Large-scale active-set box-constrained optimization method with spectral projected gradients

Ernesto G. Birgin * José Mario Martínez †

December 11, 2001

Abstract

A new active-set method for smooth box-constrained minimization is introduced. The algorithm combines an unconstrained method, including a new line-search which aims to add many constraints to the working set at a single iteration, with a recently introduced technique (spectral projected gradient) for dropping constraints from the working set. Global convergence is proved. A computer implementation is fully described and a numerical comparison assesses the reliability of the new algorithm.

Keywords: Box-constrained minimization, numerical methods, active-set strategies, Spectral Projected Gradient.

1 Introduction

The problem considered in this paper consists in the minimization of a smooth function $f : \mathbb{R}^n \to \mathbb{R}$ with bounds on the variables. The feasi-

ble set Ω is defined by

$$\Omega = \{x \in I\!R^n \mid \ell \leq x \leq u\}. \tag{1}$$

Box-constrained minimization algorithms are used as subalgorithms for solving the subproblems that appear in many augmented Lagrangian and penalty methods for general constrained optimization. See [11, 12, 16, 17, 18, 19, 20, 21, 26, 28, 31]. A very promising novel application is the reformulation of equilibrium problems. See [1] and references therein. The methods introduced in [11] and [26] are of trust-region type. For each iterate $x_k \in \Omega$, a quadratic approximation of f is minimized in a trust-region box. If the objective function value at the trial point is sufficiently smaller than $f(x_k)$, the trial point is accepted. Otherwise, the trust region is reduced. The difference between [11] and [26] is that, in [11], the trial point is in the face defined by a "Cauchy point", whereas in [26] the trial point is obtained by means of a specific box-constrained quadratic solver, called QUACAN. See [2, 15, 23, 25, 31] and [13] (p. 459). Other trust-region methods for box-constrained optimization have been introduced in [3, 29].

QUACAN is an active-set method that uses conjugate gradients within the faces, approximate internal-face minimizations, projections to add constraints to the active set and an "orthogonal-to-the-face" direction to leave the current face when an approximate minimizer in the face is met. In [17] a clever physical interpretation for this direction was given.

Numerical experiments in [16] suggested that the efficiency of the algorithm [26] relies, not in the trust-region strategy, but in the strategy of QUACAN for dealing with constraints. This motivated us to adapt the strategy of QUACAN to general box-constrained problems. Such adaptation involves two main decisions. On one hand, one needs to choose an unconstrained minimization algorithm to deal with the objective function within the faces. On the other hand, it is necessary to define robust and efficient strategies to leave faces and to add active constraints. Attempts for the first decision have been made in [6] and [10]. In [10] a secant multipoint minimization algorithm is used and in [6] the authors use the second-order minimization algorithm of Zhang and Xu [36].

In this paper we adopt the leaving-face criterion of [6], that employs the spectral projected gradients defined in [7, 8]. See, also, [4, 5, 32, 33, 34].

For the internal minimization in the faces we introduce a new general algorithm with a line search that combines backtracking and extrapolation. The compromise in every line-search algorithm is between accuracy in the localization of the one-dimensional minimizer and economy in terms of functional evaluations. Backtracking-like line-search algorithms are cheap but, sometimes, tend to generate excessively small steps. For this reason, backtracking is complemented with a simple extrapolation procedure here. The direction chosen at each step is arbitrary, provided that an angle condition is satisfied.

In the implementation described in this paper, we suggest to choose the direction using the truncated-Newton approach. This means that the search vector is an approximate minimizer of the quadratic approximation of the function in the current face. We use conjugate gradients to find this direction, so the first iterate is obviously a descent direction, and this property is easily monitorized through successive conjugate gradient steps.

The present research is organized as follows. In Section 2 we describe an "unconstrained" minimization algorithm that deals with the minimization of a function on a box. The algorithm uses the new line-search technique. Due to this technique it is possible to prove that either the method finishes at a point on the boundary where, perhaps, many constraints are added, or it converges to a point in the box where the gradient vanishes. The box-constrained algorithm is described in Section 3. Essentially, we use the algorithm of Section 2 to work within the "current face" and spectral projected gradients [7] to leave constraints. The spectral projected gradient technique also allows one to leave many bounds and to add many others to the working set at a single iteration. This feature can be very important for large-scale calculations. In this section we prove the global convergence of the box-constrained algorithm. The computational description of the code (GENCAN) is given in Section 4. In Section 5 we show numerical experiments using the CUTE collection. In Section 6 we report experiments using some very large problems (up to 10^7 variables). Finally, in Section 6 we make final comments and suggest some lines for future research.

2 A general "unconstrained" algorithm

In this section we assume that $f : I\!R^{\bar{n}} \to I\!R$, $f \in C^1(I\!R^n)$ and

$$\mathcal{B} = \{x \in I\!R^{\bar{n}} \mid \bar{\ell} \leq x \leq \bar{u}\}.$$

The set $\mathcal{B}$ will represent each of the closed faces of Ω in Section 3. The dimension $\bar{n}$ in this section is the dimension of the reduced subspace of the Section 3 and the gradient of this section is composed by the derivatives with respect to free variables in Section 3. We hope that using the notation ∇f in this section will not lead to confusion.

From now on, we denote $g(x) = \nabla f(x)$ and $g_k = g(x_k) = \nabla f(x_k)$. Our objective is to define a general iterative algorithm that starts in the interior of $\mathcal{B}$ and, either converges to an unconstrained stationary point, or finishes in the boundary of $\mathcal{B}$ having decreased the functional value. This will be the algorithm used "within the faces" in the box-constrained method. Algorithm 2.1 is based on line searches with Armijo-like conditions and extrapolation. Given the current point x_k and a descent direction d_k, we finish the line search if x_k+d_k satisfies a sufficient descent criterion and if the directional derivative is sufficiently larger than $\langle g(x_k), d_k\rangle$. If the sufficient descent criterion does not hold, we do backtracking. If we obtained sufficient descent but the increase of the directional derivative is not enough, we try extrapolation.

Let us explain why we think that this philosophy is adequate for large-scale box-constrained optimization.

1. Pure backtracking is enough for proving global convergence of many optimization algorithms. However, to accept the first trial point when it satisfies an Armijo condition can lead to very small steps in critical situations. Therefore, steps larger than the unity must be tried when some indicator says that this is worthwhile.

