33 ABSTRACT

34 Culverts can restrict movement of stream-dwelling fish. Motivation to enter and ascend
35 these structures is an essential precursor for successful passage. However, motivation is
36 challenging to quantify. Here, we use attempt rate to assess motivation of 447 brook trout
37 entering three culverts under a range of hydraulic, environmental and biological conditions. A
38 passive integrated transponder system allowed for the identification of passage attempts and
39 success of individual fish. Attempt rate was quantified using time-to-event analysis allowing for
40 time-varying covariates and recurrent events. Attempt rate was greatest during the spawning
41 period, at elevated discharge, at dusk, and for longer fish. It decreased during the day and with
42 increasing number of conspecifics downstream of the culvert. Results also show a positive
43 correlation between elevated motivation and successful passage. This study enhances
44 understanding of factors influencing brook trout motivation to ascend culverts and shows that
45 attempt rate is a dynamic phenomenon, variable over time and among individuals. It also
46 presents methods that could be used to investigate other species' motivation to pass natural or
47 anthropogenic barriers.

49 RÉSUMÉ

50 Les ponceaux peuvent limiter les déplacements des espèces d'eau douce. La motivation
51 à entrer dans le ponceau constitue un élément essentiel au succès de passage. Elle est
52 cependant difficile à quantifier. Dans la présente étude, nous utilisons la fréquence des
53 tentatives pour évaluer la motivation de 447 ombles de fontaine tentant de franchir des
54 ponceaux sous une gamme de conditions hydrauliques et environnementales. Un système à
55 transpondeurs passifs intégrés a permis de quantifier les tentatives et le succès de passage des

56 ombles sur une base individuelle. La fréquence des tentatives a été déterminée en utilisant des
57 analyses de temps à l'événement permettant de considérer les variables fluctuant dans le temps
58 et les événements récurrents. La fréquence des tentatives était plus élevée en période de
59 reproduction, à un débit élevé, au crépuscule et pour les ombles de taille supérieure. À l'inverse,
60 la fréquence des tentatives diminuait durant le jour et avec la présence d'un nombre élevé
61 d'ombles en aval du ponceau. Les résultats démontrent également un lien entre une motivation
62 accrue et le succès de passage. Cette étude procure une meilleure compréhension des facteurs
63 influençant la motivation de l'omble de fontaine à franchir les ponceaux et montre que celle-ci
64 est un phénomène dynamique, variable dans le temps et entre les individus. Elle présente par
65 ailleurs des techniques pouvant être utilisées pour déterminer la motivation de d'autres espèces
66 à franchir des obstacles d'origine naturelle ou anthropique.

67 INTRODUCTION

68 Connectivity plays a key role in the ecology of fish species (Fausch et al. 2002). Natural or
69 anthropogenic features may limit the ability of fish to access fluvial habitats, thus impeding the
70 persistence of healthy fish populations (Letcher et al. 2007, Morita and Yamamoto 2002, Perkin
71 and Gido 2012). Road-stream crossings constitute some of the most ubiquitous structures that
72 contribute to habitat fragmentation. Culverts can pose partial or complete barriers to fish
73 movements by being perched, providing insufficient flow depth, or excessive velocities that fish
74 are unable to negotiate. (Burford et al. 2009, Gibson et al. 2005, Goerig et al. 2016, Mahlum et
75 al. 2013).

76 Assessments of fish passage through culverts have been based on coarse filters using culvert
77 characteristics (Coffman 2005, Poplar-Jeffers et al. 2009), empirical studies of fish ascending
78 culverts (Goerig et al. 2016) or experimental studies on swimming performance and maximal

79 distances of ascent in controlled laboratory environments (Castro-Santos 2005, Sanz-Ronda et
80 al. 2015). Many studies have focused on physiological limits of fish (Castro-Santos et al. 2013,
81 Peake et al. 1997, Weaver 1963) but few have quantified behavioral factors that may also
82 influence passage.

83 Motivation to enter a culvert is an essential step towards successful passage. Indeed, even a
84 culvert with favorable conditions becomes a barrier if fish do not enter the structure and
85 attempt to pass. This highlights the importance of considering causal mechanisms influencing
86 their motivation and the implication for passage success. However, motivation is difficult to
87 quantify, in part because it lacks a discrete and uniformly accepted definition. In general,
88 motivation refers to conditions that prompt an individual to movement or action (Marriam-
89 Webster 2006). It also refers to the internal condition influencing the relationship between
90 stimulus and responses (Barnard 2012). Various models have been developed to explain and
91 quantify motivation, with their respective strengths and drawbacks (Barnard 2004, 2012,
92 McFarland 1999). In the context of culvert passage, we define motivation as the willingness to
93 enter the structure and swim upstream. The rate at which fish attempt to surmount obstacles
94 provides an index of motivation that is both intuitive and appropriate for understanding passage
95 success.

96 Motivation to move upstream results both from the physiological condition of the fish and
97 its response to external factors like flow, temperature, or predation (Agostinho et al. 2007,
98 Castro-Santos et al. 2013, Hasler and Scholz 2012). In a fluctuating environment, fish motivation
99 is likely to vary over time. Furthermore, fish may exhibit diversified and complex behavior in
100 response to a new or challenging environment and so variability among individuals is to be
101 expected (Adams et al. 2000, Magurran 1986). Nevertheless, the attraction exerted by the

102 culvert, as well as environmental variables such as diel period or water temperature, may be
103 important to stimulate fish to initiate an attempt.

104 The brook trout (*Salvelinus fontinalis*) is a widely distributed species that can exhibit long-
105 distance movements (Gowan and Fausch 1996, Rodriguez 2002) and is negatively impacted by
106 barriers. Attempt rate and swimming performance of brook trout has been studied in an open
107 flume (Castro-Santos et al. 2013) but not in their natural habitat. A recent study described
108 passage of brook trout through culverts (Goerig et al. 2016), but only the individuals that staged
109 attempts were used in the analysis. Here we present field observations of brook trout
110 attempting to pass culverts under a range of conditions, with the aim of developing a method to
111 quantify their motivation and its importance on passage success. The methods we describe here
112 could be readily applied to other species and locations.

