

Jamming Games in the MIMO Wiretap Channel With an Active Eavesdropper

Amitav Mukherjee, *Student Member, IEEE*, and A. Lee Swindlehurst, *Fellow, IEEE*

Abstract—This paper investigates reliable and covert transmission strategies in a multiple-input multiple-output (MIMO) wiretap channel with a transmitter, receiver and an adversarial wiretapper, each equipped with multiple antennas. In a departure from existing work, the wiretapper possesses a novel capability to act either as a passive eavesdropper or as an active jammer, under a half-duplex constraint. The transmitter therefore faces a choice between allocating all of its power for data, or broadcasting artificial interference along with the information signal in an attempt to jam the eavesdropper (assuming its instantaneous channel state is unknown). To examine the resulting trade-offs for the legitimate transmitter and the adversary, we model their interactions as a two-person zero-sum game with the ergodic MIMO secrecy rate as the payoff function. We first examine conditions for the existence of pure-strategy Nash equilibria (NE) and the structure of mixed-strategy NE for the strategic form of the game. We then derive equilibrium strategies for the extensive form of the game where players move sequentially under scenarios of perfect and imperfect information. Finally, numerical simulations are presented to examine the equilibrium outcomes of the various scenarios considered.

Index Terms—Game theory, jamming, MIMO wiretap channel, Nash equilibria, physical layer security, secrecy rate.

I. INTRODUCTION

THE two fundamental characteristics of the wireless medium, namely *broadcast* and *superposition*, present different challenges in ensuring secure and reliable communications in the presence of adversaries. The broadcast nature of wireless communications makes it difficult to shield transmitted signals from unintended recipients, while superposition can lead to the overlapping of multiple signals at the receiver. As a result, adversarial users are commonly modeled either as (1) a passive *eavesdropper* that tries to listen in on an ongoing transmission without being detected, or (2) a malicious transmitter (*jammer*) that tries to degrade the signal quality at the intended receiver. Two distinct lines of research have developed to analyze networks compromised by either type of adversary, as summarized below.

A network consisting of a transmitter-receiver pair and a passive eavesdropper is commonly referred to as the *wiretap* channel. The information-theoretic aspects of this scenario have been explored in some detail [1]–[3]. In particular, this work led to the development of the notion of *secrecy capacity*, which quantifies the maximal rate at which a transmitter can reliably send a secret message to the receiver, without the eavesdropper being able to decode it. Ultimately, it was shown that a non-zero secrecy capacity can only be obtained if the eavesdropper’s channel is of lower quality than that of the intended recipient. The secrecy capacity metric for the multiple-input multiple-output (MIMO) wiretap channel, where all nodes may possess multiple antennas, has been studied in [4]–[9], for example. There are two primary categories of secure transmission strategies for the MIMO wiretap channel, depending on whether the instantaneous channel realization of the eavesdropper is known or unknown at the transmitter. In this work we assume that this information is not available, and thus the transmitter incorporates an “artificial interference” signal [7]–[10] along with the secret message in an attempt to degrade the eavesdropper’s channel, as elaborated on in Section II.

The impact of malicious jammers on the quality of a communication link is another problem of long-standing interest, especially in mission-critical and military networks. A common approach is to model the transmitter and the jammer as players in a game-theoretic formulation with the mutual information as the payoff function, and to identify the optimal transmit strategies for both parties [11]–[13]. Recent work has extended this technique to compute the optimal spatial power allocation for MIMO and relay channels with various levels of channel state information (CSI) available to the transmitters [14]–[17].

In this paper, we consider a MIMO communication link in the presence of a more sophisticated and novel adversary, one with the dual capability of either passively eavesdropping or actively jamming any ongoing transmission, with the objective of causing maximum disruption to the ability of the legitimate transmitter to share a secret message with its receiver. The legitimate transmitter now faces the dilemma of establishing a reliable communication link to the receiver that is robust to potential jamming, while also ensuring confidentiality from interception. Since it is not clear *a priori* what strategies should be adopted by the transmitter or adversary per channel use, a game-theoretic formulation of the problem is a natural solution due to the mutually opposite interests of the agents. Unlike the jamming scenarios mentioned above that do not consider link security, the game payoff function in our application is chosen to be the ergodic *MIMO secrecy rate* between the legitimate transmitter-receiver pair. Related concurrent work on the active

Fig. 1. MIMO wiretap channel with dual-mode active eavesdropper.

eavesdropper scenario [18], [19] has focused on single-antenna nodes without the use of artificial interference, possibly operating together with additional ‘helping’ relays. The single-antenna assumption leads to a much more restrictive set of user strategies than the MIMO scenario we consider.

The contributions of the paper are as follows: (1) we show how to formulate the MIMO wiretap channel with a jamming-capable eavesdropper as a two-player zero-sum game, (2) we characterize the conditions under which the strategic version of the game has a pure-strategy Nash equilibrium, (3) we derive the optimal mixed strategy profile for the players when the pure-strategy Nash equilibrium does not exist, and (4) we study the extensive or Stackelberg version of the game where one of the players moves first and the other responds, and we also characterize the various equilibrium outcomes for this case under perfect and imperfect information. These contributions appear in the paper as follows. The assumed system model and CSI assumptions are presented in the next section. The strategic formulation of the wiretap game is described in Section III, where the two-player zero-sum payoff table is developed, the conditions for existence of pure-strategy Nash equilibria are derived, and the optimal mixed strategy formulation is discussed. The extensive version of the wiretap game with perfect and imperfect information where the players move sequentially is detailed in Section IV. Outcomes for the various game formulations are studied via simulation in Section V, and conclusions are presented in Section VI.

Notation: We will use $\mathcal{CN}(0, 1)$ to denote a circular complex Gaussian distribution with zero-mean and unit variance. We also use $\mathcal{E}\{\cdot\}$ to denote expectation, $I(\cdot; \cdot)$ for mutual information, $(\cdot)^T$ for the transpose, $(\cdot)^H$ for the Hermitian transpose, $(\cdot)^{-1}$ for the matrix inverse, $\text{Tr}(\cdot)$ for the trace operator, $|\cdot|$ to denote the matrix determinant, $\lambda_i(\mathbf{A})$ is the i^{th} ordered eigenvalue of \mathbf{A} , and \mathbf{I} represents an identity matrix of appropriate dimension.

II. SYSTEM MODEL

We study the MIMO wiretap problem in which three multiple-antenna nodes are present: an N_a -antenna transmitter (Alice), an N_b -antenna receiver (Bob), and a malicious user (Eve) with N_e antennas, as shown in Fig. 1. We assume that Alice does not have knowledge of the instantaneous CSI of the eavesdropper, only the statistical distribution of its channel, which is assumed to be zero-mean with a scaled-identity co-

variance. The lack of instantaneous eavesdropper CSI at Alice precludes the joint diagonalization of the main and eavesdropper channels [9]. Instead, as we will show, Alice has the option of utilizing all her power for transmitting data to Bob, regardless of channel conditions or potential eavesdroppers, or optimally splitting her power and simultaneously transmitting the information vector and an ‘artificial interference’ signal that jams any unintended receivers other than Bob. The artificial interference scheme does not require knowledge of Eve’s instantaneous CSI, which makes it suitable for deployment against passive eavesdroppers [7], [9], [20]–[22]. Eve also has two options for disrupting the secret information rate between Alice and Bob: she can either eavesdrop on Alice or jam Bob, under a half-duplex constraint.