2. If the directional derivative $\langle g(x_k + d_k), d_k\rangle$ is sufficiently larger than $\langle g(x_k), d_k\rangle$ we consider that there is not much to decrease increasing the steplength in the direction of d_k and, so, we accept the unit steplength provided it satisfies the Armijo condition. This is reasonable since, usually, the search direction contains some amount of

second-order information that makes the unitary steplength desirable from the point of view of preserving a satisfactory order of convergence.

3. If the unitary steplength does not satisfy the Armijo condition, we do backtracking. In this case we judge that it is not worthwhile to compute gradients of the new trial points, which would be discarded if the point is not accepted.

4. Extrapolation is especially useful in large-scale problems, where it is important to try to add as many constraints as possible to the working set. So, we extrapolate in a rather greedy way, multiplying the steplength by a fixed factor while the function value decreases.

5. We think that the algorithm presented here is the most simple way in which extrapolation devices can be introduced with a reasonable balance between cost and efficiency. It is important to stress that this line search can be coupled with virtually any minimization procedure that computes descent directions.

For all $z \in I\!R^n$, the Euclidean projection of z onto a convex set S will be denoted $P_S(z)$. In this section, we denote $P(y) = P_{\mathcal{B}}(y)$. The symbol $\|\cdot\|$ represents the Euclidean norm throughout the paper.

Algorithm 2.1: Line-search based algorithm
The algorithm starts with $x_0 \in Int(\mathcal{B})$. The non-dimensional parameters $\gamma \in (0, 1/2)$, $\beta \in (0, 1)$, $\theta \in (0, 1)$, $N > 1$ and $0 < \sigma_1 < \sigma_2 < 1$ are given. We also use the small tolerances $\epsilon_{abs}, \epsilon_{rel} > 0$. Initially, we set $k \leftarrow 0$.

Step 1. *Computing the search direction*

Step 1.1 If $\|g_k\| = 0$, stop.

Step 1.2 Compute $d_k \in I\!R^n$ such that

$$\langle g_k, d_k \rangle \leq -\theta \|g_k\| \|d_k\|. \tag{2}$$

Step 2. *Line-search decisions*

Step 2.1 Compute $\alpha_{\max} \leftarrow \max\{\alpha \geq 0 \mid [x_k, x_k + \alpha d_k] \subset \mathcal{B}\}$ and
set $\alpha \leftarrow \min\{\alpha_{\max}, 1\}$.
If ($\alpha_{\max} > 1$, so $x_k + d_k \in Int(\mathcal{B})$) then go to Step 2.2

else go to Step 2.3.

Step 2.2 (At this point we have $x_k + d_k \in Int(\mathcal{B})$.)

If $(f(x_k + d_k) \leq f(x_k) + \gamma\langle g_k, d_k)\rangle$ then (3)

if $(\langle d_k, g(x_k + d_k)\rangle \geq \beta\langle g_k, d_k\rangle)$ then (4)

take $\alpha_k = 1$, $x_{k+1} = x_k + d_k$ and go to Step 5

else go to Step 3 (Extrapolation)

else go to Step 4 (Backtracking).

Step 2.3 (At this point we have $x_k + d_k \notin Int(\mathcal{B})$.)

If $(f(x_k + \alpha_{\max} d_k) < f(x_k))$ then

take $\alpha_k \geq \alpha_{\max}$ and $x_{k+1} = P(x_k + \alpha_k d_k) \in \mathcal{B} - Int(\mathcal{B})$ such that $f(x_{k+1}) \leq f(x_k + \alpha_{\max} d_k)$ and go to Step 5 (In practice, such a point is obtained performing Step 3 of this algorithm (Extrapolation).)

else go to Step 4 (Backtracking).

Step 3. *Extrapolation*

Step 3.1 If $(\alpha < \alpha_{\max}$ and $N\alpha > \alpha_{\max})$ then set $\alpha_{trial} \leftarrow \alpha_{\max}$ else set $\alpha_{trial} \leftarrow N\alpha$.

Step 3.2 If $(\alpha \geq \alpha_{\max}$ and $\|P(x_k + \alpha_{trial} d_k) - P(x_k + \alpha d_k)\|_\infty < \max(\epsilon_{abs}, \epsilon_{rel}\|P(x_k + \alpha d_k)\|_\infty))$ then

take $\alpha_k = \alpha$, $x_{k+1} = P(x_k + \alpha d_k)$ and terminate the execution of Algorithm 2.1.

Step 3.3 If $(f(P(x_k + \alpha_{trial} d_k)) \geq f(P(x_k + \alpha d_k)))$ then (5)

take $\alpha_k = \alpha$, $x_{k+1} = P(x_k + \alpha d_k)$ and go to Step 5

else set $\alpha \leftarrow \alpha_{trial}$ and go to Step 3.1.

Step 4. *Backtracking*

Step 4.1 Compute $\alpha_{new} \in [\sigma_1\alpha, \sigma_2\alpha]$ and set $\alpha \leftarrow \alpha_{new}$.

Step 4.2 If $(f(x_k + \alpha d_k) \leq f(x_k) + \gamma\alpha\langle g_k, d_k\rangle)$ then (6)

take $\alpha_k = \alpha$, $x_{k+1} = x_k + \alpha d_k$ and go to Step 5

else go to Step 4.1.

Step 5. If $\alpha_k \geq \alpha_{max}$ terminate the execution of Algorithm 2.1

else set $k \leftarrow k+1$ and go to Step 1.

Remarks. Let us explain here the main steps of Algorithm 2.1 and their motivations. The algorithm perform line-searches along directions that satisfy the angle-cosine condition (2). In general, this line search will be used with directions that possess some second-order information, so that the "natural" step $\alpha = 1$ must be initially tested and accepted if sufficient-descent and directional-derivative conditions ((3) and (4)) are satisfied.

The first test, at Step 2.1, asks whether $x_k + d_k$ is interior to the box. If this is not the case, but $f(x_k + \alpha_{max} d_k) < f(x_k)$, we try to obtain smaller functional values multiplying the step by a fixed factor and projecting onto the box. This procedure is called "Extrapolation". If $x_k + d_k$ is not interior and $f(x_k + \alpha_{max} d_k) \geq f(x_k)$ we do backtracking.