113 To achieve our objectives, we use an analytical approach considering all available fish to
114 model the effect of hydraulic, environmental and biological variables on the timing and rate of
115 attempts, which we interpret as an index of motivation. We then consider the effect of these
116 variables as well as that of individual variability in motivation, on passage success.

117 **METHODS**

118 **Study sites**

119 Brook trout passage attempts were recorded during field trials at three culverts located
120 in the Sainte-Marguerite River watershed (Québec, Canada), on the Morin, Allaire and Résimond
121 streams. Culverts were 18 to 45 m in length and 1.6 to 2.2 m in diameter. They were made of
122 either corrugated metal or smooth material (Table 1). One culvert had multiple pipes, bringing
123 the total number of tested pipes to six.

124 **Fish collection and tagging**

125 Fish were caught by electrofishing (Smith-Root backpack electrofisher, model 15-C,
126 Vancouver, Washington, USA) 0-500 m upstream of the culverts. In order to increase sample
127 size, some fish were also caught 0-500 m downstream of the Morin culvert and in a nearby
128 stream, the Épinette. (Table 2; Figure 1). The Morin, Allaire and Épinette streams are located
129 within 10 km of each other while the Résimond stream, by contrast, is > 26 km distant from the
130 others.

131 Fish were anesthetized by immersion in a 1:9 solution of clove oil and 95% ethanol,
132 diluted in water (0.8-1.2 ml of solution for 1400 ml of water). They were measured (fork length,
133 mm), weighed (wet mass, gr) and surgically tagged with half-duplex passive integrated
134 transponders (PIT) tags (Texas Instruments, 23 mm in length, 3 mm in diameter; mass in air: 0.6
135 g; tag-to-fish mass ratio:0.42%–8.22%). The PIT-tags were inserted in the fish peritoneal cavity
136 and cyanoacrylate glue (Vetbond, 3M) was used to close the incision. Fish were placed in
137 holding pens in the river for a recovery period of 2 (6.7%), 4 (86%) or 18h (7.6%). . After
138 recovery, fish were transported in buckets and released in the cage below the culverts. The
139 collection and tagging procedures were in conformance with the guidelines of the Canadian
140 Council of Animal Care in science (CCPA).

141 **Study design and instrumentation**

142 Passage trials lasted 24-48h, and were conducted between July and October. Fish were
143 released in a large cage (2 x 2 x 1 m) secured to the downstream extremity of the culverts and
144 allowed to volitionally stage passage attempts. To ensure that entry into the culvert was truly
145 volitional, each cage contained rocks and other substrate, providing ample resting areas under
146 all tested conditions. Thus there was no coercion of fish to stage attempts. For the culvert with
147 multiple pipes, the cage was fixed to a single pipe during a given trial and the other pipes were
148 blocked. Flow depth and water temperature of each stream were recorded every 60 min by a

149 data logger (Onset, HOBO 020-001-04) located 20 m upstream of the culvert. We derived
150 discharge rating curves for each stream by correlating depth data with on-site flow
151 measurements (Marsh-McBirney Flow-Mate 2000 electromagnetic velocimeter). Assuming no
152 significant backflow or hydraulic loss, this method provided a reasonable approximate of the
153 flow discharge inside the culvert (Chow 1959).

154 The tested pipes were instrumented with a telemetry system consisting of four antennas evenly
155 spaced along the pipe. The first antenna was located at the downstream end of the culvert and
156 the fourth was located at the upstream end. Antennas were placed above the water surface to
157 avoid flow disturbances. Their dimensions varied with the culvert's diameter, ranging from 0.45
158 m × 1 m to 0.45 m × 2 m. The antennas interfaced with a half-duplex PIT reader via a multiplexer
159 (Technologie Aquartis, control module Quatro, multi-antennas system HDX-134.2 kHz). The
160 reader recorded tag number, antenna number, and time to the nearest 1 s. Detection efficiency
161 of the PIT system was assessed by comparing detections at the upstream-most antenna with
162 those downstream. This allowed us to quantify detection efficiency of antennas 1-3, but not
163 antenna 4, which we assumed to be 100%.

164 Detections within 1 s were grouped together, representing discrete exposure to an
165 antenna. The direction of the fish's movement was assessed by the order of detection at the
166 four antennas, and an attempt was defined as an upstream movement beginning at the
167 downstream-most antenna (antenna 1). The attempt was considered successful if the fish
168 reached the upstream-most antenna (antenna 4) before the end of the trial. A threshold of 60
169 seconds between detections at the first antenna was used to differentiate among attempts. This
170 threshold was identified based on the distribution of time intervals between successive
171 detections at antenna 1 (Castro-Santos and Perry 2012). Data were screened for false readings,

172 resulting from simultaneous detections at two antennas. These were very rare and were
 173 corrected before processing the data for statistical analysis.

174 **Statistical analysis**

175 We used time-to-event analysis (Allison 2014, Castro-Santos 2004, Hosmer et al. 1999)
 176 to quantify attempt rate of fish released downstream of culverts. Attempt rate refers to the
 177 percentage of fish staging an attempt per unit of time (% t⁻¹). In the context of the current
 178 study, it is the proportion of the fish available to stage a given attempt that a particular
 179 individual represents at the moment it stages an attempt. Each attempt constitutes a single
 180 event, and has an associated instantaneous event rate (or 'hazard'). Cox regression estimates
 181 the relative effect of covariates on the hazard function (Armstrong and Herbert 1997, Castro-
 182 Santos and Haro 2003). Cox regression assumes covariate effects on the hazard remain
 183 proportional, meaning that explanatory variables do not interact with time and so have a
 184 constant effect over the time interval considered.

185 Cox regression mixed models were fit to the data using the package Coxme in R 3.2.0 (R
 186 Core Team 2015, Therneau 2015a), by including fixed effects and nested random effects (e.g.
 187 frailty terms) for stream of origin and individual fish. This model structure accounted for the
 188 heterogeneity related to the stream of origin and the statistical dependence among repeated
 189 events from the same fish (Armstrong and Herbert 1997, Therneau et al. 2003). It is expressed
 190 by

$$191 \quad (1) \quad \lambda(t) = \lambda_0(t) e^{X\beta + Zb}$$

$$192 \quad (2) \quad b \sim G(0, \Sigma(\theta))$$

193 Where $\lambda(t)$ is the baseline hazard function (i.e., attempt rate) modeled as a function of time (t).
 194 The time interval preceding each attempt is considered in the analysis, along with X and Z

195 representing the matrices of fixed and random effect values, respectively. β is the vector of
196 fixed-effects coefficients and b is the vector of random effects coefficients. The distribution of
197 random effects G is modeled as Gaussian with a mean of 0 and a variance matrix Σ , which
198 depends a vector of parameters θ (Therneau 2015a). The random effects estimate the variance
199 among streams of origin and individual fish in the baseline hazard function, that is, after
200 controlling for fixed effects. The random effect for each individual measures its deviation from
201 the baseline attempt rate. Negative values represent less-than-average attempt rate whereas
202 positive values measure higher-than-average attempt rate.

