoidal heat sources in the SAW welding of APIX65 pipeline steel has not been fully

Fig. 2 Typical SAW plate weld bead with a controlled welding process (400 A, 34 V, speed 1200 mm/min)

investigated. In particular, the heat source modelling techniques to increase the accuracy of the temperature and stress prediction require careful consideration.

In this work, a 2D axi-symmetric and a 3D FE model of transient thermal analysis were developed based on two Goldak' s double ellipsoidal heat sources to achieve higher accuracy prediction of temperature and stress in molten pool and heat-affected area (HAZ) of SAW welding. The thermo-physical material properties were taken into account. The temperature field, residual stresses and fusion zone profile were predicted for both 2D and 3D scenarios. The calculated thermal cycle and weld geometry in the fusion zone were compared with experimental results obtained under similar parameters.

2 Experimental procedure

The material used in this study was API X65 steel plates. The S2MO welding wire with 3.2-mm diameter and AMA OP 139 welding flux were employed for the welding process. The chemical compositions of the base metal welding wire and flux are given in [33, 34]. A weld bead on the plate was deposited using submerged arc welding process with 400 A, 34 V, and 1200 mm/min welding speed (Fig. 2). The size of the metal plate was 200-mm length × 100-mm width with 14.3-mm thicknesses. In order to obtain geometry of weldment (weld width, weld depth, and length) and HAZ, the weld cross section was polished up to 1 μm and etched using Nital (5 %) reagent.

3 Formulation and grid structure

3.1 Thermal analysis

The FEA analysis was developed in ABAQUS software to model welding temperature fields for submerged arc bead-on-plate weldment. The problem of heat conduction in the weldment has been solved using heat transfer analysis to obtain thermal distribution histories. The formulation considers the contributions of the transient temperature field, as well as temperature-dependent thermo-physical properties. Figure 3 shows the initial mesh employed for the FEA analysis of

Fig. 4 Comparison of temperature distribution sensitivity (obtained from 3D FE model) to numbers of elements

SAW process. Because of the symmetry condition, only half of the welded plate is modelled for both 2D and 3D cases (Fig. 3). Filler material has also been taken into account for butt-joints of API X65 as can be seen in Fig. 3b. A variable spacing grid system with a fine grid near the heat source and a course grid away from the heat source has been used. The 3D computational domain in FEA model has the same dimension as the experimental sample and is modelled by 19430 eight-node brick solid elements of type DC3D8. The 2D computational domain however is modelled by 19430 four-node brick solid elements of type DC2D4 (Fig. 3a). Since the mesh size has significant role on calculation of temperature distribution, the peak temperature is used as the key parameter to measure the sensitivity of the analysis. Figure 4 shows the peak temperature versus the maximum number of elements. It can be seen from the figure that at 6000 elements, the variation of peak temperatures falls to less that 2 %. However, despite of stabilised temperature variation at 6000 elements, stress variation has stabilised around 19430 elements. As a result, a smoother thermal history and tension field are obtained at 19430 elements. The ambient temperature was set at 25 °C. The thermo-mechanical properties [35, 36] of API X65 used in the analysis are detailed in Table 1. The properties of filler wire are assumed to be same as the API X65 due to its significantly higher dilution rate in weld.

A code written as subroutine (DFLUX) in the FORTRAN programming language was used in order to apply a heat flux as a transient boundary condition on the top surface of the

weld. A moving volumetric heat source has been considered for modelling of welding arc, based on the double ellipsoidal distribution proposed by Goldak [24] (Fig. 5), which is expressed by the following equations. For the front heat source:

$$q_f = \frac{6\sqrt{3}\eta Q f_f}{\pi\sqrt{\pi}abc_f}e^{-3\left(\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c_f^2}\right)} \qquad (1)$$