If $x_k + d_k$ is interior but the Armijo condition (3) does not hold, we also do backtracking. Backtracking stops when the Armijo condition (6) is fulfilled. If (3) holds, we test the directional derivative condition (4). As we mentioned above, if (4) is satisfied too, we accept $x_k + d_k$ as new point. However, if (3) holds and (4) does not, we judge that, very likely, taking larger steps along the direction d_k will produce further decrease of the objective function. So, in this case we also do Extrapolation.

In the Extrapolation procedure we try successive projections of $x_k + \alpha d_k$ onto the box, with increasing values of α. If the entry point $x_k + \alpha d_k$ is interior but $x_k + N\alpha d_k$ is not, we make sure that the point $x_k + \alpha_{max} d_k$ will be tested first. The extrapolation finishes when decrease of the function is not obtained anymore or when the distance between two consecutive projected trial points is negligible.

The iteration of Algorithm 2.1 finishes at Step 5. If the corresponding iterate x_{k+1} is on the boundary of $\mathcal{B}$, the algorithm stops, having encountered a boundary point where the functional value decreased with respect to all previous ones. If x_{k+1} is in the interior of $\mathcal{B}$ the execution continues increasing the iteration number.

The flux-diagrams in Figures 1 and 2 help to understand the structure of the line-search procedure.

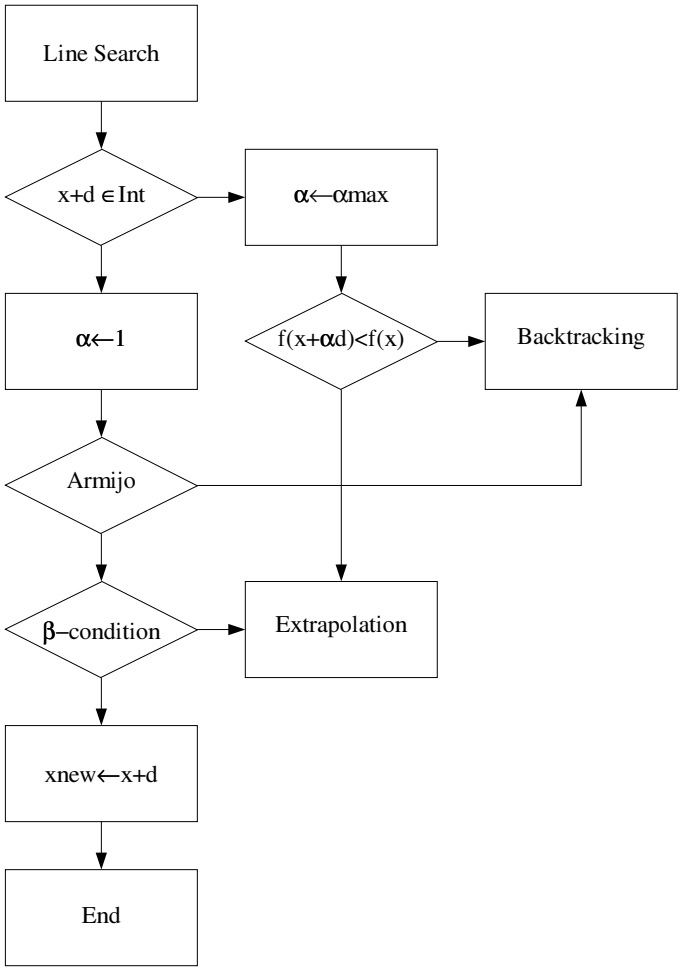

Figure 1: Line Search procedure.

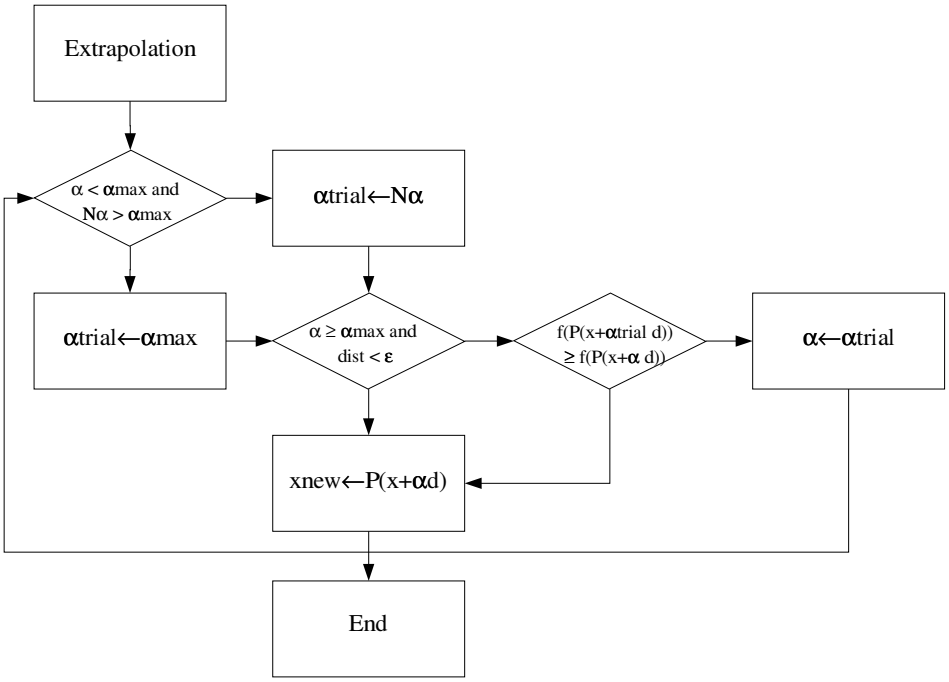

Figure 2: Extrapolation strategy.

In the following theorem we prove that any sequence generated by Algorithm 2.1, either stops at an unconstrained stationary point, or stops in the boundary of $\mathcal{B}$, or generates, in the limit, unconstrained stationary points.

Theorem 2.1. *Algorithm 2.1 is well defined and generates points with strictly decreasing functional values. If $\{x_k\}$ is a sequence generated by Algorithm 2.1, one of the following possibilities holds.*

(i) The sequence stops at x_k, with $g(x_k) = 0$.