A. Signal Model

When Eve is in passive eavesdropping mode, the signal received by Bob is

$$\mathbf{y}_b = \mathbf{H}_{ba}\mathbf{x}_a + \mathbf{n}_b, \quad (1)$$

where \mathbf{x}_a is the signal vector transmitted by Alice, \mathbf{H}_{ba} is the $N_b \times N_a$ channel matrix between Alice and Bob with i.i.d elements drawn from the complex Gaussian distribution $\mathcal{CN}(0, 1)$, and \mathbf{n}_b is additive complex Gaussian noise. When Eve is not jamming, she receives

$$\mathbf{y}_e = \sqrt{g_1}\mathbf{H}_{ea}\mathbf{x}_a + \mathbf{n}_e, \quad (2)$$

where \mathbf{H}_{ea} is the $N_e \times N_a$ channel matrix between Alice and Eve with i.i.d elements drawn from the complex Gaussian distribution $\mathcal{CN}(0, 1)$, and \mathbf{n}_e is additive complex Gaussian noise. The background noise at all receivers is assumed to be spatially white and zero-mean complex Gaussian: $\mathcal{E}\{\mathbf{n}_k\mathbf{n}_k^H\} = \sigma_k^2\mathbf{I}$, where $k = b, e$ indicates Bob or Eve, respectively. The receive and transmit channels of the eavesdropper have gain factors $\sqrt{g_1}$ and $\sqrt{g_2}$, respectively. These scale factors may be interpreted as an indicator of the relative distances between Eve and the other nodes.

On the other hand, when Eve decides to jam the legitimate channel, Bob receives

$$\mathbf{y}_b = \mathbf{H}_{ba}\mathbf{x}_a + \sqrt{g_2}\mathbf{H}_{be}\mathbf{x}_e + \mathbf{n}_b, \quad (3)$$

where \mathbf{x}_e is the Gaussian jamming signal from Eve and \mathbf{H}_{be} is the $N_b \times N_e$ channel matrix between Eve and Bob with i.i.d elements distributed as $\mathcal{CN}(0, 1)$. Due to the half-duplex constraint, Eve receives no signal when she is jamming ($\mathbf{y}_e = 0$).

Alice’s transmit power is assumed to be bounded by P_a :

$$\mathcal{E}\{\mathbf{x}_a\mathbf{x}_a^H\} = \mathbf{Q}_a \quad \text{Tr}(\mathbf{Q}_a) \leq P_a,$$

and similarly Eve has a maximum power constraint of P_e when in jamming mode. To cause maximum disruption to Alice and Bob’s link, it is clear that Eve will transmit with her full available power P_e when jamming. In the most general scenario where Alice jams Eve by transmitting artificial interference, we have

$$\mathbf{x}_a = \mathbf{T}\mathbf{z} + \mathbf{T}'\mathbf{z}', \quad (4)$$

where \mathbf{T}, \mathbf{T}' are the $N_a \times d, N_a \times (N_a - d)$ precoding matrices for the $d \times 1$ information vector \mathbf{z} and uncorrelated $(N_a - d) \times 1$ jamming signal \mathbf{z}' , respectively. To ensure that the artificial interference does not interfere with the information signal, a common approach taken in the literature [7], [9], [20]–[25] is to make these signals orthogonal when received by Bob. If Alice knows \mathbf{H}_{ba} , this goal can be achieved by choosing \mathbf{T} and \mathbf{T}' as disjoint sets of the right singular vectors of \mathbf{H}_{ba} . Note that if the users have only a single antenna, the effect of the artificial interference cannot be eliminated at Bob, and it will degrade the SNR of both Bob and Eve. This makes it unlikely that Alice will employ a non-zero artificial interference signal when she has only a single transmit antenna, which significantly restricts Alice's transmission strategy. The matrix \mathbf{Q}_a may be expressed as

$$\mathbf{Q}_a = \mathbf{T}\mathbf{Q}_z\mathbf{T}^H + \mathbf{T}'\mathbf{Q}'_z\mathbf{T}'^H, \quad (5)$$

where $\mathbf{Q}_z, \mathbf{Q}'_z$ are the covariance matrices associated with \mathbf{z} and \mathbf{z}' , respectively. If we let ρ denote the fraction of the total power available at Alice that is devoted to the information signal, then $\text{Tr}(\mathbf{T}\mathbf{Q}_z\mathbf{T}^H) = \rho P_a$ and $\text{Tr}(\mathbf{T}'\mathbf{Q}'_z\mathbf{T}'^H) = (1 - \rho)P_a$. Due to the zero-forcing constraint, it is clear that any power available to Alice that is not used for the desired signal \mathbf{x}_a will be used for jamming, so between the signal and artificial interference, Alice will transmit with full power P_a . The covariance matrices of the received interference-plus-noise at Bob and Eve are

$$\mathbf{K}_b = \begin{cases} g_2 \mathbf{H}_{be} \mathbf{Q}_{be} \mathbf{H}_{be}^H + \sigma_b^2 \mathbf{I} & \text{if Eve jams} \\ \sigma_b^2 \mathbf{I} & \text{if Eve listens} \end{cases} \quad (6)$$

$$\mathbf{K}_e = g_1 \mathbf{H}_{ea} \mathbf{T}' \mathbf{Q}'_z \mathbf{T}'^H \mathbf{H}_{ea}^H + \sigma_e^2 \mathbf{I}, \quad (7)$$

where \mathbf{Q}_{be} is the covariance of the jamming signal transmitted by Eve, $\text{Tr}(\mathbf{Q}_{be}) \leq P_e$.

Note that we have assumed that Alice's jamming signal (if any) is orthogonal to the information signal received by Bob, and hence, from the point of view of mutual information, can be ignored in the expression for \mathbf{K}_b . For our purposes, we assume that Alice splits her transmit power between a stochastic encoding codebook and artificial interference for every channel use in *all* scenarios, while Bob employs a deterministic decoding function [1], [3]. Firstly, this ensures that the general encoding and decoding architecture of the Alice-Bob link remains fixed irrespective of Eve's actions. Secondly, for a point-to-point channel without an eavesdropper (i.e., when the eavesdropper is jamming and not listening), using a stochastic codebook does not offer any advantage over a conventional codebook, but it does not hurt either, i.e., the receiver still reliably decodes the transmitted codeword [3].

B. CSI Model

Given the signal framework introduced above, we are ready to discuss the important issue of CSI. We have already indicated that Alice knows \mathbf{H}_{ba} in order to appropriately precode the jamming and information signals via \mathbf{T} and \mathbf{T}' , conceivably obtained by public feedback from Bob after a training phase. At the receiver side, we will assume that Eve knows the channel from Alice \mathbf{H}_{ea} and the covariance \mathbf{K}_e of the interference and noise, and similarly we will assume that Bob knows \mathbf{H}_{ba} and

\mathbf{K}_b . All other CSI at the various nodes is assumed to be non-informative; the only available information is that the channels are composed of independent $\mathcal{CN}(0, 1)$ random variables. This implies that when Eve jams Bob, her lack of information about \mathbf{H}_{be} and the half-duplex constraint prevents her from detecting the transmitted signal \mathbf{z} and applying correlated jamming [14]. Consequently, she will be led to uniformly distribute her available power over all N_e transmit dimensions, so that $\mathbf{Q}_{be} = \frac{P_e}{N_e} \mathbf{I}$. Similarly, when Alice transmits a jamming signal, it will also be uniformly distributed across the $N_a - d$ available dimensions: $\mathbf{Q}'_z = \frac{(1-\rho)P_a}{N_a-d} \mathbf{I}$. While in principle Alice could use her knowledge of \mathbf{H}_{ba} to perform power loading, for simplicity and robustness we will assume that the power of the information signal is also uniformly distributed, so that $\mathbf{Q}_z = \frac{\rho P_a}{d} \mathbf{I}$.