And for the rear heat source:

$$q_r = \frac{6\sqrt{3}\eta Q f_r}{\pi\sqrt{\pi}abc_r}e^{-3\left(\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c_r^2}\right)} \qquad (2)$$

where Q is the welding heat source power, x, y and z are the local coordinates of the double ellipsoid model aligned with the weld line. The parameters a, b, C_r and C_f are associated to the features of welding heat source and were calibrated with
respect to the measured size of the fused zone (weld depth, weld width and length in front and back half of the weld). These parameters are obtained from experimental analysis of the fusion zone and are adjusted to create a desired melted zone according to the welding conditions. In addition, the moving coordinate system is assumed to be matched with the stationary coordinate C at time $t = 0$ for f_i for $i = f, r$ indicates the percentage of the total welding power Q in the front (f_f) or rear quarter (f_r) of the two ellipsoidal regions and is linearly related to the dimensions of these regions by Goldak [24, 39, 40]:

$$f_i = \frac{2c_i}{c_f + c_r}, \quad (i = f, r) \qquad (3)$$

It is worth mentioning that thermal gradient is far superior in the front of the arc compare to that of the back. The arc efficiency η is assumed to be 90 % for the SAW welding process [15, 41, 42]. These parameters are detailed in Table 2 for both weld reinforcement and fusion zone. In order to have a higher accuracy in prediction of thermal distribution, two Goldak's double ellipsoidal heat sources are used in this

Fig. 5 Schematic diagram of Goldak model [38]

Fig. 8 Welding direction and temperature fields at the middle of weld line

paper, one for the fusion zone and the other one for the deposited flux (weld reinforcement, excess of weld). The latter is modelled inversely to the one used for fusion zone as presented in Fig. 6.

In the thermal analysis, the transient temperature field T is a function of time (t) and the spatial coordinates (x, y, z), and is determined by the three-dimensional nonlinear heat transfer equation:

$$\rho c \frac{\partial T}{\partial t}(x, y, z, t) = -\nabla \cdot \vec{q}(x, y, z, t) + Q(x, y, z, t) \quad (4)$$

where ρ is the density of the materials, c is the mass-specific heat capacity, T is the current temperature, $\vec{q}$ is the heat flux vector, Q is the internal heat source rate, x, y and z are the coordinates in the reference system, t is the time, and ∇ is the spatial gradient operator.

The non-liner isotropic Fourier heat flux constitutive equation is used [28]:

$$\vec{q} = -k\nabla T \quad (5)$$

where k is the temperature-dependent thermal conductivity. On the boundary or the surfaces of the work-piece, convection and radiation in heat transfer are responsible for heat loss to the ambient. To simulate the combined thermal boundary condition and avoid complexities with radiation modelling, a user-defined subroutine was developed. The total temperature-dependent heat transfer coefficient is provided by Eq. (5) [28, 43]:

$$h = \begin{cases} = 0.68T \times 10^{-8}\left(W / mm^2\right) & 0 < T < 500^\circ C \\ = (0.231T - 82.1) \times 10^{-6}\left(W / mm^2\right) & T > 500^\circ C \end{cases}$$

$$(6)$$

where h is the heat transfer coefficient and T is the temperature in degree Celsius. For the purpose of fusion zone and HAZ geometry prediction, a user defined field (USDFLD) subroutine was developed to determine the peak temperatures in the FE thermal analysis. The subroutine can keep a record of the peak temperatures by equating a state field variable in the subroutine to the temperature whenever the latter is on the rise. The state field variable can then be plotted from the results file as the peak temperature throughout the process of welding. In this code, the melting point of the material is defined as 1493 °C. Based on Francis et al. [44], there are two critical regions in HAZ where the grain coarsening and phase transformation lead to major variation in microstructure and service performance of the weld. Therefore, the HAZ is differentiated in the code to grain coarsening region (HAZ 1) where the material has been heated to temperatures in the range of 1100–1440 °C, and grain-refining region (HAZ 2) in which the material has been heated to temperatures in the range of 823(AC$_3$)–1100 °C [44].