(ii) The sequence stops at $x_k \in \mathcal{B} - Int(\mathcal{B})$ and $f(x_k) < f(x_{k-1}) < \ldots < f(x_0)$.

(iii) The sequence is infinite, it has at least one limit point, and every limit point x_* satisfies $g(x_*) = 0$.

Proof. Let us prove first that the algorithm is well defined and that it generates a sequence with strictly decreasing function values. To see that it is well defined we prove that the loops of Steps 3 and 4 necessarily finish in finite time. In fact, at Step 3 we multiply the nonnull direction d_k by a number greater than one, or we take the maximum allowable feasible step. Therefore, eventually, the boundary is reached or the increase condition (5) is met. The loop of Step 4 is a classical backtracking loop and finishes because of well-known directional derivative arguments. See [14]. On exit, the algorithm always requires that $f(x_k + \alpha_k d_k) < f(x_k)$, so the sequence $\{f(x_k)\}$ is strictly decreasing.

It remains to prove that, if neither (i) nor (ii) hold, then any cluster point x_* of the generated sequence satisfies $g(x_*) = 0$. Let K_1 be an infinite subset of $I\!N$ such that

$$\lim_{k \in K_1} x_k = x_*.$$

Define $s_k = x_{k+1} - x_k$ for all $k \in I\!N$. Suppose first that $\|s_k\|$ is bounded away from zero for $k \in K_1$. Therefore, there exists $\rho > 0$ such that $\|s_k\| \geq \rho$ for all $k \in K_1$. By (3) or (6) we have that

$$f(x_{k+1}) \leq f(x_k) + \gamma \langle g_k, s_k \rangle$$

for all $k \in K_1$. Therefore, by (2),

$$f(x_{k+1}) \leq f(x_k) - \gamma\theta \|g_k\| \|s_k\| \leq f(x_k) - \gamma\theta\rho \|g_k\|.$$

By the continuity of f this implies that $\lim_{k\in K_1} \|g_k\| = 0$ and, so, $g(x_*) = 0$.

Suppose now that $\|s_k\|$ is not bounded away from zero for $k \in K_1$. So, there exists K_2, an infinite subset of K_1, such that $\lim_{k\in K_2} \|s_k\| = 0$. Let $K_3 \subset K_2$ be the set of indices such that α_k is computed at Step 2.2 for all $k \in K_3$. Analogously, let $K_4 \subset K_2$ be the set of indices such that α_k is computed at Step 3 for all $k \in K_4$ and let $K_5 \subset K_2$ be the set of indices such that α_k is computed at Step 4 for all $k \in K_5$. We consider three possibilities:

(i) K_3 is infinite.

(ii) K_4 is infinite.

(iii) K_5 is infinite.

Consider, first, the case (i). By (4) we have that

$$\langle g(x_k + s_k), s_k\rangle \geq \beta\langle g_k, s_k\rangle$$

and

$$\langle g(x_k + s_k), \frac{s_k}{\|s_k\|}\rangle \geq \beta\langle g_k, \frac{s_k}{\|s_k\|}\rangle \tag{7}$$

for all $k \in K_3$. Since K_3 is infinite, taking an convergent subsequence $s_k/\|s_k\| \to d$, taking limits in (7) and using continuity, we obtain that

$$\langle g(x_*), d\rangle \geq \beta\langle g(x_*), d\rangle. \tag{8}$$

Since $\beta \in (0, 1)$, this implies that $\langle g(x_*), d\rangle \geq 0$. But, by (2) and continuity, $\langle g(x_*), d\rangle \leq -\theta\|g(x_*)\|$. So, $g(x_*) = 0$.

Consider, now, Case (iii). In this case, K_5 is infinite. For all $k \in K_5$ there exists s'_k such that

$$f(x_k + s'_k) \geq f(x_k) + \gamma\langle g_k, s'_k\rangle \tag{9}$$

and

$$\|s'_k\| \leq \|s_k\|/\sigma_1. \tag{10}$$

By (10), $\lim \|s'_k\| = 0$. Now, by (9), we have for all $k \in K_5$,

$$f(x_k + s'_k) - f(x_k) \geq \gamma\langle g_k, s'_k\rangle.$$

So, by the Mean-Value theorem, there exists $\xi_k \in [0,1]$ such that

$$\langle g(x_k + \xi_k s'_k), s'_k \rangle \geq \gamma \langle g_k, s'_k \rangle$$

for all $k \in K_5$. Dividing by $\|s'_k\|$, taking limits for a convergent subsequence $(s'_k/\|s'_k\| \to d)$ we obtain that

$$\langle g(x_*), d \rangle \geq \beta \langle g(x_*), d \rangle.$$

This inequality is similar to (8). So, $g(x_*) = 0$ follows from the same arguments.

Consider, now, Case (ii). Since we are considering cases where an infinite sequence is generated it turns out that, in (5), $P(x_k + \alpha d_k) = x_k + \alpha d_k$. Moreover, by Step 3.1, $\alpha_{trial} \leq N\alpha$ and $P(x_k + \alpha_{trial} d_k) = x_k + \alpha_{trial} d_k$. Therefore, for all $k \in K_4$, writing $\alpha'_k = \alpha_{trial}$, we have that $\alpha'_k \in (\alpha_k, N\alpha_k]$ and

$$f(x_k + \alpha'_k d_k) \geq f(x_k + \alpha_k d_k). \tag{11}$$

Therefore, by the Mean-Value theorem, for all $k \in K_4$ there exists $\xi_k \in [\alpha_k, \alpha'_k]$ such that

$$\langle g(x_k + \xi_k d_k), (\alpha'_k - \alpha_k) d_k \rangle \geq 0.$$

Thus, for all $k \in K_4$, since $\alpha'_k > \alpha_k$, we have that

$$\langle g(x_k + \xi_k d_k), d_k \rangle \geq 0.$$

Since $\|\alpha_k d_k\| \to 0$ we also have that $\|\alpha'_k d_k\| \to 0$ and $\|\xi_k d_k\| \to 0$. So, dividing by $\|d_k\|$ and taking a convergent subsequence of $d_k/\|d_k\|$, we obtain:

$$\langle g(x_*), d \rangle \geq 0.$$

But, by (2), taking limits we get $\langle g(x_*), d \rangle \leq -\theta \|g(x_*)\|$. This implies that $-\theta \|g(x_*)\| \geq 0$. So, $g(x_*) = 0$. This completes the proof. □

3 The box-constrained algorithm

The problem considered in this section is

$$\text{Minimize } f(x) \text{ subject to } x \in \Omega, \tag{12}$$

where Ω is given by (1).