Given the above assumptions, (5)–(7) will simplify to

$$\mathbf{Q}_a = \frac{\rho P_a}{d} \mathbf{T}\mathbf{T}^H + \eta_a \mathbf{T}'\mathbf{T}'^H \quad (8)$$

$$\mathbf{K}_b = \frac{g_2 P_e}{N_e} \mathbf{H}_{be} \mathbf{H}_{be}^H + \sigma_b^2 \mathbf{I} \quad (9)$$

$$\mathbf{K}_e = g_1 \eta_a \mathbf{H}_{ea} \mathbf{T}'\mathbf{T}'^H \mathbf{H}_{ea}^H + \sigma_e^2 \mathbf{I}, \quad (10)$$

where we have defined $\eta_a = \frac{(1-\rho)P_a}{N_a-d}$.

C. Secrecy Rates and Transmit Strategies

The MIMO secrecy capacity between Alice and Bob is obtained by solving [4], [6], [9]

$$C_s = \max_{\mathbf{Q}_a \succeq 0} I(\mathbf{X}_a; \mathbf{Y}_b) - I(\mathbf{X}_a; \mathbf{Y}_e), \quad (11)$$

where $\mathbf{X}_a, \mathbf{Y}_b, \mathbf{Y}_e$ are the random variable counterparts of the realizations $\mathbf{x}_a, \mathbf{y}_b, \mathbf{y}_e$. Given the CSI constraints discussed above, such an optimization cannot be performed since Alice is unaware of the instantaneous values of all channels and interference covariance matrices. Consequently, we choose to work with the lower bound on the MIMO ergodic secrecy capacity based on Gaussian inputs and uniform power allocation at all transmitters [7]:

$$C_s \geq \mathcal{E}_{\mathbf{H}} \left\{ \log_2 \left| \mathbf{I} + \frac{\rho P_a}{d} \mathbf{H}_{ba} \mathbf{T}\mathbf{T}^H \mathbf{H}_{ba}^H \mathbf{K}_b^{-1} \right| - \log_2 \left| \mathbf{I} + \frac{g_1 \rho P_a}{d} \mathbf{H}_{ea} \mathbf{T}\mathbf{T}^H \mathbf{H}_{ea}^H \mathbf{K}_e^{-1} \right| \right\}, \quad (12)$$

where we define $\mathbf{H} \triangleq \{\mathbf{H}_{ba}, \mathbf{H}_{be}, \mathbf{H}_{ea}\}$. This serves as a reasonable metric to assess the relative security of the link and to explain the behavior of the players. Recall that we assume Alice has instantaneous CSI for the link to Bob and only statistical CSI for Eve, and the achievability of an ergodic secrecy rate for such a scenario was shown in [26]. Using ergodic secrecy as the utility function for the game between Alice and Eve implies that a large number of channel realizations will occur intermediate to any changes in their strategy. That is, the physical layer parameters are changing faster than higher (e.g., application) layer functions that determine the user's strategy. Thus, the expectation is taken over all channel matrices (including \mathbf{H}_{ba}), which in turn provides Alice and Eve with a common objective function, since neither possesses the complete knowledge of \mathbf{H} that is needed to compute the instantaneous MIMO secrecy rate.

Eve must decide whether to eavesdrop or jam with an arbitrary fraction of her transmit power. Alice's options include determining how many spatial dimensions are to be used for data and artificial interference (if any), and the appropriate fraction ρ that determines the transmit power allocated to them. As described in [7], [21]–[23], [25], there are several options available to Alice for choosing ρ and d depending upon the accuracy of her CSI, ranging from an exhaustive search for optimal values to lower-complexity approaches based on fixed-rate assumptions. Numerical results from this previous work have indicated that the achievable secrecy rate is not very sensitive to these parameters, and good performance can be obtained for a wide range of reasonable values. The general approach of this paper is applicable to essentially any value for ρ and d , although the specific results we present in the simulation section use a fixed value for d and find the optimal value for ρ based on d under the assumption that the eavesdropper is in fact eavesdropping, and not jamming.

In Section III we show that it is sufficient to consider a set of two strategies for both players without any loss in optimality. In particular, we show that Alice need only consider the options of either transmitting the information signal with full power, or devoting an appropriate amount of power and signal dimensions to a jamming signal. On the other hand, Eve's only reasonable strategies are to either eavesdrop passively or jam Bob with all her available transmit power.

We will denote Eve's set of possible actions as $\{E, J\}$ to indicate either "Eavesdropping" or "Jamming," while Alice's will be expressed as $\{F, A\}$ to indicate "Full-power" devoted to the information signal, or a non-zero fraction of the power allocated to "Artificial interference." The secrecy rates that result from the resulting four possible scenarios will be denoted by R_{ik} , where $i \in \{F, A\}$ and $k \in \{E, J\}$.

Assuming Gaussian inputs \mathbf{z} and \mathbf{z}' , the MIMO secrecy rate between Alice and Bob when Eve is in eavesdropping mode is

$$R_{iE} = \mathcal{E}_{\mathbf{H}} \left\{ \log_2 \left| \mathbf{I} + \frac{\rho P_a}{d \sigma_b^2} \mathbf{H}_{ba} \mathbf{T} \mathbf{T}^H \mathbf{H}_{ba}^H \right| - \log_2 \left| \mathbf{I} + \frac{g_1 \rho P_a}{d} \mathbf{H}_{ea} \mathbf{T} \mathbf{T}^H \mathbf{H}_{ea}^H \mathbf{K}_e^{-1} \right| \right\}, \quad (13)$$

whereas the secrecy rate when Eve is jamming reduces to

$$R_{iJ} = \mathcal{E}_{\mathbf{H}} \left\{ \log_2 \left| \mathbf{I} + \frac{\rho P_a}{d} \mathbf{H}_{ba} \mathbf{T} \mathbf{T}^H \mathbf{H}_{ba}^H \mathbf{K}_b^{-1} \right| \right\}, \quad (14)$$

where $i = F, A$ denotes the transmission strategies available to Alice. We refer to (14) as a secrecy rate even though there is technically no eavesdropper, since Eve's mutual information is identically zero and Alice still uses a stochastic encoder (cf. Section II). Therefore, when evaluating the secrecy rate definition (11) for the case where Eve chooses to jam, the second term is zero which yields R_{FJ} and R_{AJ} in (14) as the effective secrecy rate. Recall that the definition of the secrecy rate is the maximum transmission rate which can be reliably decoded by Bob while remaining perfectly secret from Eve, which is still satisfied by the rates in (14). Note also that when Alice employs artificial interference, a choice for ρ and d must be made that holds regardless of Eve's strategy. Therefore, the values of ρ and d that are numerically computed to maximize R_{AE} in (13) [7] remain unchanged for R_{AJ} in (14). When Alice transmits

with full power, then $d = r$, where $r = \min(N_a, N_b)$, and the precoder \mathbf{T} consists of the right singular vectors of \mathbf{H}_{ba} corresponding to the r largest singular values.

While Alice uses the same type of encoder regardless of Eve's strategy, achieving the rates in (13)–(14) requires adjustments to the code rate that *will* depend on Eve's actions. For example, if Alice is transmitting with full power (strategy F), the code rate needed to achieve either R_{FE} or R_{FJ} in (13) or (14) will be different. Thus, we assume that Alice can be made aware of Eve's strategy choice, for example through feedback from Bob, in order to make such adjustments¹. Such behavior is not limited to just Alice and Bob; Eve also makes adjustments based on Alice's choice of strategy. In particular, when Eve is eavesdropping, her method of decoding Alice's signal will depend on whether or not Alice is transmitting artificial interference. We do not consider adjustments such as these as part of Alice or Eve's strategy *per se*, which in our game theory framework is restricted to the decision of whether or not to use artificial interference. We assume that minor adaptations to the coding or decoding algorithm for Alice and Eve occur relatively quickly, and that any resulting transients are negligible due to our use of ergodic secrecy rate as the utility function. The more interesting question is whether or not Alice and Eve decide to change strategies based on the actions of the other is addressed in Section IV.

