The observed intensity ratio of the $3s^2$ $^1S_0$ - $3s3p$ $^1P_1$ to the $3s^2$ $^1S_0$ - $3s3p$ $^3P_1$ transitions in MgI-like ions has always presented those who model plasma spectra with a challenge; the observed intensity of the intercombination line is always several times greater than what simple models predict. We offer a model that takes into account the contribution to the MgI-like emission features from autoionizing levels of the adjacent AlI-like charge state. Models in the present work, which include the effects of configuration interaction on ionic wavefunctions, and the contribution of both direct, impact ionization and autoionization channels from the AlI-like ion to the MgI-like ion, give good agreement with the observed resonant/intercombination (R/I) emission ratio only when a departure from ionization equilibrium is assumed. We also identify, for the first time, intercombination lines of the form $3s3p$ $^1P_1$ - $3p^2$ $^3P_2$ in several elements relevant to both astrophysical and magnetically-confined fusion plasmas.

1. Introduction

Radiative transitions with very different characteristic rates can serve as important diagnostics of local conditions in a plasma. The $3s^2$ $^1S_0$ - $3s3p$ $^1P_1$ resonant line and $3s^2$ $^1S_0$ - $3s3p$ $^3P_1$ intercombination line of MgI-like ions have transition rates that differ by orders-of-magnitude; the difference in transition rates means the slower transition will be strongly quenched by collisions relative to the faster transition as the local electron density changes. The use of high-Z elements in several magnetically-confined fusion experiments (e.g. Alcator C-Mod tokamak, Frascati Tokamak Upgrade), and the presence of high-Z dopants in laser-produced plasmas are but two motivations for the study of the kinetics of highly ionized, high-Z materials. For astrophysical plasmas, like the solar corona, VUV- and XUV-observations of ionic line radiation are often the only source of information about the local plasma conditions.

The FeXV $3s^2$ $^1S_0$ - $3s3p$ $^3P_1$ intercombination line has been studied in spectra taken of the solar corona during flare events [1] and in the quiet solar corona [2]. Attempts to explain the observed ratio of the emissivity of the FeXV $3s^2$ $^1S_0$ - $3s3p$ $^3P_1$ intercombination line to the emissivity of the $3s^2$ $^1S_0$ - $3s3p$ $^1P_1$ resonant line (R/I) were made by Bhatia and Kastner [3]. Bhatia and Kastner offered the inclusion of the $3s3d$ and $3p^2$ excited configurations in the collisional-radiative model to account for both radiative cascades from excited levels and the effect on collision strengths from wavefunction mixing. Christensen, Norcross and Pradhan [4] (CNP) found the R-matrix collision strengths from the ground state of MgI-like iron to the levels of the $3s3p$ excited configuration to be a factor of two greater than the DWA-collision strengths used by earlier researchers. Dufton, Kingston and Widing [5] (DKW) discuss the kinetics of the FeXV spectrum. One important result in DKW is that the R-matrix collision strengths of CNP do not effect the FeXV R/I ratio as much as might be expected; the narrowness of the resonance region compared to the temperature at which FeXV is expected to exist means the collision-rates from the ground state to the levels of the $3s3p$ configuration are enhanced by at most 10%.

A model which uses innershell ionization from the $3s$-subshell of the AlI-like ion to explain the observed R/I line ratio in MgI-like selenium was offered by Finkenthal et al. [6]. There, Finken-

Table 1

Observed and calculated ratio for the emissivity of the $3s^2$ $^1S_0$ - $3s3p$ $^1P_1$ over the $3s^2$ $^1S_0$ - $3s3p$ $^3P_1$ line. Columns are (from left to right) the observed intensity ratio (from tokamaks and the active solar corona), the ratio calculated with no ionization channels between adjacent charge states, with ionization equilibrium between adjacent charge states, and with ionization channels between adjacent charge states and twice as much of the AlI-like ion as the MgI-like ion present.

Ion	IP (eV)	Observed Ratio	No Ionization	Ionization Equil.	$n_{AlI}:n_{MgI} = 2:1$
TiXI	265	11.5 [a]	26.7	16.9	11.1
VXII	308	10.7 [a]	25.6	16.0	10.5
CrXIII	354	10.0 [a]	24.4	15.7	9.9
FeXV	456	11.9 [b]	22.4	16.6	10.9
GeXXI	836	8.7 [c,d]	15.5	10.4	8.7
SeXXIII	988	8.1 [c,d]	13.1	9.9	8.6
MoXXXI	1728	6.2 [e]	6.3	5.8	5.6

Details of the experiments for Ti, V and Cr have been published [8]. The value of R/I for FeXV is from a measurement on the active solar corona in Ref. [7]. The data specific to the measurements for Ge and Se have also been published [9,6]. The value of R/I for FeXV is from a measurement on the active solar corona in Ref. [7]. The measurement of R/I for MoXXXI made in the C-Mod tokamak for the present work had $T_e \approx 1.6 keV$ and $N_e \approx 1.0 \times 10^{14}$ cm^{-3}.