As in [23], let us divide the feasible set Ω into disjoint open faces, as follows. For all $I \subset \{1, 2, \ldots, n, n+1, n+2, \ldots, 2n\}$, we define

$$F_I = \{x \in \Omega \mid x_i = \ell_i \text{ if } i \in I,\ x_i = u_i \text{ if } n+i \in I,\ \ell_i < x_i < u_i \ \text{ otherwise}\}.$$

We also define V_I the smallest affine subspace that contains F_I and S_I the parallel linear subspace to V_I. The (continuous) projected gradient at $x \in \Omega$ is defined as

$$g_P(x) = P_\Omega(x - g(x)) - x.$$

For all $x \in F_I$, we define

$$g_I(x) = P_{S_I}[g_P(x)].$$

The main algorithm considered in this paper is described below.

Algorithm 3.1: GENCAN

Assume that $x_0 \in \Omega$ is an arbitrary initial point, $\eta \in (0, 1)$ and $0 < \sigma_{min} \leq \sigma_{max} < \infty$. Let F_I be the face that contains the current iterate x_k. Assume that $g_P(x_k) \neq 0$ (otherwise the algorithm terminates). At the main iteration of the algorithm we perform the test

$$\|g_I(x_k)\| \geq \eta \|g_P(x_k)\|. \tag{13}$$

If (13) takes place, we judge that it is convenient that the new iterate belongs to $\bar{F}_I$ (the closure of F_I) and, so, we compute x_{k+1} doing one iteration of Algorithm 2.1, with the set of variables restricted to the free variables in F_I. So, the set $\mathcal{B}$ of the previous section corresponds to $\bar{F}_I$ here.

If (13) does not hold, we decide that some constraints should be abandoned and, so, the new iterate x_{k+1} is computed doing one iteration of the SPG method described by Algorithm 3.2. In this case, before the computation of x_{k+1} we compute the spectral gradient coefficient σ_k in the following way. If $k = 0$ or $\langle (x_k - x_{k-1}), (g(x_k) - g(x_{k-1}) \rangle \leq 0$ then

$$\sigma_k = \max\{1, \|x_k\| / \|g_P(x_k)\|\}.$$

Otherwise, define

$$\sigma'_k = \frac{\langle (x_k - x_{k-1}), (g(x_k) - g(x_{k-1})) \rangle}{\|x_k - x_{k-1}\|^2}$$

and

$$\sigma_k = \min\{\sigma_{\max}, \max\{\sigma_{\min}, \sigma'_k\}\}.$$

Algorithm 3.2 is the algorithm used when it is necessary to leave the current face, according to the test (13).

Algorithm 3.2: SPG

Compute x_{k+1} as the next iterate of a monotone SPG iteration [7, 8] with the spectral step σ_k. Namely, we define the search direction d_k as

$$d_k = P_\Omega(x_k - \sigma_k g(x_k)) - x_k$$

and we compute $x_{k+1} = x_k + \alpha_k d_k$ in such a way that

$$f(x_{k+1}) \leq f(x_k) + \gamma \alpha_k \langle g(x_k), d_k \rangle,$$

trying first $\alpha_k = 1$ and, perhaps, reducing this coefficient by means of a safeguarded quadratic interpolation procedure.

Remark. Observe that $x_{k+1} \notin \bar{F}_I$ if $x_k \in F_I$ and x_{k+1} is computed by Algorithm 3.2. In this case, (13) does not hold, so $\|g_P(x_k)\| > \|g_I(x_k)\|$. Since the components corresponding to the free variables of $g_I(x_k)$ and $g_P(x_k)$ are the same, this means that $g_P(x_k)$ has nonnull components corresponding to fixed variables. Therefore, $x_k + \alpha g_P(x_k) \notin \bar{F}_I$ for all $\alpha > 0$. So, $P_\Omega(x_k + \alpha g_P(x_k)) \notin \bar{F}_I$ for all $\alpha > 0$. But, according to the SPG iteration,

$$x_{k+1} = x_k + \alpha'[P_\Omega(x_k + \alpha g_P(x_k)) - x_k]$$

for some $\alpha > 0$, $\alpha' > 0$. This implies that $x_{k+1} \notin \bar{F}_I$.

We finish this section giving some theoretical results. Roughly speaking, we prove that the algorithm is well defined and that a Karush-Kuhn-Tucker

point is computed up to an arbitrary precision. Moreover, under dual-nondegeneracy, the (infinite) algorithm identifies the face to which the limit belongs in a finite number of iterations.

Theorem 3.1. *Algorithm 3.1 is well defined.*

Proof. This is a trivial consequence of the fact that Algorithm 2.1 and Algorithm 3.2 (the SPG algorithm [7]) are well defined. □

Theorem 3.2. *Assume that $\{x_k\}$ is generated by Algorithm 3.1. Suppose that there exists $\bar{k} \in \{0, 1, 2, \ldots\}$ such that $x_k \in F_I$ for all $k \geq \bar{k}$. Then, every limit point of $\{x_k\}$ is first-order stationary.*

Proof. In this case, x_{k+1} is computed by Algorithm 2.1 for all $k \geq \bar{k}$. Thus, by Theorem 2.1, the gradient with respect to the free variables tends to zero. By a straightforward projection argument, it follows that $\|g_I(x_k)\| \to 0$. Since (13) holds, this implies that $\|g_P(x_k)\| \to 0$. So, every limit point is first-order stationary. □

Theorem 3.3. *Suppose that for all $k \in \{0, 1, 2, \ldots\}$, $x_k \in F_I$, there exists $k' > k$ such that $x_{k'} \notin F_I$. Then, there exists a limit point of $\{x_k\}$ that is first-order stationary.*