In the game-theoretic analysis of the next two sections, we will utilize the following general properties of the MIMO wiretap channel:

$$(P1) \quad R_{FE} \leq R_{AE}$$

$$(P2) \quad R_{AJ} \leq R_{FJ}$$

The validity of (P2) is obvious; if Alice employs artificial interference, it reduces the power allocated to the information signal, which in turn can only decrease the mutual information at Bob. Since Eve is jamming, her mutual information is zero regardless of Alice's strategy, so R_{AJ} can never be larger than R_{FJ} . The validity of (P1) can be established by recalling that Alice chooses a value for ρ that maximizes R_{AE} , assuming Eve is eavesdropping. Since $\rho = 1$ is an available option and corresponds to R_{FE} , Alice can do no worse than R_{FE} in choosing the optimal ρ for strategy R_{AE} .

III. STRATEGIC WIRETAP GAME

In this section we construct the zero-sum model of the proposed wiretap game. We define the payoff to Alice as the achievable MIMO secrecy rate between her and Bob. Modeling the strategic interactions between Alice and Eve as a strictly competitive game leads to a zero-sum formulation, where Alice tries to maximize her payoff and Eve attempts to minimize it.

Formally, we can define a compact strategy space A_i , $i = 1, 2$, for both Alice and Eve: Alice has to optimize the pair $(d, \rho) \in A_1$, where ρ is chosen from the unit interval $[0, 1]$ and $d \in \{1, \dots, r = \min(N_a, N_b)\}$; and Eve can choose her jamming power $P_j \in A_2$ from the interval $[0, P_e]$, where zero jamming power corresponds to the special case of passive eavesdropping. In other words, each player theoretically has a con-

¹Based on such feedback, Alice could also in principle switch from a stochastic encoder to a more standard non-secure code if she discovers that Eve is jamming and not eavesdropping. In either case, the rate expressions in (13)–(14) will be valid.

TABLE I
PAYOFF MATRIX \mathbf{R} OF THE STRATEGIC FORM OF THE MIMO WIRETAP GAME.

		Eve	
		Eavesdrop (E)	Jam Bob (J)
Alice	Full Power (F)	R_{FE}	R_{FJ}
	Artificial Noise (A)	R_{AE}	R_{AJ}

tinuum of (pure) strategies to choose from, where the payoff for each combination of strategies is the corresponding MIMO secrecy rate. In the following discussion, let (d_s^*, ρ_s^*) represent the choice of Alice's parameters that maximizes the ergodic secrecy rate R_{AE} .

The complete set of mixed strategies for player i is the set of Borel probability measures on A_i . Let Δ_i be the set of all probability measures that assign strictly positive mass to every nonempty open subset of A_i . The optimal mixed strategy for player i must belong to Δ_i , since any pure strategies that are assigned zero probability in equilibrium can be pruned without changing the game outcome. Furthermore, as in the case of finite games, the subset of pure strategies included in the optimal mixed strategy must be *best responses* to particular actions of the opponent [27]. Consider Alice: when Eve chooses the action of eavesdropping, (d_s^*, ρ_s^*) is Alice's corresponding best response pure strategy since by definition it offers a payoff at least as great as *any* other possible choice of (d, ρ) [cf. (P1)]. Similarly, when Eve chooses to jam with any arbitrary power, Alice's best response pure strategy is $(d = r, \rho = 1)$ [cf. (P2)]. Therefore, these two pure strategies are Alice's best responses for any possible action by Eve, and it is sufficient to consider them alone in the computation of the optimal mixed strategy since all other pure strategies are assigned zero probability. A similar argument holds for Eve with her corresponding best responses of $P_j = 0$ and $P_j = P_e$.

Therefore, it is sufficient to consider the following strategy sets \mathcal{X}, \mathcal{Y} for the players: Alice chooses between transmitting with full power for data (F) or devoting an appropriate fraction of power to jam Eve (A), described as $\mathcal{X} = \{F, A\}$. Eve must decide between eavesdropping (E) or jamming Bob with full power P_e (J) at every channel use, represented by $\mathcal{Y} = \{E, J\}$.

A. Pure-Strategy Equilibria

The strategic form of the game where Alice and Eve move simultaneously without observing each other's actions can be represented by the 2×2 payoff matrix \mathbf{R} in Table I. Our first result establishes the existence of Nash equilibria for the strategic game.

Proposition 1: For an arbitrary set of antenna array sizes, transmit powers and channel gain parameters, the following unique pure-strategy saddle-points or Nash Equilibria (NE) (x^*, y^*) exist in the proposed MIMO wiretap game:

$$\mathbf{R}(x^*, y^*) = \begin{cases} R_{AE} & \text{if } R_{AE} \leq R_{AJ} & (15a) \\ R_{FJ} & \text{if } R_{FJ} \leq R_{FE}. & (15b) \end{cases}$$

Proof: Of the 24 possible orderings of the four rate outcomes, only six satisfy both conditions (P1)–(P2) of the previous section. Furthermore, it is easy to check that only two of these six mutually exclusive outcomes results in a pure NE. If

$R_{AE} \leq R_{AJ}$, then assumptions (P1) and (P2) imply the following rate ordering

$$R_{FJ} \geq R_{AJ} \geq \underbrace{R_{AE}}_{NE} \geq R_{FE}. \quad (16)$$

In this case, R_{AE} represents an NE since neither Alice nor Eve can improve their respective payoffs by switching strategies; i.e., the secrecy rate will decrease if Alice chooses to transmit the information signal with full power, and the secrecy rate will increase if Eve decides to jam. Similarly, when $R_{FJ} \leq R_{FE}$, then (P1)–(P2) result in the rate ordering

$$R_{AE} \geq R_{FE} \geq \underbrace{R_{FJ}}_{NE} \geq R_{AJ}, \quad (17)$$

and R_{FJ} will be the mutual best response for both players. Evidently only one such ordering can be true for a given wiretap game scenario. ■

B. Mixed-Strategy Equilibria

Proposition 1 establishes that there is no single pure strategy choice that is always optimal for either player if the inequalities in (16)–(17) are not satisfied. This occurs in four of the six valid rate orderings of the entries of \mathbf{R} that satisfy conditions (P1)–(P2). Therefore, since the minimax theorem guarantees that any finite zero-sum game has a saddle-point in randomized strategies [29], in such scenarios Alice and Eve should randomize over $\mathcal{X} \times \mathcal{Y}$; that is, they should adopt mixed strategies.