203 Independent explanatory variables deemed likely to have an effect on attempt rate
204 were considered in the analysis, representing the fixed effects in the model. These included fish
205 fork length, fish condition factor ($k = 10^5 * \text{weight} / \text{length}^3$), diel period (dawn, day, dusk or night),
206 hourly discharge, relative change in discharge ($(Q_2 - Q_1) / Q_1$), hourly water temperature, change in
207 water temperature ($T_2 - T_1$) and number of fish in the cage. The spawning period was included as
208 a categorical variable. It was coded 0 for periods greater than two weeks from the expected
209 spawning time and 1 for periods within two weeks of expected spawning time. In the Ste.
210 Marguerite watershed, spawning occurs in mid- September. The effect of independent variables
211 on attempt rate was modeled as linear, since an analysis of the residuals of the full model did
212 not detect any nonlinear trends (Fox 2002, Therneau et al. 1990) A suite of candidate models,
213 each consisting of a reasonable combination of explanatory variables and the nested random
214 effects, was developed according to the following criteria: i) minimum of one and maximum of
215 six main effects ii) no interactions iii) change of temperature was always used along with water
216 temperature iv) relative change in discharge was used with and without discharge v) water
217 temperature and discharge were never used together in a model due to their correlation ($r = -$
218 0.67, $p < .0001$), as well as fish fork length and fish condition factor ($r = 0.30$, $p < .0001$)

219 The time interval between the beginning of the trial and the beginning of the first
220 attempt was recorded for each fish, corresponding to the pre-attempt interval. When fish
221 returned to the cage and became available to stage a subsequent attempt, the time interval
222 between the arrival in the cage and the beginning of the second attempt was recorded. The
223 time interval between the end of the last attempt and the termination of the trial was also
224 recorded. The occurrence of an event, as well as the sequence of event (attempt number), were
225 indicated in the dataset. Right censoring, consisting in fish having not yet staged an attempt at
226 the end of the trial, was indicated by 0 for censored and 1 for complete observations.

227 One of the strengths of time-to-event analysis is that it allows for explicit measurement
228 of effects of covariates that change over time. These were integrated with the dataset so that
229 each discrete value of the number of fish in the cage, diel period, flow discharge and water
230 temperature had a distinct record, with an associated start and an end time (Castro-Santos and
231 Perry 2012). Start and end times of diel periods (dawn, day, dusk and night) were determined
232 for each trial using the sunrise/sunset calculator of the National Research Council of Canada
233 (NSERC). The number of fish in the cage was set to a starting value corresponding to the number
234 of fish released at the beginning of the trial. It was then allowed to vary instantaneously
235 according to individuals staging attempts and others returning downstream after an attempt.
236 Tagged fish returning downstream from previous trials, although not considered in the
237 quantification of attempt rate, contributed to the number of fish in the cage. To account for
238 eventual reverse causation created by the intrinsic link between the number of individuals in the
239 cage and the attempt rate, we used in the analysis the most recent value observed prior to the
240 attempt (Allison 2014).

241 Models were selected by minimizing the Akaike Information Criterion (AIC), defined as:

242 (3)
$$AIC = -2 \log L + 2K$$

243 Where L is the model's likelihood, and K is the number of parameters.

244 Fixed and random effects coefficients, as well as standard errors, were extracted from
245 the selected model. Hazard ratios were obtained by exponentiating the coefficients estimated
246 for each covariate. Functions to extract residuals and plot Kaplan-Meier and survival curves
247 were not available in the Coxme package. To test the assumption for proportionality of hazards,
248 we used the Survival package (Therneau 2015b) to fit the same model with a random effect on
249 stream and used it to extract residuals. We also extracted the baseline hazard and used it, along
250 with the parameter coefficients estimated in the Cox mixed model, to plot survival curves
251 adjusted for a given set of covariate values.

252 We modeled passage success for fish that staged attempts and assessed the relationship
253 between individual motivation and passage performance. Individual variability in motivation
254 was estimated by the random effect coefficients for each fish in the attempt rate model
255 described above. The probability of successful passage was modeled as a function of a random
256 effect on trial and fixed effects on fish fork length and motivation, using logistic regression (R
257 3.2.0, package lme4, function glmer). The random effect accounted for most of the variability in
258 passage performance due to the characteristic of the trials (water temperature, mean flow
259 depth and velocity) and those of the culverts (culvert type, slope and length). The fixed effects
260 allowed the assessment of the specific effects of fork length and motivation on passage success.

261 **RESULTS**

262 **Trial conditions**

263 A total of 447 fish were released during 19 passage trials: 14 in corrugated metal
264 culverts and 5 in smooth-material culverts. Each trial consisted of a group of 15 to 25 tagged
265 individuals, of fork length ranging from 90 to 263 mm (Table 2). Trials were conducted from late
266 June to mid-October, at water temperatures from 3 to 20°C (Table 3). Flow discharge ranged

267 from 55.5 to 715.5 L s⁻¹ while the number of fish in the cage varied between 2 and 28 (Table 2).
268 The detection efficiency of the PIT system for a fish moving upstream was greater than 97% for
269 antennas 1, 2 and 3. Despite the fact that detection efficiency could not be quantified for
270 antenna 4, we can infer a high value based on these results.

271 One hundred ninety three fish staged no attempts during the trials. This represents 43 %
272 of the available fish, and these were included in the analysis as censored observations on the
273 first attempt.

274 Some trout staged several attempts during the trials. The rate at which the first attempt
275 occurred was slower than the rate of subsequent ones, as illustrated in the empirical cumulative
276 incidence curves (Figure 2). The rate thereafter increased with subsequent attempts. Because
277 trials were of finite duration, fish that staged more attempts necessarily staged them at a
278 greater rate.

