(Dated: November 4, 2018)

Yields for J/ψ production in Cu+Cu collisions at $\sqrt{s_{NN}} = 200$ GeV have been measured over the rapidity range $|y| < 2.2$ and compared with results in $p+p$ and Au+Au collisions at the same energy.

The Cu+Cu data offer greatly improved precision over existing Au+Au data for J/ψ production in collisions with small to intermediate numbers of participants, in the range where the Quark Gluon Plasma transition threshold is predicted to lie. Cold nuclear matter estimates based on ad hoc fits to d +Au data describe the Cu+Cu data up to $N_{\text{part}} \sim 50$, corresponding to a Bjorken energy density of at least $1.5 \text{ GeV}/\text{fm}^3$.

PACS numbers: 25.75.Dw,12.38.Mh,21.65.Qr,25.75.Nq

High-energy heavy-ion collisions provide the opportunity to study strongly interacting matter at very high energy densities where Quantum Chromodynamics (QCD) predicts a transition from normal nuclear matter to a deconfined system of quarks and gluons, the Quark-Gluon Plasma (QGP) [1]. At the Relativistic Heavy Ion Collider (RHIC) the energy density in central Au+Au collisions is well in excess of the critical energy density expected for this transition [2].

Over the past twenty years, there has been intense theoretical and experimental work on J/ψ production. First predicted by Matsui and Satz [3], suppression of quarkonia production in ultra-relativistic heavy ion collisions was expected to be an unambiguous signature for the formation of a QGP. It is now recognized that in order to interpret J/ψ production as a QGP probe one has to consider cold nuclear matter effects such as initial state energy loss [4] and shadowing [5], as well as charm quark energy loss [6], co-mover interactions [7], corrections for feed-down from higher mass charmonium states, and secondary production mechanisms, such as recombination of initially uncorrelated $c\bar{c}$ pairs [8].

Experiment NA50 reported suppression of J/ψ production in Pb+Pb collisions at $\sqrt{s_{NN}} = 17.3 \text{ GeV}$ [9] that exceeds expectations based on their measurements of cold nuclear matter effects in $p + A$ collisions [10]. NA60 observed similar behavior in In+In collisions at the same energy [11]. The PHENIX experiment [12] at RHIC has characterized effects of the nuclear medium on J/ψ production at $\sqrt{s_{NN}} = 200 \text{ GeV}$. The basic invariant yield reference is obtained from $p+p$ data [13, 14, 15]. Cold nuclear matter effects are studied using d +Au data [14, 16]. Cold and hot nuclear matter effects are studied for large numbers of participants (N_{part}) using Au+Au data [17, 18], and for smaller N_{part} using Cu+Cu data, the subject of this paper. The results are presented as a nuclear modification factor, R_{AA} , the ratio of the yield in heavy ion collisions to the yield in $p+p$ collisions scaled by the number of binary nucleon-nucleon collisions (N_{coll}), which is appropriate for point-like processes.

Lattice QCD calculations [19] indicate that the threshold energy density for QGP formation is of order $1 \text{ GeV}/\text{fm}^3$. At $\sqrt{s_{NN}} = 200 \text{ GeV}$ this is expected to occur below $N_{\text{part}} = 100$ [20], in a region where Au+Au data have limited statistical and systematic precision [18]. High statistics measurements with the intermediate sized system Cu+Cu provide crucial information in that important region.

In this Letter we present results obtained by PHENIX during the 2005 RHIC run on the production of J/ψ in Cu+Cu collisions at $\sqrt{s_{NN}} = 200 \text{ GeV}$. J/ψ invariant yields were studied via $J/\psi \rightarrow e^+e^-$ decays measured at midrapidity with the central arm spectrometers ($|y| \leq 0.35$, $\Delta\phi = 2 \times 90^\circ$), and $J/\psi \rightarrow \mu^+\mu^-$ decays measured at forward rapidity with the two muon arm spectrometers ($1.2 < |y| < 2.2$, $\Delta\phi = 360^\circ$). Event centrality and the location of the collision vertex along the beam axis (z_{vtx}) are measured with two Beam-Beam Counters (BBC) located at $3.0 < |\eta| < 3.9$. A Glauber model and a simulation of the BBC response was used to determine N_{part} and N_{coll} and their systematic uncertainties for different collision centrality ranges [21].