Let $\mathbf{p} = (p, 1 - p)$ and $\mathbf{q} = (q, 1 - q)$, $0 \leq p, q \leq 1$, represent the probabilities with which Alice and Eve randomize over their strategy sets $\mathcal{X} = \{F, A\}$ and $\mathcal{Y} = \{E, J\}$, respectively. In other words, Alice plays $x = F$ with probability p , while Eve plays $y = E$ with probability q . Alice obtains her optimal strategy by solving

$$\max_p \min_q \mathbf{p}^T \mathbf{R} \mathbf{q}, \quad (18)$$

while Eve optimizes the corresponding minimax problem. For the payoff matrix \mathbf{R} in Table I, the optimal mixed strategies and unique NE value v of the game can be easily derived as [28], [29]

$$(p^*, 1 - p^*) = \frac{(R_{AJ} - R_{AE}, R_{FE} - R_{FJ})}{D} \quad (19a)$$

$$(q^*, 1 - q^*) = \frac{(R_{AJ} - R_{FJ}, R_{FE} - R_{AE})}{D} \quad (19b)$$

$$v(p^*, q^*) = \frac{(R_{FE}R_{AJ} - R_{FJ}R_{AE})}{D}, \quad (19c)$$

where $D = R_{FE} + R_{AJ} - R_{FJ} - R_{AE}$. The mixed NE above is unique according to the classic properties of finite matrix games [28], since the optimization in (18) has a unique solution. A graphical illustration of the saddle-point in mixed strategies as p and q are varied for a specific wiretap channel is shown in Fig. 2. For the specified parameters $N_a = 5, N_b = 3, N_e = 4, d = 2, P_a = P_e = 20$ dB, $g_1 = 1.1, g_2 = 0.9$, the rate ordering turns out to be $R_{AE} = 5.04 > R_{FJ} = 5.02 > R_{AJ} = 2.85 > R_{FE} = 0$, which results in a mixed NE with optimal mixing probabilities $(p^* = 0.307, q^* = 0.294)$ and value $v = 3.45$. Alice's bias towards playing $x = A$ more frequently is expected

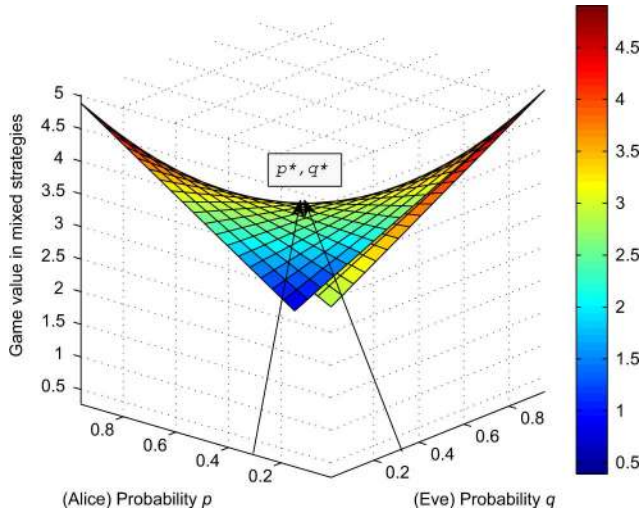

Fig. 2. Game value in mixed strategies as the mixing probabilities at Alice and Eve are varied, $N_a = 5, N_b = 3, N_e = 4, d = 2, P_a = P_e = 20$ dB, and $g_1 = 1.1, g_2 = 0.9$.

since that guarantees a secrecy rate of at least 2.85, whereas playing $x = F$ risks a worst-case payoff of zero. Eve is privy to Alice's reasoning and is therefore biased towards playing $y = J$ more frequently since she prefers a game value close to R_{AJ} .

The *repeated* wiretap game is a more sophisticated strategic game model in which Alice and Eve play against each other repeatedly over multiple stages in time. At each stage, the set of player strategies and payoff function representation is identical to the single-stage zero-sum game \mathbf{R} in Table I. In our context, the single-stage game can be considered to represent the transmission of a single codeword, with the repeated game spanning the successive transmission of multiple codewords. Let the payoff to Alice at stage k be denoted as $R[k]$. Under the *standard repeated game model* [29], the payoffs are accrued after each stage, and both players have perfect information of the adversary's moves. If the game is repeated over an infinite time horizon, the cumulative payoff (of Alice) over the duration of the game is given by

$$R_p = (1 - \delta) \sum_{k=0}^{\infty} \delta^k R[k] \quad (20)$$

where the discounting factor δ , $0 \leq \delta < 1$, ensures that R_p is finite. Unlike general nonzero-sum repeated games where players can improve payoffs via cooperation over time [30], the strictly competitive nature of the zero-sum wiretap game results in Alice and Eve repeatedly playing their single-stage game NE strategies. For example, it is clear that Eve minimizes R_p by minimizing $R[k]$ at each stage k , which is achieved by playing as dictated by Proposition 1 or (19) at each stage. If the game is played over a finite number of stages instead, the players will continue to play their single-stage game NE strategies by the same argument. The concepts developed in Section IV-B are applicable to the more involved repeated game scenario where Alice and Eve have imperfect observations of each other's actions.

Fig. 3. Extensive form game tree with perfect information $\Gamma^{e,1}$ where Alice moves first and Eve moves second.

IV. EXTENSIVE FORM WIRETAP GAME

Given the strategic game analysis of the previous section, we can now proceed to analyze the actions of a given player in response to the opponent's strategy. Here, one player is assumed to move first, followed by the opponent's response, which can then lead to a strategy (and code rate) change for the first player, and so on. Accordingly, in this section we examine the sequential or *extensive form* of the MIMO wiretap game, which is also known as a Stackelberg game. The standard analysis of a Stackelberg game is to cast it as a dynamic or extensive-form game and elicit equilibria based on backward induction [28]. We begin with the worst-case scenario where Alice moves first by either playing F or A , which is observed by Eve who responds accordingly. It is convenient to represent the sequential nature of an extensive-form game with a rooted tree or directed graph, as shown in Fig. 3. The payoffs for Alice are shown at each terminal node, while the corresponding payoffs for Eve are omitted for clarity due to the zero-sum assumption. In this section, we explore extensive-form games with and without perfect information, and the variety of equilibrium solution concepts available for them.

A. Perfect Information

Assuming that Eve can distinguish which move was adopted by Alice, and furthermore determine the exact jamming power $(1 - \rho)P_a$ if she is being jammed by Alice, then the extensive game is classified as one of *perfect information*. In the sequel, we will make use of the notions of an *information state* and a *subgame*. A player's information state represents the node(s) on the decision tree at which she must make a move conditioned on her knowledge of the previous move of the opponent. For the case of perfect information in Fig. 3, Alice has a single information state, while Eve has two information states (each with a single node) based on Alice's choice, since she has perfect knowledge of Alice's move. A subgame is a subset (subgraph) of a game that starts from an information state with a single node, contains all of that node's successors in the tree, and contains all or none of the nodes in each information state [29].

Next, we analyze *subgame-perfect equilibria* (SPE) of the extensive game, which are a more refined form of NE that eliminate irrational choices within subgames [28], [29]. It is well known that in extensive games with perfect information, a sequential equilibrium in pure strategies is guaranteed to exist [29, Theorem 4.7]. The equilibrium strategies can be obtained by a process of backward induction on the extensive game tree, as shown below.

Fig. 4. Extensive form game tree with perfect information $\Gamma^{e,2}$ where Eve moves first and Alice moves second.

Proposition 2: In the extensive form wiretap game $\Gamma^{e,1}$ with perfect information where Alice moves first, the unique subgame-perfect equilibrium rate with pure strategies is determined by the following:

$$\text{SPE}(\Gamma^{e,1}) = \begin{cases} R_{A,E} & \text{if } R_{A,E} \leq R_{A,J} \\ R_{F,J} & \text{if } R_{F,J} \leq R_{F,E} \\ \max[R_{F,E}, R_{A,J}] & R_{F,E} \leq R_{F,J}, \\ & R_{A,J} \leq R_{A,E}. \end{cases}$$

Proof: The extensive game tree for this problem, depicted in Fig. 3, is comprised of three subgames: the two subgames at Eve's decision nodes, and the game itself with Alice's decision node as the root. Consider the scenario $R_{FE} \leq R_{FJ}$ and $R_{AJ} \leq R_{AE}$. Under this assumption, Eve always plays E in the lower-left subgame of Fig. 3, whereas Eve picks J in the lower-right subgame. By backward induction, Alice then chooses the larger of $[R_{FE}, R_{AJ}]$ at her decision node. The other two SPE outcomes can be established in a similar manner. ■

Proposition 3: The extensive form game $\Gamma^{e,2}$ with perfect information where Eve moves first and Alice moves second has the following subgame-perfect equilibrium rate outcome and corresponding strategies:

$$\text{SPE}(\Gamma^{e,2}) = \min[R_{FJ}, R_{AE}]. \quad (21)$$

Proof: The extensive game tree for this scenario is depicted in Fig. 4, and is comprised of three subgames: the two subgames at Alice's decision nodes, and the game itself with Eve's decision node as the root. Based on properties (P1)–(P2), Alice always plays A in the lower-left subgame and F in the lower-right subgame. By backward induction, Eve then chooses the action corresponding to the smaller payoff between $[R_{AE}, R_{FJ}]$ at her decision node. ■

Note that in the scenario where Alice moves first, she chooses her coding parameters based on the assumption that Eve acts rationally and adopts the equilibrium strategy in Proposition 2. We see from both propositions that, when conditions for one of the pure-strategy NEs hold, the outcome of both $\Gamma^{e,1}$ and $\Gamma^{e,2}$ will be the corresponding NE. This is also true of an extensive game with more than 2 stages; if an NE exists, the overall SPE outcome will be composed of repetitions of this constant result.