Fig. 7 Comparison of simulated (left side) and experimental (right side) weld bead cross section profiles: from FE model (a) and from experiment (b)
3.2 Mechanical analysis

The stress distortions in weld are mainly caused by the thermally induced expansion and shrinkage and phase transformation-induced volume change. The residual stresses from phase transformation have not taking into consideration in this study. The residual stresses are calculated by employing the temperature distribution obtained from thermal analysis as input data. The material properties relevant to residual stresses are Young's modulus, yield strength, Poisson's ratio and the coefficient of thermal expansion. By considering the elastic–plastic material properties, the total strain in the SAW weld can be decomposed into three components as given by [45]:

$$\varepsilon = \varepsilon^e + \varepsilon^p + \varepsilon^t \tag{7}$$

Where ε^e, ε^p and ε^t are elastic strain, plastic strain and thermal strain, respectively. Elastic strain is modelled using the isotropic Hooke's law with temperature-dependent Young's modulus and Poisson's ratio. The thermal strain is calculated using temperature-dependent coefficient of thermal expansion. For the plastic strain, a plastic model is employed with von Mises yield criterion, temperature-dependent mechanical properties and linear kinematic hardening model. Kinematic hardening is considered because material points undergo both loading and unloading in the welding process, which has been widely used in the welding residual stress simulation [28, 46]. The boundary conditions taken into consideration in the mechanical analysis assume that one edge of the butt joint is fixed, and the other one is only transversely shrinkage free.

4 Results and discussion

The main objective of this research is to develop a FEA model that is capable of predicting the SAW thermal cycle and residual stress with higher accuracy compare to the available results in literature. To do this, a two Goldak heat sources are developed for fusion zone and weld reinforcement. Using the modified heat source, the 2D and 3D models are developed,
Fig. 10 Comparison between the proposed Goldak model prediction (*left*) and test fusion zone geometry (*right*)

and their thermal distribution and residual stresses are compared with each other.

Figure 7a shows the weld bead temperature distribution using the Goldak model. Considering the melting point of the steel as 1493 °C, it is evident from etched cross section of weld (Fig. 7b) that the fusion zone width and depth are predicted somewhat wider and deeper than the experiments. The reason for that is mainly because the calculation does not consider the amount of the energy which is used to melt the deposited wire into the fusion zone. This simplification will result in (a) higher peak temperature in fusion zone (3800 °C), (b) larger geometry for fusion zone and HAZ, and consequently lack of accuracy of the model. Therefore, two Goldak's double ellipsoidal heat sources are used in this paper, one for the fusion zone and the other one for the deposited flux (weld reinforcement, excess of weld).

4.1 Simulated results of 3D model

The welding direction and temperature contours are shown in Fig. 8. Welding started from one end of the work-piece, and after sweeping along the weld line, it ends at the other end. From this figure, it can be also observed that the maximum temperature at the fusion zone is about 2000 °C.

Figure 9a shows peak temperature distribution on weld surface versus distance from the weld centre line for various time steps. As can be seen from the figure, the temperature of the points close to weld centre line decreases as the time increases. However, the temperature of the points away from the

Fig. 9 Temperature distribution versus distance from the weld centre line (**a**): on weld surface (**b**) through the thickness

(a)   (b)

(a)

(b)

(c)