Data were recorded using lepton triggers in coincidence with a minimum bias trigger which required a coincidence between the BBC detectors and a valid z_{vtx} . After applying a cut of $|z_{vtx}| < 30 \text{ cm}$ and quality assurance criteria, the data correspond to a sampled luminosity of about 2.1 nb^{-1} (1.3 nb^{-1}) in the e^+e^- ($\mu^+\mu^-$) analysis.

Electron detection at midrapidity used the Drift Chambers for momentum measurement, the Pad Chambers for pattern recognition and track location, and the Ring Imaging Cherenkov (RICH) detector plus Electromagnetic Calorimeter (EMCal) for electron identification. Charged particle tracks were matched with a RICH ring and an EMCal hit to select electron candidates by requiring at least two RICH phototube hits inside an annulus around the projected ring center, ring quality cuts, track/cluster position matching cuts at the EMCal, and a cut on the ratio of EMCal energy to track momentum, $E/p - \langle E/p \rangle > -2\sigma$.

The $J/\psi \rightarrow e^+e^-$ trigger required one signal above a certain energy threshold in the EMCal and a matching RICH hit. Two energy thresholds were used during the run, 1.1 GeV and 0.8 GeV , yielding average J/ψ trigger efficiencies of $\sim 65\%$ and 82% , respectively. The $J/\psi \rightarrow e^+e^-$ signal extraction method was very similar to the method used in the recent Au+Au [18] and $p+p$ [15] analyses. The like sign invariant mass spectrum was subtracted from the unlike sign spectrum. The remaining yield in the J/ψ mass region ($2.9 \leq M_{inv} \leq 3.3 \text{ GeV}/c^2$) was corrected for pairs lost to the radiative tail and pairs added by the continuum signal under the peak [15]. The total J/ψ count in the e^+e^- channel was $\approx 2,050$. The signal to background ratio (S/B) was $\approx 1(6)$ for the most central(peripheral) collisions.

Muon detection at forward and backward rapidities

used the muon arms, consisting of cathode strip tracking chambers in a magnetic field (MuTr) and Iarocci tube planes interleaved with thick steel absorbers (MuID). Muon candidates were identified by penetration to the last MuID gap, and their momenta were measured by their bend through the MuTr.

The dimuon trigger required two candidate tracks to penetrate the MuID, point back to the event vertex, and pass an opening angle cut ($\theta > 19^\circ$). The dimuon combinatorial background was estimated using the product of the like sign counts, $2\sqrt{N^{++} \cdot N^{--}}$, and was subtracted from the unlike sign spectra. The residual background (notably from the open charm pairs and Drell-Yan) was evaluated using an exponential form. The $J/\psi \rightarrow \mu^+\mu^-$ signal was estimated by direct counting of the remaining pairs above the exponential fit in the mass range $2.6 \leq M_{inv} \leq 3.6 \text{ GeV}/c^2$ and also by using two fits with different parameterizations (single and double Gaussian) of the J/ψ line shapes, as described in [15, 18]. The average of the results gave the signal count and the variation gave the systematic error. The total J/ψ yield was $\approx 9,000$. The S/B was $\approx 0.3(1.0)$ for the most central(peripheral) collisions.

The J/ψ invariant yield in the appropriate centrality, rapidity and transverse momentum bin is given by :

$$\frac{B_U}{2\pi p_T} \frac{d^2 N_{J/\psi}}{dp_T dy} = \frac{1}{2\pi p_T} \frac{N_{J/\psi}}{N_{\text{evt}} \Delta y \Delta p_T A \epsilon}, \quad (1)$$

with B_U the branching ratio for $J/\psi \rightarrow l^+l^-$; $N_{J/\psi}$ the number of observed J/ψ ; N_{evt} the number of events; Δy the rapidity range; Δp_T the transverse momentum range, and $A\epsilon$ the acceptance and efficiency correction (including trigger efficiency).

The determination of $A\epsilon$ is done with a full GEANT simulation. The method is described in more detail in [15]. $A\epsilon$ decreases with the collision centrality due to overlapping hits in the RICH and the EMCAL in the central arm, and in the MuTr for the forward arms, leading to an increasing fraction of misreconstructed tracks in higher multiplicity events. This effect is evaluated by embedding simulated single J/ψ events in real events. The efficiency loss in the most central collisions is 3% for dielectron measurements and 20% (16%) for dimuon measurements at positive (negative) rapidity.