B. Imperfect Information

We now consider extensive wiretap games with imperfect information, where the player moving second has an imperfect estimate of the prior move made by her opponent. Let $\Gamma_f^{e,3}$ and

$\Gamma_f^{e,4}$ denote the games where Alice and Eve move first, respectively. The game tree representation of $\Gamma_f^{e,3}$ can be drawn by connecting the decision nodes of Eve in Fig. 3 to indicate her inability to correctly determine Alice's move in the initial phase of the game. Thus, in this case, Eve effectively only possesses a single information state. While no player has an incentive to randomize in the game with perfect information in Section IV-A, mixed strategies enter the discussion when the game is changed to one of imperfect information. The subgame perfect equilibrium solution is generally unsatisfactory for such games, since the only valid subgame in this case is the entire game $\Gamma_f^{e,3}$ itself. Therefore, *sequential equilibrium* is a stronger solution concept better suited for extensive games of imperfect information.

An extreme case of imperfect information in $\Gamma_f^{e,3}$ is the scenario where it is common knowledge at all nodes that Eve is *completely unable* to determine what move was made by Alice in the first stage of the game. Let Eve then assign the *a priori* probabilities $(\alpha, 1 - \alpha)$ to Alice's moves over $\{F, A\}$ for some ρ and d , while Eve herself randomizes over $\{E, J\}$ with probabilities $(\gamma, 1 - \gamma)$. Therefore, Eve's left and right decision nodes are reached with probability α and $(1 - \alpha)$, respectively. There are three possible supports for Eve's moves at her information state: pure strategies $\{E\}$ or $\{J\}$ exclusively, or randomizing over $\{E, J\}$. In the general scenario where Eve randomizes over $\{E, J\}$ with probabilities $(\gamma, 1 - \gamma)$, her expected payoff can be expressed as

$$-\alpha[\gamma R_{FE} + (1 - \gamma)R_{FJ}] + (\alpha - 1)[\gamma R_{AE} + (1 - \gamma)R_{AJ}].$$

Using a probabilistic version of backward induction, it is straightforward to compute the sequential equilibrium of $\Gamma_f^{e,3}$, which in fact turns out to be identical to the mixed-strategy NE in (19). A similar argument holds for $\Gamma_f^{e,4}$ with no information at Alice, which arises if no feedback is available from Bob.

It is much more reasonable to assume that the player moving second is able to form some estimate of her opponent's move, known as the *belief vector* [29]. An example of how such a scenario may play out is described here. Consider the game $\Gamma_f^{e,4}$, where Alice's belief vector represents the posterior probabilities of Eve having played $\{E\}$ and $\{J\}$ in the first stage. Assume that Bob collects M signal samples and provides Alice with an inference of Eve's move via an error-free public feedback channel. The competing hypotheses at Bob are

$$\begin{aligned} \mathcal{H}_0 : \mathbf{y}_b[n] &= \mathbf{H}_{ba}\mathbf{x}_a[n] + \mathbf{n}_b[n] \\ \mathcal{H}_1 : \mathbf{y}_b[n] &= \mathbf{H}_{ba}\mathbf{x}_a[n] + \sqrt{g_2}\mathbf{H}_{be}\mathbf{x}_e[n] + \mathbf{n}_b[n], \end{aligned} \quad (22)$$

for $n = 0, \dots, M - 1$, where the null hypothesis \mathcal{H}_0 corresponds to Eve listening passively and the alternative hypothesis \mathcal{H}_1 is that she is jamming Bob. Here, the channels are assumed to be constant over the sensing interval [31] and known to Bob since he possesses local CSI. Aggregating the samples into a $(N_b \times M)$ matrix $\mathbf{Y}_b = [\mathbf{y}_b[0] \ \dots \ \mathbf{y}_b[M - 1]]$, we observe that $\mathbf{Y}_b \sim \mathcal{CN}(\mathbf{0}, \mathbf{Z}_0)$ under \mathcal{H}_0 and $\mathbf{Y}_b \sim \mathcal{CN}(\mathbf{0}, \mathbf{Z}_0 + \mathbf{Z}_1)$ under \mathcal{H}_1 , where

$$\begin{aligned} \mathbf{Z}_0 &\triangleq \mathbf{H}_{ba}\mathbf{Q}_a\mathbf{H}_{ba}^H + \sigma_b^2\mathbf{I} \\ \mathbf{Z}_1 &\triangleq \begin{pmatrix} P_e \\ N_e \end{pmatrix} \mathbf{H}_{be}\mathbf{H}_{be}^H. \end{aligned}$$

Assuming that Bob employs a minimum probability of error (MPE) detector [32], the hypothesis test is

$$\frac{f(\mathbf{Y}_b|\mathcal{H}_1)}{f(\mathbf{Y}_b|\mathcal{H}_0)} \underset{\mathcal{H}_0}{\overset{\mathcal{H}_1}{\gtrless}} \frac{\Pr(\mathcal{H}_1)}{\Pr(\mathcal{H}_0)} = \eta \quad (23)$$

where $\Pr(\mathcal{H}_1)$ and $\Pr(\mathcal{H}_0)$ are prior probabilities assigned to the hypotheses by Bob. A worst-case assumption for the prior probabilities is given by Eve's minimax mixing probabilities in (19b). Taking the logarithm on both sides of (29) and inserting the appropriate densities

$$f(\mathbf{Y}_b|H_1) = \pi^{-MN_b} |\mathbf{Z}_0 + \mathbf{Z}_1|^M \times \exp\left(-\text{Tr}\left((\mathbf{Z}_0 + \mathbf{Z}_1)^{-1} \mathbf{Y}_b \mathbf{Y}_b^H\right)\right) \quad (24)$$

$$f(\mathbf{Y}_b|H_0) = \pi^{-MN_b} |\mathbf{Z}_0|^M \exp\left(-\text{Tr}\left(\mathbf{Z}_0^{-1} \mathbf{Y}_b \mathbf{Y}_b^H\right)\right), \quad (25)$$

after some manipulations we obtain the test

$$\text{Tr}\left(\left(\mathbf{Z}_0^{-1} - (\mathbf{Z}_0 + \mathbf{Z}_1)^{-1}\right) \mathbf{Y}_b \mathbf{Y}_b^H\right) \underset{\mathcal{H}_0}{\overset{\mathcal{H}_1}{\gtrless}} \eta' \quad (26)$$

where $\eta' = \ln(\eta) + |\mathbf{Z}_0 + \mathbf{Z}_1|^M + |\mathbf{Z}_0|^M$.