279 **Model for attempt rate**

280 Among the 191 models estimated, one model had an optimal fit to the data (Δ AIC from
281 closest competing model = 2, Akaike weight = 0.71, Table 4). This model includes proximity of the
282 spawning period, flow discharge, diel periods, number of fish in the cage and fork length.

283 Examination of Schoenfeld residuals indicated that the selected model did not violate the
284 proportional hazards assumption, meaning that covariate effects were consistent over time
285 (Hosmer et al. 1999).

286 Fish staged attempts at a higher rate at the approach of spawning, the estimated hazard of
287 attempt being 1.80 times higher within two weeks of the expected spawning time than outside
288 this period (HR = 1.809, Table 5).

289 Discharge had a positive effect on the attempt rate: an increase of 1 L s^{-1} led to a 0.3 %
290 increase in the hazard of staging an attempt (HR = 1.003, Table 5). This means that the attempt
291 rate was ~ 7 times faster at the maximum discharge tested (715 L s^{-1}) compared with the
292 minimum discharge (55 L s^{-1}). For an average culvert, $\sim 60\%$ of the released fish would have
293 attempted to pass the culvert when there was 100 L s^{-1} , compared to $\sim 80\%$ at 300 L s^{-1} and \sim
294 90% at 500 L s^{-1} (Figure 3).

295 Attempt rate was 25% higher at dusk than at dawn (HR = 1.253, Table 5). Attempt rate was
296 similar between night and dawn periods, but it was reduced during the day by $\sim 15\%$ (HR =
297 0.841, Table 5). Attempt rate also decreased with an increase of the number of conspecifics in
298 the cage, each new fish in the cage leading to a decrease of 4 % in the attempt rate (HR = 0.963,
299 Table 5). Longer fish had a higher attempt rate, each additional mm increasing the rate by 0.8%
300 (HR = 1.008, Table 5). This means that the longest individual tested (263 mm) had an attempt
301 rate ~ 3 times faster than the smallest one (85 mm).

302 After accounting for the fixed effects in the model, some unexplained variability in attempt
303 rate remained, with the variance of the random effects for stream of origin and individual fish
304 being respectively 0.472 and 1.158 (Table 5). Controlling for covariates, trout from Allaire and
305 Épinette streams had greater attempt rates 42% greater than the average (HR = 1.427 and
306 1.362, Table 5). Trout from Résimond stream staged attempts at 0.37 times the average rate of
307 the study, or a reduction of 63% (Table 4). The proportion of released fish having staged
308 attempts after twelve hours was between 70 and 80 % for trout from Allaire, Épinette, Morin
309 and Morin DS streams, but only 35% for trout from Résimond stream (Figure 4).

310 The estimated random effect coefficients for all fish follow a bimodal distribution, with
311 lower values representing less motivated individuals, and higher values representing more

312 motivated individuals, as indicated by reduced or elevated attempt rates, respectively (Figure 5).
313 We hypothesize that the two modes correspond at least partially to the fish that did not stage
314 attempts during the course of the trial and the ones that did. This does not respect the
315 assumption of a normal distribution for the random effect in the Cox mixed model and may
316 suggest that a bimodal unmeasured variable is influencing individual motivation. The random
317 effects were not correlated to the distribution of other covariates, except for the number of fish
318 in the cage ($r = 0.22$, $p < 0.001$). As fish were attempting and eventually passing the culvert, the
319 number of conspecifics in the cage decreased. For a passable culvert, the number of fish in the
320 cage was low at the end of the trial and the ones remaining were the less motivated fish (e.g.
321 those that staged few or no passage attempts).

322 **Effect of motivation on passage success**

323 When estimating the probability of passage success in the study, we found a substantial
324 variance for the random effect on trials (7.273, Table 5). This was to be expected as most of the
325 variability in passage performance was due to differences in conditions in flow and water
326 temperature during the trials, as well as in the characteristics of the culverts. The individual
327 variability in motivation, represented by the coefficient estimated for each fish in the attempt
328 rate model, has a significant positive effect on passage success (OR = 2.109, Table 6 & Figure 5).
329 This means that a trout with a high level of motivation (coefficient = 1) had a probability of
330 successful passage twice that of a fish with an average level of motivation (coefficient = 0). Fork
331 length had a small positive impact on passage success, each additional cm increased the
332 probability of success by ~ 1% (OR = 1.011, Table 6). A likelihood ratio chi-square test indicated
333 that the model including motivation and fish fork length was better over the one comprising
334 only the random effects on trial (chi-square = 5.697, df = 2, $p = 0.057$).

335 **DISCUSSION**

336 This study used attempt rate as an index of the motivation of wild fish to pass culverts in
337 their native environment. The study design offered the opportunity to assess the impact of
338 environmental and biological variables on motivation, with results suggesting that motivation is
339 a dynamic phenomenon, variable over time and among individuals. In this study, brook trout
340 attempt rate in culverts was influenced by hydraulics, diel period and fish behavior and
341 physiology. After accounting for these effects, individual variability in attempt rate was still
342 observed in the study, with important implications for passage success.

343 **Effect of covariates on attempt rate**

344 Trout staged attempts more frequently at a higher discharge. Similar behavior was observed
345 for brook trout and other species attempting to ascend experimental flumes (Castro-Santos
346 2004, Castro-Santos et al. 2013, Weaver 1963). This finding emphasizes the importance of
347 providing attraction flow below culverts in order to stimulate fish to enter.

348 Trout showed greatest motivation to ascend the culvert at dusk. Motivation was similar at
349 dawn and night but decreased during the day. These results are consistent with those of a study
350 of fish passage in an experimental culvert (Peterson et al. 2013) and previous findings showing
351 that salmonids are more active and moved greater distances at twilight and night, with a sharp
352 decline in overall activity during the day (Bunnell et al. 1998, Roy et al. 2013, Young 1999). Such
353 patterns may be the result of competition or predator avoidance. Fish are indeed less visible
354 when light declines and can leave their shelter and move more safely. Reduced movement can
355 also result from avoidance of sudden changes in luminosity, the difference between the open
356 stream and the culvert being more pronounced during the day. Also, drift feeding is known to be
357 more efficient for salmonids during the day (Fraser and Metcalfe 1997, Jenkins Jr 1969). Because
358 they often restrict the flow area and increase the density of drifting invertebrates, culverts may

359 constitute ideal feeding spots. This can increase the propensity of the fish to remain
360 downstream of the culvert during daylight and explain the reduced attempt rate at this period.
361 Considering all this, the higher attempt rate of brook trout at dusk and, to a lesser extent, at
362 night and dawn, may represent an opportunistic behavior.