(d)
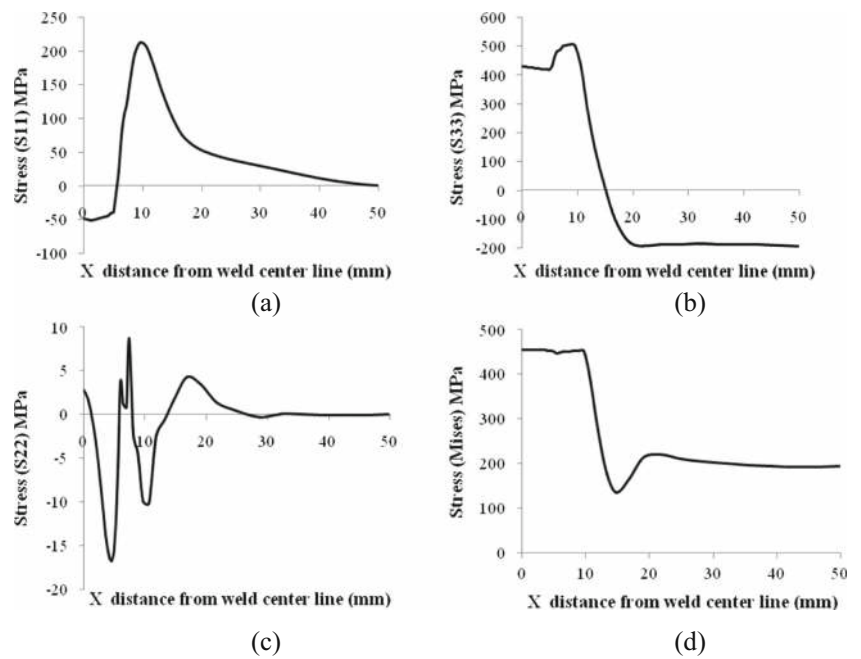

weld increases by increasing the time. One reason for the temperature rise can be attributed to higher thermal gradient of the close region to fusion zone which consequently results in faster undercooling and sooner temperature drop in comparison to the regions that are away from the weld boundary (which experience less thermal gradient and heat transfer).

Fig. 12 Residual stresses on the upper surface of the 3D model: transverse residual stress distributions (MPa) (**a**), longitudinal residual stress (**b**), through thickness residual stresses (**c**)

(a)

(b)