Observations indicate that, in every case, the emitting ion is localized to a region of the plasma with an electron temperature very nearly equal to the ionization potential of the MgI-like ion. The result of introducing the ionization channels into the model is a significant increase in the strength of the intercombination line of the lighter elements in this study. This occurs because the ionization channels (both the resultant cascades from the excitation-autoionization channels and the direct ionization channels) have a much larger relative contribution to the net flux into the $3s3p$ $^3P_1$ level than to the flux into the $^1P_1$ level.

The agreement between the models with twice as much AlI-like ion as MgI-like ion present and the observations made for Ti, V and Cr is excellent; the conclusion drawn is that the ions are swept inward to a region of the tokamak plasma with a high temperature faster than they are ionized; this is consistent with transport studies done on TFR. MoXXXI, the heaviest ion in this paper, exists in the core of the (C-Mod) tokamak. In this case, MoXXXI ions can not be swept inward, and hence, the ionization equilibrium model is adequate for predicting the R/I ratio.

The QSS-CR models reveal that the feeding of the intercombination line comes primarily from radiative cascades from the $J=2$ levels of the $3p^2$ and $3s3d$ configurations (see Fig. 1). In VXII, for example, in the model with ionization equilibrium enforced between adjacent charge states (column three of Table 1), 85% of the flux into the $3s3p$ $^3P_1$ level comes from radiative cascades, 10% of the flux is from collisional excitation directly from the ground state, and the rest of the flux is from the direct, impact ionization from the AlI-like ion. In SeXXIII, the cascades and excitation channels account for 55% and 40%, respectively of the flux into the $3s3p$ $^3P_1$ state. The high strength of the line is partly due to wavefunction mixing effects; as the ionization state increases, the wavefunctions of the MgI-like $3s3p$ configuration begin to assume a jj-characteristic. Hence, the numbers in Table 1 decrease down the columns; the intercombination line is becoming "less" forbidden.

We identify in Table 2 the $3s3p$ $^1P_1$ - $3p^2$ $^3P_2$ line for Ti, V and Cr. Observations made in the TFR tokamak [18] during injections of Ti, V and Cr find lines with the same temporal behavior as the MgI-like intercombination line, and which are emitted from the same spatial position in the plasma. Based on the temporal and spatial behavior of these lines, and based on *ab initio* predictions for the wavelengths of these transitions, we now identify them as new intercombination lines. The right-most column in Table 2 shows the predicted ratio of the brightness of the $3s^2$ $^1S_0$ - $3s3p$ $^1P_1$ resonant line over the brightness of the new intercombination lines.

Due to the slow nature of triplet-singlet tran-

Table 2
Measured and predicted wavelengths for the $3s3p\ ^1P_1$ - $3p^2\ ^3P_2$ transitions in MgI-like ions. Columns contain, respectively, the observed wavelength and the wavelength as calculated by RELAC. The last column has the predicted R/I* ratio from the QSS-CR models.

Ion	$\lambda_{obs.}$ (Å)	$\lambda_{theor.}$ (Å)	R/I

[a] Ref. [18]

sitions, the $3s3p\ ^1P_1$ - $3p^2\ ^3P_2$ line (I*) is not expected to be observable in light elements in any plasma source. However, the $3p^2\ ^3P_2$ state has a significant admixture of the $3s3d\ ^1D_2$ and the $3p^2\ ^1D_2$ levels. For VXII, for example, $3p^2\ ^3P_2$ has 11% of its amplitude from $3p^2\ ^1D_2$ and 1.5% from $3s3d\ ^1D_2$. The result is that the upper state, $3p^2\ ^3P_2$, has a strong singlet characteristic, and is fed by an enhanced collisionality with the ground state (which arises from the 3s3d states which mix with the $3p^2$ levels). The singlet characteristic also allows the $3p^2\ ^3P_2$ level to have an 'enhanced' decay rate to the $3s3p\ ^1P_1$ level. The expected R/I* ratio for the $3s3p\ ^1P_1$ - $3p^2\ ^3P_2$ lines in Table 2 are very approximate. A treatment of the cascades from the MgI-like levels of the $3l4l'$ configurations for $l=p$ and d, as well as further study of the wavefunctions of the $3p^2$ states is needed; these issues will be addressed in a forthcoming work.

4. Conclusion

The present work offers models of the R/I ratio in several MgI-like ions. The models find the contribution to the emissivity of the intercombination line from autoionizing states of the AlI-like ion is insignificant. In the future, *ab initio* calculations of direct, impact ionization rates may further improve the agreement between observations and models for the R/I ratio. Also, new intercombination lines between excited states, which are enabled by wavefunction mixing, are identified in the present paper. Work supported under the auspices of U. S.