Finally, Alice determines her best response based on the posterior probabilities (beliefs) of the hypotheses, which is the definition of a sequentially rational strategy [29]. The requisite posterior probabilities are $\alpha_i \triangleq \Pr\{\mathcal{H}_i|\mathbf{Y}_b\} = \frac{f(\mathbf{Y}_b|\mathcal{H}_i) \Pr\{\mathcal{H}_i\}}{f(\mathbf{Y}_b)}$, $i = 0, 1$, with $\alpha_1 = 1 - \alpha_0$ and $f(\mathbf{Y}_b) = \sum_i (f(\mathbf{Y}_b|\mathcal{H}_i) \Pr\{\mathcal{H}_i\})$. At equilibrium, Alice has by definition no incentive to switch actions, which implies that her expected payoffs are the same. Since her expected payoff if she plays $\{F\}$ is $\alpha_0 R_{FE} + (1 - \alpha_0) R_{FJ}$, and $\alpha_0 R_{AE} + (1 - \alpha_0) R_{AJ}$ if she plays $\{A\}$, it follows that Alice's best response is given by

$$BR_A(\alpha_0) = \begin{cases} F & \text{if } \alpha_0 \leq \frac{(R_{FJ} - R_{AJ})}{(R_{AE} - R_{FE} + R_{FJ} - R_{AJ})} \\ A & \text{otherwise.} \end{cases} \quad (27)$$

On the other hand, since Eve moves first in $\Gamma_f^{e,4}$, she does not have causal knowledge of Alice's beliefs, and therefore continues to play her minimax strategies in (19b).

For the game $\Gamma_f^{e,3}$ where Eve moves second, she forms her beliefs about Alice's move ($\{F\}$ or $\{A\}$) from the binary hypothesis test

$$\begin{aligned} \mathcal{H}_0: \mathbf{y}_e &= \sqrt{g_1} \mathbf{H}_{ea} \mathbf{z} [n] + \mathbf{n}_e [n] \\ \mathcal{H}_1: \mathbf{y}_e &= \sqrt{g_1} \mathbf{H}_{ea} \mathbf{T} \mathbf{z} [n] + \sqrt{g_1} \mathbf{H}_{ea} \mathbf{T}' \mathbf{z}' [n] + \mathbf{n}_e [n] \end{aligned} \quad (28)$$

for $n = 0, \dots, M - 1$. The $(N_e \times M)$ sample matrix $\mathbf{Y}_e = [\mathbf{y}_e[0] \dots \mathbf{y}_e[M-1]]$ follows the distributions $\mathbf{Y}_e \sim \mathcal{CN}(\mathbf{0}, \mathbf{Z}_0)$ under \mathcal{H}_0 and $\mathbf{Y}_e \sim \mathcal{CN}(\mathbf{0}, \mathbf{Z}_1)$ under \mathcal{H}_1 , where

$$\begin{aligned} \mathbf{Z}_0 &\triangleq \left(\frac{g_1 P_a}{N_a}\right) \mathbf{H}_{ea} \mathbf{H}_{ea}^H + \sigma_e^2 \mathbf{I} \\ \mathbf{Z}_1 &\triangleq \left(\frac{g_1 P_a}{N_a}\right) \mathbf{H}_{ea} \mathbf{T} \mathbf{T}^H \mathbf{H}_{ea}^H \\ &\quad + \left(\frac{g_1 (1 - \rho) P_a}{N_a}\right) \mathbf{H}_{ea} \mathbf{T}' \mathbf{T}'^H \mathbf{H}_{ea}^H + \sigma_e^2 \mathbf{I}. \end{aligned}$$

The MPE test at Eve thus simplifies to

$$\text{Tr}\left(\left(\mathbf{Z}_0^{-1} - (\mathbf{Z}_1)^{-1}\right) \mathbf{Y}_e \mathbf{Y}_e^H\right) \underset{\mathcal{H}_0}{\overset{\mathcal{H}_1}{\gtrless}} \eta' \quad (29)$$

where $\eta' = \ln(\eta) + |\mathbf{Z}_1|^M + |\mathbf{Z}_0|^M$, and η is the ratio of worst-case prior probabilities based on (19a). By the equivalence of equilibrium payoffs, Eve's best response based on her computed posterior probabilities $(\alpha_0, 1 - \alpha_0)$ is

$$BR_E(\alpha_0) = \begin{cases} E & \text{if } \alpha_0 \leq \frac{(R_{AE} - R_{AJ})}{(R_{AE} - R_{FE} + R_{FJ} - R_{AJ})} \\ J & \text{otherwise.} \end{cases} \quad (30)$$

Since Alice has no means of estimating the beliefs possessed by Eve, Alice plays her maximin strategy as specified by (19a) when she moves first.

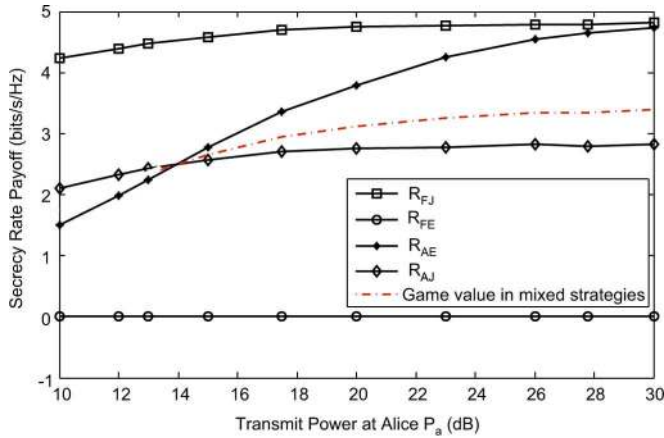

V. SIMULATION RESULTS

In this section, we present several examples that show the equilibrium secrecy rate payoffs for various channel and user configurations. All displayed results are based on the actual numerically computed secrecy rates with 5000 independent trials per point. NE rates are depicted using a dashed red line where applicable. In all of the simulations, the noise power was assumed to be the same for both Bob and Eve: $\sigma_b^2 = \sigma_e^2 = 1$.

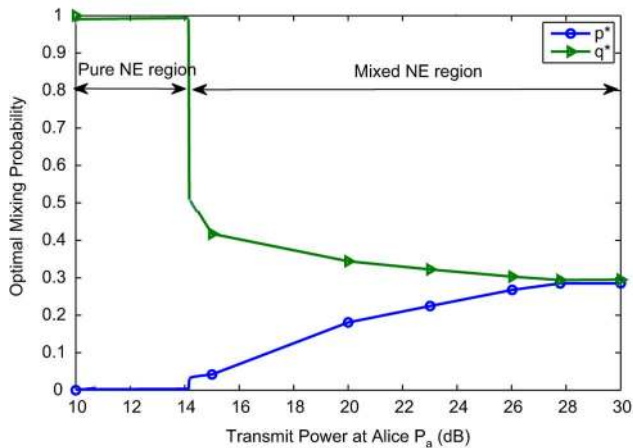

For the strategic game in Fig. 5 we set $N_a = N_e = 8$, $N_b = 6$, and Eve's power is larger than Alice's: $P_e = 4P_a$. The optimal choice for the signal dimension in this scenario is $d = 4$. Prior to the cross-over, a pure strategy NE in R_{AE} is the game outcome since the rate ordering is that of (16), whereas after the cross-over it is optimal for both players to play mixed strategies according to (19). In this case, randomizing strategies clearly leads to better payoffs for the players as Eve's jamming power increases, compared to adopting a pure strategy. The optimal mixing probabilities are shown in Fig. 5(b) with a clear division between pure and mixed strategy NE regions. The pure NE is lost as P_a increases since R_{AE} grows more quickly than R_{AJ} . This is because increasing P_a under AE both improves Bob's rate and reduces Eve's rate, since more power is available for both signal and jamming. For AJ , increasing P_a can only improve Bob's rate since Eve is not impacted by the artificial interference (any power devoted to artificial interference is wasted).