Proof. See Theorem 3.3 of [6]. □

Theorem 3.4. *Suppose that all the stationary points of (12) are nondegenerate. ($\frac{\partial f}{\partial x_i}(x) = 0$ only if $\ell_i < x_i < u_i$.) Then, the hypothesis of Theorem 3.2 (and, hence, its thesis) must hold.*

Proof. See Theorem 3.4 of [6]. □

Theorem 3.5. *Suppose that $\{x_k\}$ is a sequence generated by Algorithm 3.1 and let ε be an arbitrary positive number. Then, there exists $k \in \{0, 1, 2, \ldots\}$ such that $\|g_P(x_k)\| \leq \varepsilon$.*

Proof. This result is a direct consequence of Theorems 3.2 and 3.3. □

4 Implementation

At iteration k of Algorithm 2.1 the current iterate is x_k and we are looking for a direction d_k satisfying condition (2). We use a truncated-Newton approach to compute this direction. To solve the Newtonian system we call Algorithm 4.1 (described below) with $A \approx \nabla^2 f(x_k)$, $b = g(x_k)$, $\bar{l} = l - x_k$, $\bar{u} = u - x_k$, and $\Delta = \max(\Delta_{\min}, 10\|x_k - x_{k-1}\|)$ ($\Delta = \max(\Delta_{\min}, 0.1\|x_0\|)$, if $k = 0$).

The following algorithm applies to the problem

$$\min q(s) = \frac{1}{2} s^T A s + b^T s. \tag{14}$$

The initial approximation to the solution of (14) is $s_0 = 0$. The algorithm finds a point s^* which is a solution or satisfies $q(s^*) < q(s_0)$. Perhaps, the final point is on the boundary of the region defined by $\|s\| \leq \Delta$ and $\bar{l} \leq s \leq \bar{u}$.

Algorithm 4.1: Conjugate gradients

The parameters $\bar{\epsilon} << 1$ and $k_{\max} \in I\!N$ are given. The algorithm starts with $k \leftarrow 0$, s_0 given, $r_0 = As_0 - b$ and $\rho_0 = \|r_0\|^2$.

Step 1. *Test stopping criteria*

If ($\sqrt{\rho_k} \leq \bar{\epsilon}\|b\|$ or $k \geq k_{\max}$) then
set $s^* = s_k$ and terminate.

Step 2. *Compute conjugate gradient direction*

Step 2.1 If ($k = 0$) then set $p_k = -r_k$
else compute $\beta_k = \rho_k / \rho_{k-1}$ and $p_k = -r_k + \beta_k p_{k-1}$.

Step 2.2 If ($p_k^T r_k > 0$), replace $p_k \leftarrow -p_k$.

Step 3. *Compute step*

Step 3.1 Compute $\alpha_{\max} \leftarrow \max\{\alpha \geq 0 \mid s_k + \alpha p_k \in S\}$, where
$S = \{x \in I\!R^{\bar{n}} \mid \|x\| \leq \Delta \text{ and } \bar{l} \leq x \leq \bar{u}\}$.

Step 3.2 Compute $w_k = Ap_k$ and $\gamma_k = p_k^T w_k$.

Step 3.3 If ($\gamma_k > 0$) then set $\alpha_k = \min(\alpha_{\max}, \rho_k / \gamma_k)$.
If ($\gamma_k \leq 0$ and $k = 0$) then set $\alpha_k = \alpha_{\max}$.

If ($\gamma_k \leq 0$ and $k > 0$) then set $\alpha_k = 0$, $s^* = s_k$ and terminate.

Step 4. *Compute new iterate*

Step 4.1 Compute $s_{k+1} = s_k + \alpha_k p_k$.

Step 4.2 If ($b^T s_{k+1} > -\theta \|b\| \|s_{k+1}\|$) then
set $s^* = s_k$ and terminate.

Step 4.3 If ($\alpha_k = \alpha_{\max}$) then
set $s^* = s_{k+1}$ and terminate.

Step 5. Compute $r_{k+1} = r_k + \alpha_k w$, $\rho_{k+1} = \|r_{k+1}\|^2$,
set $k \leftarrow k + 1$ and go to Step 1.

This algorithm is a modification of the one presented in [27] (p. 529) for symmetric positive definite matrices A and without constraints. The modifications are the following:

- At Step 2.2 we test if p_k is a descent direction at s_k, i.e., if $\langle p_k, \nabla q(s_k) \rangle < 0$. To force this condition we multiply p_k by -1 if necessary. If the matrix-vector products are computed exactly, this safeguard is not necessary. However, in many cases the matrix-vector product Ap_k is replaced by a finite-difference approximation. For this reason, we perform the test in order to guarantee that the quadratic decreases along the direction p_k.

- At Step 3.3 we test if $p_k^T A p_k > 0$. If this inequality holds, the step α_k in the direction p_k is computed as the minimum among the conjugate-gradient step and the maximum positive step preserving feasibility. If $p_k^T A p_k \leq 0$ and we are at the first iteration of CG, we set $\alpha_k \leftarrow \alpha_{\max}$. In this way CG will stop with $s^* = -\alpha_{\max} g(x_k)$ which surely satisfies the angle condition of Step 4.2. If we are not at iteration zero of CG, we keep the current approximation to the solution of (14) obtained so far.

- At Step 4.2 we test whether the angle condition (2) is satisfied by the new iterate or not. If this condition is not fulfilled, we stop the algorithm with the previous iterate. We also stop the algorithm if the boundary of the feasible set is achieved (Step 4.3).

The convergence criterion $\bar{\epsilon}$ for the conjugate-gradient algorithm is dynamic. It varies linearly with the logarithm of the norm of the continuous projected gradient, beginning with the value $\bar{\epsilon}_i$ and finishing with $\bar{\epsilon}_f$. We define

$$\bar{\epsilon} = \sqrt{10^{a_{\bar{\epsilon}} \log_{10}(\|g_P(x_k)\|_2^2) + b_{\bar{\epsilon}}}},$$

where

$$a_{\bar{\epsilon}} = \frac{\log_{10}(\bar{\epsilon}_f^2/\bar{\epsilon}_i^2)}{\log_{10}(\epsilon^2/\|g_P(x_0)\|_2^2)},$$

$$b_{\bar{\epsilon}} = \log_{10}(\bar{\epsilon}_i^2) - a_{\bar{\epsilon}} \log_{10}(\|g_P(x_0)\|_2^2),$$

and ϵ is used in the stopping criterion $\|g_P(x)\|_\infty < \epsilon$ of Algorithm 3.1.