(c)
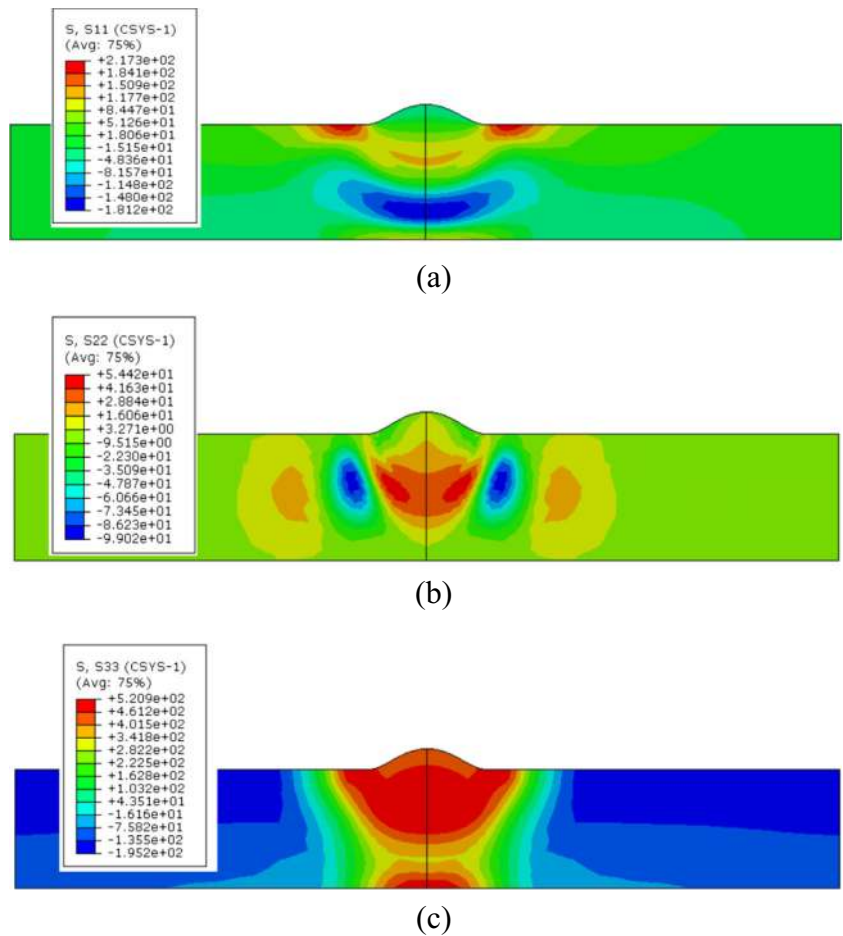

Another reason behind temperature differences may be attributed to the effect of phase transformation on carbon steel. Rate of solid state phase transformation in the different regions away from the steel's fusion absorbs a proportion of heat source energy [47]. It is also worth mentioning that the rate at which the temperature gradient becomes constant through the thickness (Fig. 9b) is higher than the corresponding rate on the surface (Fig. 9a), (20(s) through the thickness in comparison to that of 100(s) for the surface). Therefore, the weld thickness plays a more important role than the weld width in undercooling of the joint. Figure 10 shows the fusion zone and HAZ geometry obtained by FEA analysis (modified Goldak model) and experimental analysis. The weld and HAZ geometry in the model is obtained using a subroutine (USDFLD) in the model as discussed earlier. From this figure, it can be noticed that both the fusion zone and the HAZ geometry at each location are in very good agreement with the experimental measurements.

4.2 Results of mechanical analysis

The predicted distribution of transverse residual stresses for APIX65 steel at the position of $z = 180$ mm is presented in Fig. 11a. As can be seen, the stress is −50 MPa at fusion zone due to compressive forces in this region, and then it rise to 212 MPa in HAZ as a result of tensile stress of weld region during solidification. Figure 11b illustrates the longitudinal residual stress for the fusion zone and HAZ. The results show an almost similar trend to that of transverse stresses though the magnitude of the longitudinal stresses are about twice the maximum value of transverse residual stresses. The average stress is 420 MPa in fusion zone as a result of tensile force from the surrounding metals which creates tensile stresses in the region, and the maximum stress occurs in the steel HAZ for the value of 504 MPa. The results also show that by moving away from fusion zone and HAZ, the stress decreases with significantly steeper trend and reach to the compressive stress value of −200 MPa in the base metal to balance the tensile stresses in fusion zone. The stress distribution along the thickness is shown in Fig. 11c. This figure shows the minimum stress among the other directions (−17 MPa in fusion zone and 0 MPa in base metal). The von Mises equivalent residual stresses (presented in Fig. 11d) has the average of 450 MPa (~0.84 of σ_y) in fusion zone and HAZ. This value decreases to 200 MPa in the base metal. The distributions of transverse, thickness and longitudinal stresses fields in the x–y plane are displayed in Fig. 12a, b c, respectively.

4.3 2D axi-symmetric model

The 2D finite element model and weld passes are shown in Fig. 13. The numerical analysis procedure employed in 2D model is the same as the 3D model. In welding simulation, it

Temp (°C)

Fig. 13 The 2D axi-symmetric model and predicted temperature distribution of the fusion zone

is essential to develop a model which can accurately predict the thermo-mechanical behaviour of the fusion zone with less calculation time. If the 2D model can be effectively employed to predict the weld temperature distribution and residual stress, the significant amount of computational time and cost involved in 3D simulation can be avoided.

4.4 Comparison of obtained results

Figure 14 presents the simulated results of both the 2D and 3D models for peak temperature distribution on weld surface versus distance from the weld centre line. The graphs are generated after the temperature of fusion zone reach a quasi-steady state. It can be seen that pick temperatures of 2D model are marginally higher than that of 3D model for the points closer to weld centre line (1901 °C for 2D, and 1832 °C for 3D). This is because there is not heat transfer calculation in z direction in 2D model; hence, a higher peak temperature is predicted in 2D models compare to that in 3D model.