Systematic uncertainties in the measured J/ψ invariant yield depend on J/ψ rapidity and transverse momentum as well as on event centrality. Systematic uncertainties are grouped into three categories: point to point uncorrelated uncertainties (type A), which can move the points independently of each other, point to point correlated uncertainties (type B), which can move the points coherently, though not necessarily by the same amount, and global systematic uncertainties (type C). In all plots point to point uncorrelated systematic uncertainties and statistical uncertainties are quadratically summed and represented by vertical bars, point to point correlated

systematic uncertainties are represented by boxes, and global systematic uncertainties (if any) are quoted.

TABLE I: Systematic error sources, values and types for R_{AA} vs N_{part} in the two rapidity intervals. Where a range is given, it is from peripheral to central collisions.

	source	$ y < 0.3$	$ y \in [1.2, 2.2]$	type
	signal extraction	6 %	5-6 %	A
	detector + trigger efficiency	1.4-5 %	3 %	B
	run by run variation	5 %	2 %	B
	input $y + p_T$ distributions	2 %	3 %	B
	N_{coll}	14-11 %	14-11 %	B

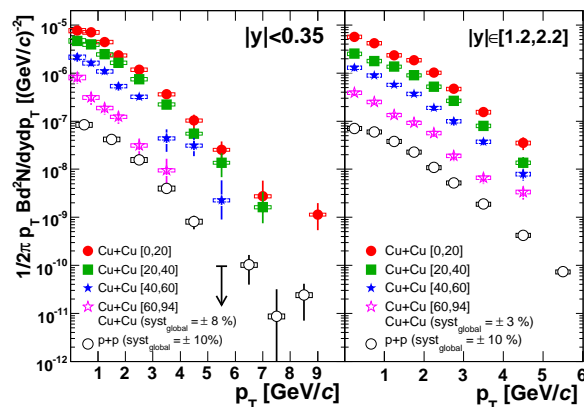

FIG. 1: (color online) J/ψ yield vs p_T at mid (left) and forward (right) rapidity for different Cu+Cu centrality bins and for $p + p$ [15]. Uncertainties are described in the text.

Systematic uncertainties of type A and B for R_{AA} vs N_{part} are summarized in Table I. Some uncertainties in the invariant yield, such as that on the acceptance, cancel out for R_{AA} and are not shown. Global systematic uncertainties for R_{AA} vs N_{part} include the $p + p$ J/ψ yield uncertainty and some $p + p$ systematic errors that do not cancel when forming R_{AA} .

Results for the two muon arms agree within uncertainties and are combined where appropriate. Fig. 1 shows the J/ψ yield vs p_T for different Cu+Cu centrality classes at mid and forward rapidity. As was done previously for the Au+Au case [18], the mean square transverse momentum, $\langle p_T^2 \rangle$, was calculated numerically from the data for $p_T < 5 \text{ GeV}/c$. The Cu+Cu data are plotted vs N_{part} and compared with the corresponding values from Au+Au [18], d +Au [16] and $p + p$ [15] collisions in Fig. 2. Within uncertainties, the data for Cu+Cu and Au+Au agree where they overlap in N_{part} , and the $\langle p_T^2 \rangle$ for the Cu+Cu data seems independent of N_{part} .

The R_{AA} values vs p_T and rapidity are shown in Fig. 3 for the 0–20% most central Cu+Cu collisions. We see similar behavior for mid and forward rapidity, and there

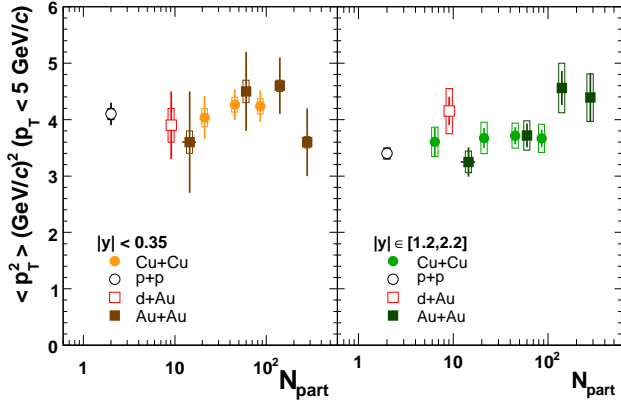

FIG. 2: (color online) The $\langle p_T^2 \rangle$ vs N_{part} for J/ψ production in Cu+Cu, p+p [15], d+Au [16] and Au+Au [18] collisions at mid (left) and forward (right) rapidity.