The parameter k_{max} is the maximum number of CG-iterations for each call of the conjugate-gradient algorithm. It also varies dynamically in such a way that more iterations are allowed at the end of the process than at the beginning. The reason is that we want to invest a larger effort in solving quadratic subproblems when we are close to the solution than when we are far from it. In fact,

$$k_{\max} = (1-\kappa)\max(1, 10\log_{10}(\bar{n})) + \kappa\bar{n},$$

where

$$\kappa = \min(0, \frac{\log_{10}(\|g_P(x_k)\|_2^2/\|g_P(x_0)\|_2^2)}{\log_{10}(\epsilon/\|g_P(x_0)\|_2^2)}).$$

In the Incremental-quotient version of GENCAN, $\nabla^2 f(x_k)$ is not computed and the matrix-vector products $\nabla^2 f(x_k)y$ are approximated by

$$\nabla^2 f(x_k)y \approx \frac{g(x_k + ty) - g(x_k)}{t} \tag{15}$$

with $t = \max(\epsilon_{abs}, \epsilon_{rel}\|x_k\|_\infty)/\|y\|_\infty$. In fact, only the components correspondent to free variables are computed and the existence of fixed variables is conveniently exploited in (15).

5 Numerical experiments with the CUTE collection

In order to assess the reliability GENCAN, we tested this method against some well-known alternative algorithms using all the non-quadratic bound-

constrained problems with more than 50 variables from the CUTE [12] collection. The algorithms that we used for comparing GENCAN are BOX-QUACAN [26] (see, also, [28]), LANCELOT [11, 12] and the Spectral Projected Gradient method (SPG) (described as SPG2 in [7]; see also [8]). All the methods used the convergence criterion $\|g_P(x)\|_\infty < 10^{-5}$. Any other stopping criteria were inhibited.

In GENCAN we used $\theta = 10^{-6}$, $\gamma = 10^{-4}$, $\beta = 0.5$, $N = 2$, $\sigma_1 = 0.1$, $\sigma_2 = 0.9$ and $\Delta_{\min} = 0.1$ (for Algorithm 2.1), $\eta = 0.1$, $\sigma_{min} = 10^{-10}$, $\sigma_{max} = 10^{10}$ and $\epsilon = 10^{-5}$ (for Algorithm 3.1), and $\bar{\epsilon}_i = 0.1$, $\bar{\epsilon}_f = 10^{-5}$ (for Algorithm 4.1). In all algorithms we used $\epsilon_{rel} = 10^{-7}$ and $\epsilon_{abs} = 10^{-10}$. The parameters of (the line search of) Algorithm 3.2 were the default parameters mentioned in [7] and the same used in (the line search of) Algorithm 2.1, i.e., $\gamma = 10^{-4}$, $\sigma_1 = 0.1$ and $\sigma_2 = 0.9$.

In LANCELOT we used exact second derivatives and we did not use preconditioning in the conjugate-gradient method. The reason for this is that, in GENCAN, the conjugate gradient method for computing directions is also used without preconditioning. The other options of LANCELOT were the default ones. A small number of modifications were made in BOX-QUACAN to provide a fair comparison. These modifications were: (i) the initial trust-region radius of GENCAN was adopted; (ii) the maximum number of conjugate-gradient iterations was fixed in $10 \log_{10}(n)$; (iii) the accuracy for solving the quadratic subproblems was dynamic in BOX-QUACAN varying from 0.1 to 10^{-5}, as done in GENCAN, (iv) the minimum trust-region radius Δ_{min} was fixed in 10^{-3} to be equal to the corresponding parameter in GENCAN.

The codes are written in Fortran 77. The tests were done using an ultra-SPARC from SUN, with 4 processors at 167 MHz, 1280 mega bytes of main memory, and Solaris 2.5.1 operating system. The compiler was `WorkShop Compilers 4.2 30 Oct 1996 FORTRAN 77 4.2`. Finally we have used the flag `-O4` to optimize the code.

In the first four tables we report the full performance of LANCELOT, SPG, BOX-QUACAN, GENCAN (true Hessian) and GENCAN (Incremental-quotients). The usual definition of iteration in LANCELOT involves only one function evaluation. However, in order to unify the comparison we call "iteration" to the whole process that computes a new iterate with lower func-

tional value, starting from the current one. Therefore, a single LANCELOT-iteration involves one gradient evaluation but, perhaps, several functional evaluations. At each iteration several trust-region problems are solved approximately and each of them uses a number of CG-iterations. Problems HADAMALS and SCON1LS have bounds where the lower limit is equal to the upper limit. BOX-QUACAN does not run under this circumstances, so the performance of this method in that situation is not reported in the corresponding table. In these tables, we report, for each method:

IT: Number of iterations;

FE: Functional evaluations;

GE: Gradient evaluations;

CG: Conjugate gradient iterations, except in the case of SPG, where CG iterations are not computed;

Time: CPU time in seconds;

$f(x)$**:** final functional value obtained;

$\|g_P(x)\|_\infty$**:** Sup-norm of the projected gradient at the final point.

The next 3 tables repeat the information of the first ones in a more compact and readable form. In Table 5 we report the final functional value obtained for each method, in the cases where there was at least one difference between them, when computed with four significant digits.

In Table 7 we report, for each method, the numbers FE and (GE+CG). The idea is that a CG iteration is sometimes as costly as a gradient-evaluation. The cost is certainly the same when we use the incremental-quotient version of GENCAN. Roughly speaking, GE+CG represents the amount of work used for solving subproblems and FE represents the work done on the true problem trying to reduce the objective function.

Table 8 reports the computer times for the problems where at least one of the methods used more than 1 second. The computer time used by LANCELOT must be considered under the warning made in [9] page 136, *"LANCELOT [...] does not require an interface using the CUTE tools. It is worth noting that LANCELOT exploits much more structure than that*

provided by the interface tools". As a consequence, although GENCAN used less iterations, less functional evaluations, less gradient evaluations and less conjugate-gradient iterations than LANCELOT in SCON1LS, its computer time is greater than the one spent by LANCELOT. In some problems, like QR3DLS and CHEBYQAD, the way in which LANCELOT takes advantage of the SIF structure is also impressive.