363 Trout became more motivated to pass when there were fewer fish present in the cage
364 downstream of the culvert. Decreasing passage rates above a certain density has also been
365 observed for alewife (Dominy 1973). Although a recent study with Coho salmon in an
366 experimental culvert failed to detect this effect (Johnson et al. 2012), the phenomenon may be
367 widespread. Salmonids are known to display a hierarchical social behavior (Höjesjö et al. 1998,
368 Newman 1956, Sundström and Johnsson 2001), with larger individuals occupying the first-order
369 positions related to drift feeding and cover (Hughes 1992). It may be that as density increases so
370 does the number of social interactions, and these interactions could have the effect of
371 suppressing attempt rate. This would lead to increased delay in passing the culvert.

372 Larger trout had a higher attempt rate than smaller individuals. A higher attempt rate in
373 experimental flumes was reported previously for larger individuals of several species (Castro-
374 Santos 2004, Peake 2008), as well as a higher propensity to move with regards to body size for
375 brown trout (Bunnell et al. 1998, Young 1999). It is possible that larger and likely older
376 individuals exhibited a stronger homing behavior or may have interacted with the culvert
377 before, either of which might have affected motivation. Moreover, if they occupied forward
378 positions (presumably preferred for feeding), they had greater opportunity to initiate attempts
379 and enter the culvert in order to seek cover or more suitable habitat upstream.

380 **Variability in motivation**

381 There were noticeable differences in attempt rate of trout from different capture locations.
382 We caught 75% of the fish upstream of the studied culverts, assuming that homing behavior

383 would increase their propensity to move and attempt to pass the culvert (Armstrong and
384 Herbert 1997). Fish caught upstream of the Résimond culvert had an overall lower attempt rate
385 than those originating from the other streams while trout caught downstream of Morin culvert
386 and in Épinette stream had a similar attempt rate than the ones caught upstream of Morin and
387 Allaire culverts. According to these results, homing behavior is not a likely candidate to explain
388 differences in attempt rate. It is more likely that unmeasured variables related to the streams of
389 origin had some influence on the fish motivation. The Résimond stream is > 26 km distant from
390 the others. Fish caught in this stream may display different movement patterns, which could in
391 part explain the observed differences.

392 Most trout staged only one attempt, but some staged more. Overall, fish with greater
393 attempt rates were more likely to pass, but sometimes individuals entered multiple times
394 without passing, even under easily-passable conditions. This suggests that culvert entry may
395 include behaviors not necessarily associated with passage attempts and that not all attempts
396 are similar in terms of produced effort and potential for success. This individual variability in
397 attempt rate highlights the fact that causal mechanisms may be missing from the current
398 thinking about entry and passage behaviors. These may include individual differences in life
399 history, responses to stimuli, physiology or personality traits. Differences in personality traits
400 have been related to risk-taking behavior and mobility for brook trout (Farwell and McLaughlin
401 2009) as well as variability in dispersal for other species (Cote et al. 2010). Intraspecific
402 variability in movement patterns has also been reported for brook trout, some individuals being
403 more mobile than others (Rodriguez 2002). In the current study, motivated fish have expressed
404 a higher willingness to take risks and stage fast attempts. Some of our study sites are also
405 believed to hold sub-populations of anadromous brook trout. If these were present in the
406 study, their behavior and motivation to pass culverts in order to access upstream spawning

407 habitat may have been different from those of resident individuals. In the absence of data on
408 sex, life history or social status, the random effects are useful to quantify the unexplained
409 variability in the attempt rate that was not accounted for by other covariates.

410 Among all tested fish, the rate at which the first attempt occurred was markedly lower than
411 the rate of subsequent attempts. This may be a result of the tagging procedures or simply the
412 acclimation of the fish to a new environment. In laboratory studies, a lower rate for the first
413 attempt was also observed for brook trout, walleye and white sucker (Castro-Santos et al.
414 2013).The importance of providing an acclimation period is broadly recognized, and is a
415 standard feature of laboratory studies (O'Neal et al. 2016); however the magnitude and
416 duration of the effect are typically not quantified in non-volitional studies. Our data provide
417 clear evidence of both the magnitude of the effect and its duration, which varies among
418 individuals, but can persist for days, even in a field-like situation.

419 **Effect of motivation on passage performance**

420 When facing a culvert, motivation to enter the structure is essential to achieve successful
421 passage. In this study, this was shown by the fact that trout with a higher level of motivation had
422 an increased probability of passage through the culverts. The individual variability in motivation
423 was based on the attempt rate of each fish, and the influence of covariates on these rates was
424 described using Cox regression. Trout with high attempt rates were fish that staged rapid
425 and/or multiple attempts.

426 The current study focused on brook trout originating from different streams, yet all located
427 within the same watershed. Trout from other locations may possibly react differently to
428 hydraulics and environmental variables. Moreover, caged fish may differ in their behavior than
429 free-ranging fish facing a wider range of alternatives. Nevertheless, the current study quantifies
430 motivation of wild fish to pass existing culverts. The methods developed here can be applied to

431 other species in order to better understand the effect of individual variability and time-varying
432 covariates on attempt rate at culverts, fishways or natural obstacles.

433 A better understanding of factors influencing the species motivation to negotiate
434 barriers has important implications for design and fish passage issues. Entry and passage are
435 however two distinct phenomena on which covariates may have differential effects. In this
436 study, we showed the positive effect of flow discharge on attraction at culverts. This poses a
437 paradox, because flow velocity is known to negatively impact passage performance through
438 barriers (Burford et al. 2009, Castro-Santos et al. 2013, Goerig et al. 2016). These findings point
439 to the importance of culvert designs that are both attractive and passable.