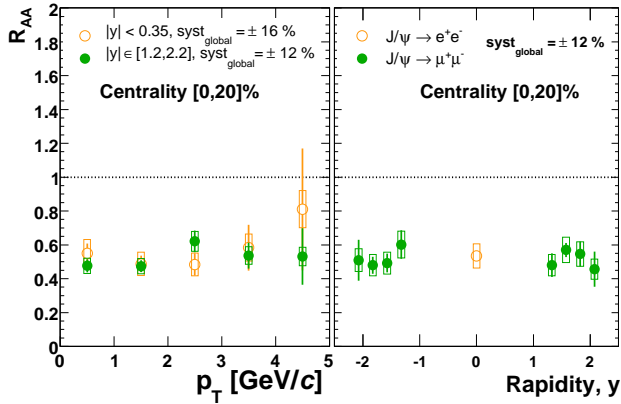

FIG. 3: (color online) R_{AA} vs p_T (left) and y (right) for J/ψ production in the most central Cu+Cu collisions.

appears to be no p_T dependence in all centrality classes. The RMS width of the rapidity distribution (evaluated directly from the data) is identical, within $\sim 2 - 3\%$ uncertainties, in p+p collisions and in all centrality classes for Cu+Cu collisions.

Figures 4(a) and 4(b) show similar behavior within uncertainties for R_{AA} in Cu+Cu and Au+Au [18] collisions at comparable values of N_{part} . Theoretical calculations [22] including only modified initial parton distribution functions and an added $J/\psi - N$ breakup cross section were fitted in [16] to d+Au J/ψ R_{AA} data. The EKS98 [23, 24] and nDSg [25] shadowing models were used. The fit was made simultaneously to all rapidities by optimizing the breakup cross section. While consistent with the low statistics d+Au data [16], this method leads to a model dependence of the CNM effects, since the rapidity shape is determined entirely by the shadowing model. In an attempt to reduce this model dependence, we used a data-driven ad hoc model to parameterize the d+Au data [16]. The ad hoc model uses EKS98 (method

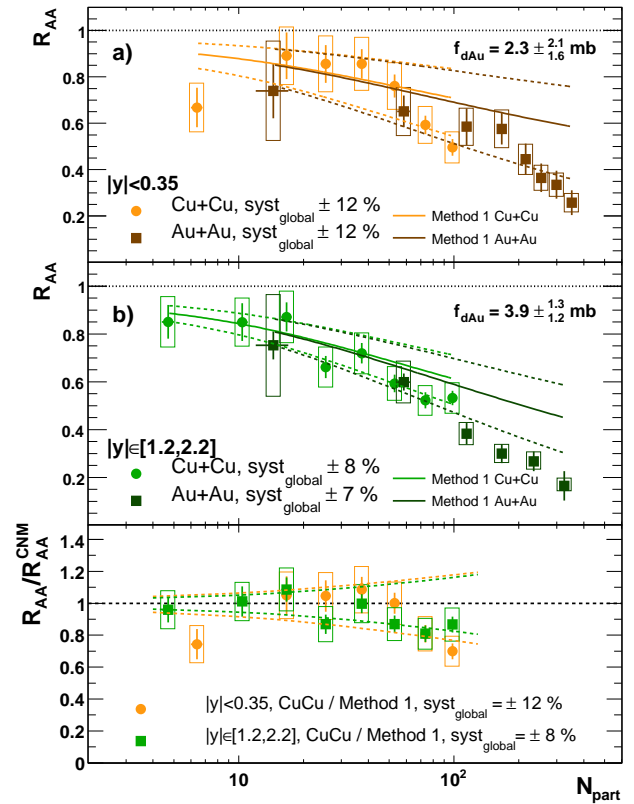

FIG. 4: (color online) (a,b) R_{AA} vs N_{part} for J/ψ production in Cu+Cu and Au+Au [18] collisions. The curves are predictions from ad hoc fits to d+Au data [16] and are discussed in the text. (c) Ratios of the measured R_{AA} values to the predicted cold nuclear matter R_{AA} . The dashed lines show the 1σ uncertainties from the d+Au fits.