For the case of equal transmit powers $P_e = P_a = 100$ and parameters $N_a = 6$, $N_b = 3$, $d = 2$, the outcomes of the strategic game as the ratio of eavesdropper to transmitter antennas varies is shown in Fig. 6. We observe that a similar dichotomy exists between a pure-strategy saddle-point region and a mixed-strategy equilibrium in terms of $\frac{N_e}{N_a}$ (with the transition roughly at $\left(\frac{N_e}{N_a}\right) = 1$ marked by the dashed red line).

Next, the SPE outcomes of the two extensive-form games $\Gamma^{e,1}$ and $\Gamma^{e,2}$ over a range of transmit power ratios $\frac{P_e}{P_a}$ are shown in Fig. 7. The red and blue dashed lines represent the subgame-perfect outcomes of the game where Alice moves first or second, respectively, as defined in Proposition 2 and Corollary 1. In the extensive form game, Alice could adjust her transmission parameters (ρ , d , \mathbf{T} , etc.) in addition to her overall strategy (A or F) in response to Eve's move. For simplicity, and to allow us to present the main result in a single figure, we have assumed instead that the transmission parameters are chosen independently of Eve's actions, as described for the strategic game. Observe that prior to the crossover point of R_{AE} and R_{AJ} , both equilibria are equal as determined by Proposition 2, since

(a)

(b)

Fig. 5. Strategic MIMO wiretap game for $P_e = 4P_a$, $N_a = N_e = 8$, $N_b = 6$, $d = 4$, $g_1 = 1.2$, $g_2 = 0.75$ as a function of the transmit power at Alice (a) Resulting secrecy rates (b) Optimal mixing probabilities.

Fig. 6. Payoff versus antenna ratio $\frac{N_e}{N_a}$ for fixed transmit powers $P_e = P_a = 100$ and $N_a = 6$, $N_b = 3$, $d = 2$, $g_1 = 1.1$, $g_2 = 0.9$.

a pure-strategy NE results. We see that it is always beneficial for Alice to move second especially as Eve's jamming power increases, which agrees with intuition.

Finally, in Fig. 8 we compare the equilibrium outcomes of the extensive-form games with perfect and imperfect information as a function of P_a , with $P_e = 2P_a$. The no-information

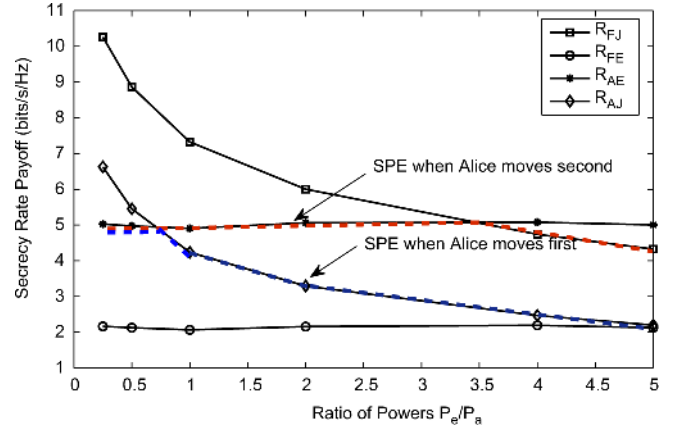

Fig. 7. Extensive-form games with perfect information, $N_a = N_b = N_e = 3$, $P_a = 20\text{dB}$, $d = 1$, $g_1 = 0.8$, $g_2 = 1.1$.

Fig. 8. Extensive-form games with perfect information, $N_a = N_b = 3$, $N_e = 2$, $P_e = 2P_a$, $d = 2$, $g_1 = 0.8$, $g_2 = 1.3$.

lower bound is given by the strategic game mixed-strategy NE. For the given choice of parameters, Alice is not significantly disadvantaged when she moves first ($\Gamma^{e,1}$) in the idealized scenario of perfect information. In sharp contrast, a carefully designed hypothesis test allows Alice to significantly improve her payoff in ($\Gamma_f^{e,4}$) given a noisy observation of Eve's move, as compared to the no-information case. Since $P_e = 2P_a$ in this example, an increase in Alice's transmit power also implies an increase in Eve's power, which aids the hypothesis test at Bob and thus Alice has a better estimate of Eve's move. On the other hand, Eve's hypothesis test does not show the same improvement as P_a increases since the ratio between data and artificial noise power remains virtually the same.

VI. CONCLUSION

We have formulated the interactions between a multi-antenna transmitter and a dual-mode eavesdropper/jammer as a novel zero-sum game with the ergodic MIMO secrecy rate as the payoff function. We derived conditions under which Nash equilibria exist and the optimal user policies in both pure and

mixed strategies for the strategic version of the game, and we also investigated subgame-perfect and sequential equilibria in the extensive forms of the game with and without perfect information. Our numerical results showed that a change in a single parameter set while others remain constant can shift the equilibrium from a pure to a mixed NE outcome or vice versa.

Amitav Mukherjee (S'06) received the B.S. degree from the University of Kansas, Lawrence, in 2005, the M.S. degree from Wichita State University, Wichita, KS, in 2007, and the Ph.D. degree from the University of California at Irvine, in 2012, all in electrical engineering.

From 2010 to 2012, he held internships with Qualcomm Inc., San Diego, CA; Mitsubishi Electric Research Labs (MERL), Cambridge, MA; Nokia Research Center, Helsinki, Finland; Intel Corporation, Santa Clara, CA; and Nokia Research Center, Berkeley, CA. His research interests encompass statistical signal processing and wireless communications, with over 45 publications and six pending patents in these areas.

Dr. Mukherjee received the Best Student Paper Award at SPAWC 2010, Marakech, and is a member of the IEEE Communications and Signal Processing Societies.

A. Lee Swindlehurst (S'83–M'84–SM'99–F'04) received the B.S. (*summa cum laude*) and M.S. degrees in electrical engineering from Brigham Young University, Provo, UT, in 1985 and 1986, respectively, and the Ph.D. degree in electrical engineering from Stanford University, Stanford, CA, in 1991.

From 1986 to 1990, he was with ESL, Inc., Sunnyvale, CA, where he was involved in the design of algorithms and architectures for several radar and sonar signal processing systems. He was on the faculty of the Department of Electrical and Computer

Engineering at Brigham Young University from 1990 to 2007, where he was a Full Professor and served as Department Chair from 2003 to 2006. During 1996–1997, he held a joint appointment as a visiting scholar at both Uppsala University, Uppsala, Sweden, and at the Royal Institute of Technology, Stockholm, Sweden. From 2006 to 2007, he was on leave working as Vice President of Research for ArrayComm LLC, San Jose, CA. He is currently a Professor of electrical engineering and computer science with the University of California at Irvine. His research interests include sensor array signal processing for radar and wireless communications, detection and estimation theory, and system identification, and he has over 225 publications in these areas.

Dr. Swindlehurst is a past Secretary of the IEEE Signal Processing Society and Editor-in-Chief of the IEEE JOURNAL ON SELECTED TOPICS IN SIGNAL PROCESSING. He is currently serving as a member of the Editorial Boards for the EURASIP JOURNAL ON WIRELESS COMMUNICATIONS AND NETWORKING and the IEEE SIGNAL PROCESSING MAGAZINE, and is a past Associate Editor for the IEEE TRANSACTIONS ON SIGNAL PROCESSING. He is a recipient of several paper awards: the 2000 IEEE W. R. G. Baker Prize Paper Award, the 2010 and 2006 IEEE Signal Processing Society's Best Paper Awards, the 2006 IEEE Communications Society Stephen O. Rice Prize in the Field of Communication Theory, and he is coauthor of a paper that received the IEEE Signal Processing Society Young Author Best Paper Award in 2001.