440 **TABLES**

441 Table 1: Study site characteristics

Site	Latitude	Longitude	Material	Diameter (m)	Length (m)	Slope (%)	Openness ratio (m)
Resimond	48°25'52"N	70°26'03"W	Corrugated metal	1.6	44.6	0.92	0.16
MorinA	48°20'50"N	70°03'39"W	Corrugated metal	1.5	33.2	1.38	0.20
MorinB	48°20'50"N	70°03'39"W	Corrugated metal	2.2	32.3	1.38	0.29
MorinC	48°20'50"N	70°03'39"W	Corrugated metal	2.2	33	1.38	0.29
MorinD	48°20'50"N	70°03'39"W	Polyethylene	2.2	32.4	1.38	0.29
Allaire	48°21'19"N	70°07'07"W	Concrete	2 x 2	18.4	0.28	0.22

442

443 Note:

444 Openness ratio is calculated by dividing the cross-sectional area of the culvert by its length. Large values
 445 correspond to short culverts with large diameters while low values correspond to long culverts with
 446 small diameters.

447

448 Table 2: Origin of tested fish

Tested pipe	Stream of origin				
	Résimond	Morin	Morin DS	Allaire	Épinette
Résimond	33	—	—	—	—
Morin A	—	—	—	27	54
Morin B	—	84	18	—	15
Morin C	—	—	—	27	27
Morin D	—	—	—	54	—
Allaire	—	—	—	108	—

449

450 Note:

451 Number of fish caught in the different streams, for each tested pipe. Fish were caught upstream of the
 452 tested pipes for Résimond, Morin and Allaire streams, and downstream for Morin DS stream. Additional
 453 fish were caught in Épinette stream, a nearby tributary of the Sainte-Marguerite river.

454 Table 3: Measured range of the explanatory variables

Study site	Allaire				Morin (A, B, C & D)				Resimond			
n trial	4				13				2			
n fish	108				305				34			
Parameter	Min	Max	Median	Mean	Min	Max	Median	Mean	Min	Max	Median	Mean
Mean flow velocity (m s ⁻¹)	0	0.81	0.58	0.62	0.58	1.81	0.77	0.86	0.79	0.85	0.85	0.82
Flow discharge (L s ⁻¹)	94.00	715.50	321.50	347	55.5	642.5	195	266.3	281.5	290	289	288
Relative change in discharge (L s ⁻¹)	0	0.39	0.02	0.04	0	0.93	0.02	0.03	0	0.018	0.003	0.004
Water temperature (°C)	8.80	19.90	11.40	11.2	2.94	18.3	12.6	11.5	10.4	12.5	10.9	11.1
Change in water temperature (°C)	0	3.20	0.10	0.27	0	8.52	0.09	0.19	0	0.39	0.05	0.08
Number of fish in the cage	2	28	17	16	4	26	22	19	11	16	14	13.8
Fish body length (mm)	93	230	123	133	90	263	125	131	95	206	119	127
Fish condition factor (Fulton k)	0.74	1.5	1.02	1.03	0.71	1.5	1.01	1.01	0.77	1.4	1.06	1.08
Number of attempts per fish	0	66	1	5	1	58	1	2	1	3	1	1

455

456 Note:

457 Relative change in discharge is calculated as $Q_2 - Q_1 / Q_1$ while change in water temperature is calculated
 458 as $T_2 - T_1$. The number of fish in the cage varies according to the number of fish released at the beginning
 459 of the trial, fish staging attempts and fish returning downstream after an attempt or from a previous
 460 trial.

461

462

463 Table 4: Model selection based on the Akaike information criterion (AIC)

Model _i	RE	-2 log (L)	K (df)	AIC _i	Δ_i AIC	w _i	w _i /w _j

464

465 Note:

466 Subset of tested models ($n = 191$) showing the four models with the lowest -2 log-likelihood (penalized)
 467 and AIC values. Explanatory variables are proximity of the spawning period (spawn), flow discharge (Q),
 468 relative change in discharge (dQr), diel periods, number of fish in the cage (Nbcage), fork length (BL)
 469 and Fulton condition factor (k). RE represents the nested random effects structure, K (df) the number of
 470 degrees of freedom in the model, Δ_i AIC is the difference between AIC of model_i and AIC of the best
 471 model. Akaike weight of model_i (w_i) is interpreted as the probability that model_i is the best model given

472 the data and w_i/w_j is the evidence ratio for model_i versus model_j. Two models emerged from the model
473 set as providing the best fit to the data. The first one, in bold, has an Akaike weight of 0.71. It is followed
474 by a second model with a weight of 0.26. The evidence ratio between these two models is 2.73,
475 indicating evidence in favor of the first one (Burham and Anderson 2002).

476 Table 5: Estimation of parameters for the selected attempt rate model

Parameter	$\beta \pm SE$	HR	p-value
Spawning	0.593 \pm 0.203	1.809	0.004

477
478 Note:
479 Estimates \pm standard error ($\beta \pm SE$) and hazard ratios (HR) of parameters for the best-fitting model..
480 Hazard ratios (HR) are computed for each parameter by exponentiating the estimates. Spawning is a
481 categorical variable with 1 = within 2 weeks of the expected spawning period and 0 = more than 2 weeks
482 than the expected spawning period.