Figure 15a, b shows the residual stress results of both 2D and 3D models in transverse and longitudinal directions. As can be seen in Fig. 15a, the average transverse residual stresses in HAZ are higher in 3D model than those in 2D model (212 MPa in 3D model to 165 MPa in 2D model). However, the differences between longitudinal direction

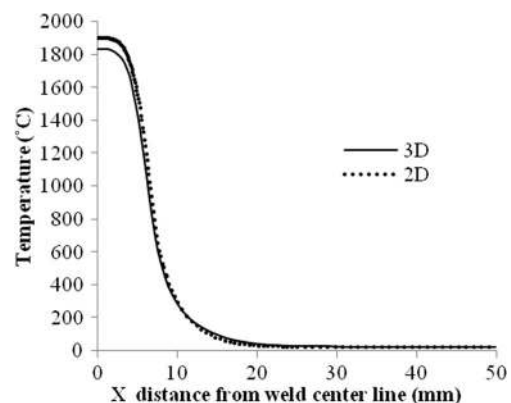

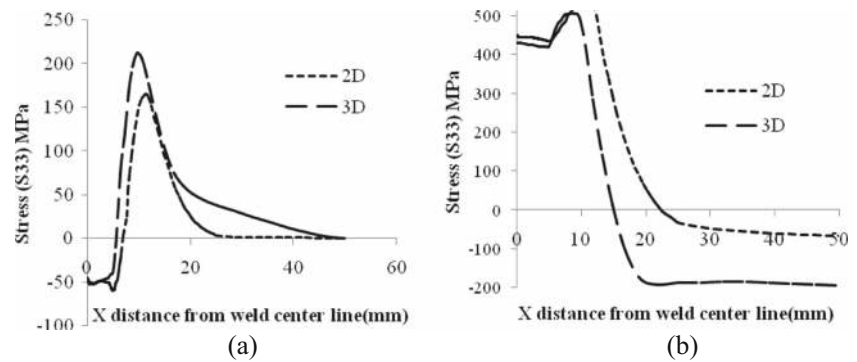

Fig. 14 Comparison between the thermal histories at weld surface computed with the 3D and 2D models

Fig. 15 Comparison of the residual stresses calculated with the 2D and 3D models in transverse direction (**a**) and longitudinal direction (**b**)

(a)   (b)

residual stresses of both 2D and 3D models in HAZ are very small (504 MPa in 3D model to 530 MPa in 2D model), and the 2D stress prediction is found to be in close agreement with 3D model. It is known that the longitudinal residual stresses are of the greater importance than the other stresses due to their higher magnitude. Therefore, 2D model can accurately predict the thermal cycles and residual stresses inside fusion zone and HAZ. The results of both the temperature fields and the residual stress distribution suggest that it is feasible and reasonable to conduct the thermal analysis and the mechanical analysis for the APIX65 steel plates using a 2D axi-symmetric model.

5 Conclusions

A new heat source distribution for SAW welding is defined in this research. A 2D axi-symmetric and 3D FE models have been developed for predicting and analysing the fusion zone temperature distribution and residual stress in submerged arc welding. The following conclusions can be drawn from the present study:

- The two Goldak's double ellipsoidal heat sources show that using both heat sources for fusion zone, and reinforcement zone can result in significant improvement for fusion zone and HAZ geometry prediction. Considering such heat source for welding with high reinforcement zone can be an appropriate approach to predict more accurate FEA results.
- There is a reasonable agreement between the predicted and the measured fusion zone geometry that verifies the validity of the employed 2D axi-symmetric and 3D FE models. Using 3D model, the detailed information of thermal history and residual stress fields can be obtained. The 3D model can provide more accurate thermal history and stress distributions; however, a significant amount of computational time can be saved by employing 2D model.
- The longitudinal stresses are found to be greater than the other directional stress and hence need to be completely considered during welding of APIX65 in order to avoid transverse cracks.
- It is shown that thermal gradient is higher through the thickness than that of the specimen width; therefore, thickness is found to have greater importance than width in cooling of the fusion zone.