1) and nDSg (method 2) shadowing parameterizations for the relative rapidity dependence within the fitted rapidity ranges, but the breakup cross section is replaced with a quantity, which we call f , that is optimized separately for $y=0$ and $|y|=1.7$. The fits using method 1 yielded $f_{dAu} = 2.3 \pm_{1.6}^{2.1}$ mb at $y=0$ and $3.9 \pm_{1.2}^{1.3}$ mb at $|y|=1.7$. The method 2 fits yielded $f_{dAu} = 0.9 \pm_{1.8}^{1.9}$ mb at $y=0$ and $3.3 \pm_{1.2}^{1.3}$ mb at $|y|=1.7$. The resulting separate parameterizations of the d+Au data vs N_{coll} at mid and forward/backward rapidity can be projected to Cu+Cu and Au+Au using the corresponding parton distribution functions for Cu and Au [22]. The results for method 1 are shown in Fig. 4 as cold nuclear matter baseline R_{AA} curves calculated from the best fit values of f (solid lines) and the one standard deviation uncertainty in f (dashed lines). The method 2 heavy ion calculations are similar to those from method 1, leading to very similar conclusions, and are not shown in Fig. 4. In Fig. 4(c) the measured R_{AA} values for Cu+Cu are shown divided by the method 1 calculations for Cu+Cu. The Cu+Cu R_{AA} is seen to be consistent with the cold nuclear matter projection within about 15% uncertainties up to $N_{\text{part}} \sim 50$. Given the

uncertainty in the cold nuclear matter reference at larger N_{part} values, we can not currently draw any strong conclusions there. However PHENIX completed in February 2008 a second $d+\text{Au}$ run, with approximately 30 times the statistics of the first $d+\text{Au}$ run in 2003. With the new reference $d+\text{Au}$ data, we expect to be able to identify if and where the measured $\text{Cu}+\text{Cu}$ R_{AA} departs from the cold nuclear matter baseline.

In summary, we present high statistics J/ψ data from $\text{Cu}+\text{Cu}$ collisions at RHIC, providing for the first time detailed information on R_{AA} and $\langle p_{\text{T}}^2 \rangle$ for $N_{\text{part}} < 100$. The RMS values of the rapidity distributions at all centralities are consistent with that for $p+p$, and the measured $\langle p_{\text{T}}^2 \rangle$ for $p_{\text{T}} < 5 \text{ GeV}/c$ is nearly independent of centrality and rapidity. At similar values of N_{part} , R_{AA} and $\langle p_{\text{T}}^2 \rangle$ are found to agree within errors for $\text{Cu}+\text{Cu}$ and $\text{Au}+\text{Au}$ collisions. Cold nuclear matter calculations based on ad hoc fits to $d+\text{Au}$ data reproduce the peripheral $\text{Cu}+\text{Cu}$ data well up to $N_{\text{part}} \sim 50$, corresponding to $\epsilon_{\text{Bjorken}} \tau \sim 1.5 \text{ GeV}/\text{fm}^2/c$ [20], where $\epsilon_{\text{Bjorken}}$ is the Bjorken energy density and τ is the formation time. For an estimate of the thermalized energy density, hydrodynamical models give thermalization times in the range of $0.6 \text{ fm}/c$ to $1.0 \text{ fm}/c$ [2], which implies that cold nuclear matter effects dominate J/ψ production up to thermalized energy densities of ~ 1.5 to $2.5 \text{ GeV}/\text{fm}^3$.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions. We acknowledge support from the Office of Nuclear Physics in DOE Office of Science and NSF (U.S.A.), MEXT and JSPS (Japan), CNPq and FAPESP (Brazil), NSFC (China), MSMT (Czech Republic), IN2P3/CNRS, and CEA (France), BMBF, DAAD, and AvH (Germany), OTKA (Hungary), DAE (India), ISF (Israel),