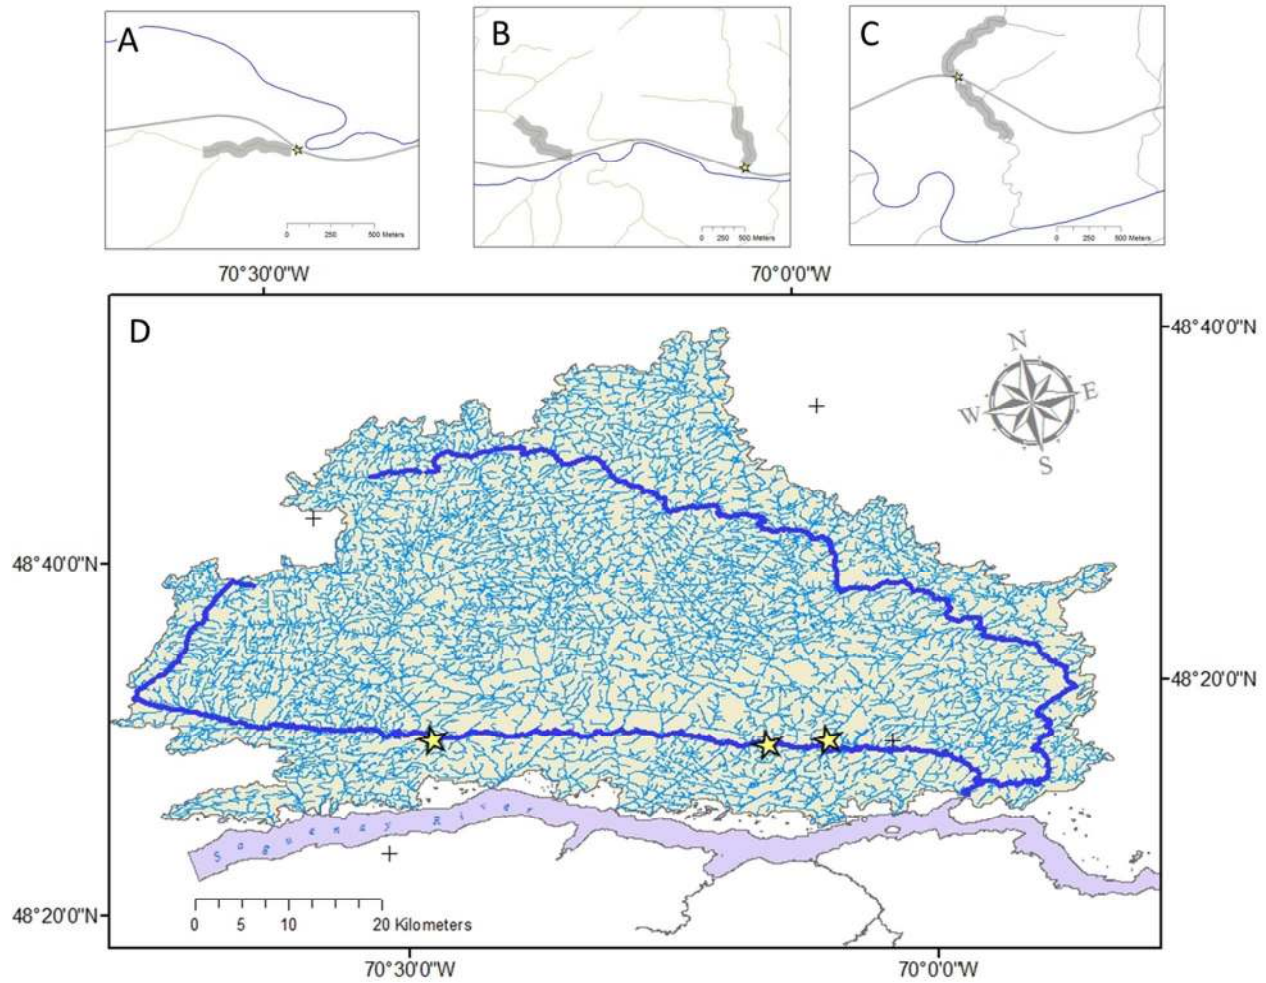

483 Table 6 : Estimation of parameters for the passage success model

Parameter	$\beta \pm SE$	OR	p-value
Intercept	-2.501 \pm 1.186	—	0.035
Individual motivation	0.746 \pm 0.380	2.109	0.049
Fish body length (mm)	0.011 \pm 0.006	1.011	0.079
Random effects		Variance	SD
Trial	7.273	2.697	

484
485

486 **Note:** Estimates \pm standard error ($\beta \pm SE$), odds ratio (OR) and chi-square p-values of parameters for the
487 best-fitting model. Odds ratios (OR) are computed by exponentiating the estimates. Individual
488 motivation was based on the attempt rate of each fish, as described in the Cox regression, and had a
489 positive effect on passage success.

490 FIGURES

491

492 Figure 1. Study sites (stars) and their location within the Ste. Marguerite river watershed (Panel D).

493 Details of studied culverts and collection locations (Tables 1 & 2) are shown in the upper panels (A:

494 Résimond; B: Allaire; and C: Morin). Roads are shown as double-lines, and collection locations are

495 indicated by transparent, heavy gray lines (Panels A, B & C). The Épinette stream collection site is shown

496 in panel B, situated to the west of the Allaire study site.

497

498

499 Figure 2: Cumulative incidence curves (1- empirical Kaplan-Meier curves) representing proportion of fish
500 attempting to pass the culverts as a function of time. Data are stratified by attempts, the black curve
501 representing the 1st attempts, the black dotted curve the attempts 2-5, the grey curve attempts 6-10,
502 and the grey dotted curve attempts > 10. The rate of the first attempt is much slower than the one of
503 subsequent ones. The rate thereafter increased with subsequent attempts.

504

505 Figure 3: Proportion of fish attempting to pass the culvert as a function of time and flow discharge,
 506 modeled from the estimated Cox model. The attempt rate increases with higher values of discharge.

507 Dashed line: 100 L s^{-1} ; solid line: 300 L s^{-1} and dotted line: 500 L s^{-1} , which corresponds to the 25th, 50th
 508 and 75th percentiles, respectively, of tested flow discharge. Others parameters are set at their mean
 509 values (number of fish in the cage = 28, and fork length = 131.6 mm).

510

511
 512 Figure 4: Proportion of fish attempting to pass the culvert as a function of time and stream of origin,
 513 modeled from the estimated Cox model. The curves represent the average attempt rate (solid grey line),
 514 fish from the stream Allaire (dotted line), Épinette (dashed line), Morin (dotdashed line), Morin DS
 515 (longdashed line) and Résimond (twodashed line). The Morin and Morin DS curves are however
 516 superposed as fish from those streams have similar average attempt rate. Other parameters of the
 517 model are set to their mean values ($Q = 294 \text{ L s}^{-1}$, number of fish in the cage = 28, and fork length =
 518 131.6 mm). The hazard of staging an attempt is highest at stream Allaire and lowest at stream
 519 Résimond. The proportion of released fish having staged attempts after twelve hours was between 70
 520 and 80 % at Allaire, Épinette, Morin and Morin DS streams, but only 35% at Résimond stream.

521

522

523 Figure 5: Estimates of random effect coefficients for individual fish in the Coxme model, as a function of
 524 stream of origin. The random effects coefficients are an index of the fish individual motivation. Each
 525 stream includes trout with low, average and high level of motivation. The dashed curve represents the
 526 predicted passage probability as a function of the fish motivation, as estimated by the logistic passage
 527 model.

528 **ACKNOWLEDGEMENTS**

529 Support for this research was provided by INRS–Centre Eau, Terre et Environnement, the GRIL,
 530 the Ministère des Transports du Québec, and research scholarships to E.G. from Natural Sciences and
 531 Engineering Research Council of Canada and the Fonds de recherche Nature et Technologies du Québec.
 532 Any use of trade, product, or firm names is for descriptive purposes only and does not imply
 533 endorsement by the Canadian or US governments. We thank the research assistants who helped
 534 conduct the field work: A. Boivin, M.A. Pouliot, F. Bérubé, J.B. Torterotot and M. Fortin. We also extend
 535 special thanks to N. E. Bergeron for his input and guidance with the experimental design of the study, as
 536 well as to B.H. Letcher and R. W. Perry for their generous assistance with the analysis and the
 537 manuscript.

tempt rate.

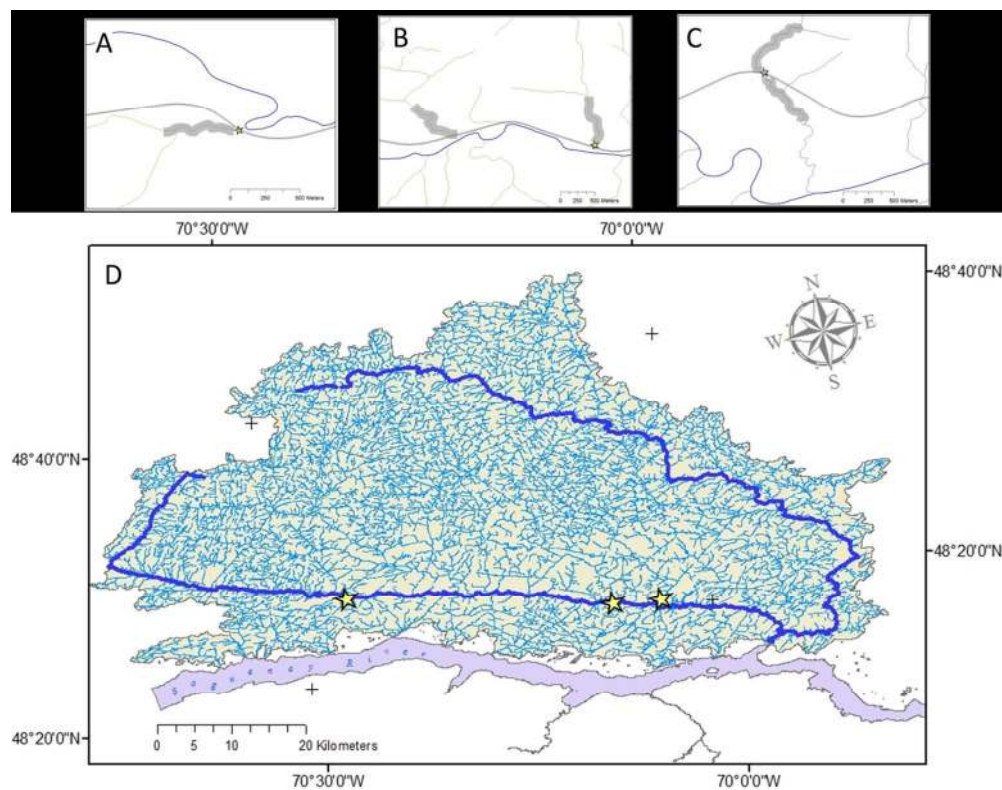

Figure 1. Study sites (stars) and their location within the Ste. Marguerite river watershed (Panel D). Details of studied culverts and collection locations (Tables 1 & 2) are shown in the upper panels (A: Résimond; B: Allaire; and C: Morin). Roads are shown as double-lines, and collection locations are indicated by transparent, heavy gray lines (Panels A, B & C). The Épinette stream collection site is shown in panel B, situated to the west of the Allaire study site.

237x185mm (150 x 150 DPI)

Figure 2: Cumulative incidence curves (1- empirical Kaplan-Meier curves) representing proportion of fish attempting to pass the culverts as a function of time. Data are stratified by attempts, the black curve representing the 1st attempts, the black dotted curve the attempts 2-5, the grey curve attempts 6-10, and the grey dotted curve attempts > 10. The rate of the first attempt is much slower than the one of subsequent ones. The rate thereafter increased with subsequent attempts.

409x204mm (72 x 72 DPI)

Figure 3: Proportion of fish attempting to pass the culvert as a function of time and flow discharge, modeled from the estimated Cox model. The attempt rate increases with higher values of discharge. Dashed line: 100 L s⁻¹; solid line: 300 L s⁻¹ and dotted line: 500 L s⁻¹, which corresponds to the 25th, 50th and 75th percentiles, respectively, of tested flow discharge. Others parameters are set at their mean values (number of fish in the cage = 28, and fork length = 131.6 mm).

345x230mm (72 x 72 DPI)

Figure 4: Proportion of fish attempting to pass the culvert as a function of time and stream of origin, modeled from the estimated Cox model. The curves represent the average attempt rate (solid grey line), fish from the stream Allaire (dotted line), Épinette (dashed line), Morin (dotdashed line), Morin DS (longdashed line) and Résimond (twodashed line). The Morin and Morin DS curves are however superposed as fish from those streams have similar average attempt rate. Other parameters of the model are set to their mean values ($Q = 294 \text{ L s}^{-1}$, number of fish in the cage = 28, and fork length = 131.6 mm). The hazard of staging an attempt is highest at stream Allaire and lowest at stream Résimond. The proportion of released fish having staged attempts after twelve hours was between 70 and 80 % at Allaire, Épinette, Morin and Morin DS streams, but only 35% at Résimond stream.

345x230mm (72 x 72 DPI)

Figure 5: Estimates of random effect coefficients for individual fish in the Coxme model, as a function of stream of origin. The random effects coefficients are an index of the fish individual motivation. Each stream includes trout with low, average and high level of motivation. The dashed curve represents the predicted passage probability as a function of the fish motivation, as estimated by the logistic passage model.