Now we include an additional table that was motivated by the observation of Table 7. It can be observed that the number of functional evaluations per iteration is larger in GENCAN than in LANCELOT and BOX-QUACAN. The possible reasons are three:

- Many SPG-iterations with, perhaps, many functional evaluations per iteration.
- Many TN-iterations with backtracking.
- Many TN-iterations with extrapolations.

We classify the iterations with extrapolation in successful and unsuccessful ones. A successful extrapolation is an iteration where the extrapolation produced a functional value smaller than the one corresponding to the first

trial point. An unsuccessful extrapolation corresponds to a failure in the first attempt to "double" the steplength. Therefore, in an unsuccessful extrapolation, an additional "unnecessary" functional evaluation is done and the "next iterate" corresponds to the first trial point. According to this, we report, in Table 9, the following features of GENCAN (incremental-quotient version):

- SPG-IT: SPG iterations, used for leaving the current face.
- SPG-FE: functional evaluations in SPG-iterations.
- TN-IT: TN iterations.
- TN-FE: functional evaluations in TN-iterations.
- TN-(Step 1)-IT: TN-iterations where the unitary step was accepted.
- TN-(Step 1)-FE: functional evaluations in TN-iterations where the unitary step was accepted. This is necessarily equal to TN-(Step 1)-IT.
- TN-(Backtracking)-IT: TN-iterations where backtracking was necessary.

Table 9: GENCAN features.

Observing Table 9 we realise that:

1. The number of SPG-iterations is surprisingly small. Therefore, only in few iterations the mechanism to "leave the face" is activated. So, in most iterations, the number of active constraints remains the same or is increased. Clearly, SPG-iterations are not responsible for the relatively high number of functional evaluations.

2. The number of iterations where backtracking was necessary is, also, surprisingly small. Therefore, extrapolations are responsible for the functional-evaluations phenomenon. Since an unsuccessful extrapolation uses only one additional (unnecessary) functional evaluations, its contribution to increasing FE is also moderate. In fact, unsuccessful extrapolations are responsible for 116 functional evaluations considering all the problems, this means less than 8 evaluations per problem. It turns out that many functional evaluations are used in successful extrapolations. Considering the overall performance of the method this seems to be a really good feature. An extreme case is BDEXP, where only one TN-iteration was performed, giving a successful extrapolation that used 11 functional evaluations and gave the solution of the problem.

Further remarks

Convergence was obtained for all the problems with all the methods tested, with the exception of SPG that did not solve SCON1LS after more than thirty hours of computer time. The method that, in most cases, obtained the lowest functional values was GENCAN-QUOT, but the differences do not seem to be large enough to reveal a clear tendency.

As was already mentioned in [7], the behavior of SPG is surprisingly good. Although it is the only method that fails to solve a problem in reasonable time, its behavior in the problems where it works is quite efficient. This indicates the existence of families of problems where SPG is, probably, the best possible alternative. This observation has already been made in [8].

BOX-QUACAN has been the less successful method in this set of experiments. This is not surprising, since the authors of [16] had observed that this method outperformed LANCELOT in quadratic problems but is

not so good when the function is far from being quadratic. In fact, it was this observation what motivated the present work. Nevertheless, there is still a large scope for improvements of BOX-QUACAN, as far as we take into account that improvements in the solution of quadratic subproblems are possible and that sophisticated strategies for updating trust-region radius can be incorporated.

6 Experiments with very large problems

We wish to place q circles of radius r in the rectangle $[0, d_1] \times [0, d_2]$ in such a way that for all $i = 1, \dots q$ and for all $j \in I_i \subset \{1, \dots, q\}$, the intersection between the circle i and the circle j is at most one point. Therefore, given $I_i \subset \{1, \dots, q\}$, $i = 1, \dots, q$, the goal is to determine $c^1, \dots, c^q \in [r, d_1 - r] \times [r, d_2 - r]$ solving the problem:

$$\text{Minimize } \sum_{i=1}^{q} \sum_{j \in I_i} \max(0, 2r - \|c^i - c^j\|_2^2)^2$$

subject to

$$r \leq c_1^i \leq d_1 - r, \text{ and}$$

$$r \leq c_2^i \leq d_2 - r, \text{ for } i = 1, \dots, q.$$

The points $c^1, \dots, c^q$ are the centers of the desired circles. If the objective function value at the solution of this minimization problem is zero, then the original problem is solved.

When $I_i = \{1, \dots, q\} - \{i\}$ for all $i = 1, \dots, q$ the problem above is known as the Cylinder Packing problem [22]. The present generalization is directed to Sociometry applications.

Table 10 describes the main features of some medium and large scale problems of this type. In the problems 9-15 the sets I_i were randomly generated with the Schrage's random number generator [35] and seed = 1. In all cases we used $r = 0.5$. Observe that n, the number of variables, is equal to 2 q.

Tables 11 and 12 show the performances of GENCAN and LANCELOT. Internal limitations of the big-problems installation of CUTE forbid the solution of larger instances of this problems using SIF. We show the CPU

Problem	n	$\#I_i$	box

times of GENCAN both using SIF (SIF-Time) and Fortran subroutines (FS-Time) for computing function and gradient. We used a random initial point (generated inside the box with the Schrage's algorithm and seed equal to 1). Both methods found a global solution in all the cases. In Table 12 we also report the number of free variables at the solution so far found by GENCAN.

7 Final remarks

Numerical algorithms must be analyzed not only from the point of view of its present state but also from considerations related to their possibility of improvement. The chances of improvement of active-set methods like the one presented in this paper come from the development of new unconstrained algorithms and from the adaptation of known unconstrained algorithms to the specific characteristics of our problem. In our algorithm, the computation of the search direction is open to many possibilities. As we mentioned in the introduction, a secant multipoint scheme (with a different procedure for leaving the faces) was considered in [10] and a negative-curvature Newtonian direction for small problems was used in [6], where leaving faces is also associated to SPG. A particularly interesting alternative is the preconditioned spectral projected gradient method introduced in [30].

The extension of the technique of this paper to general linearly constrained optimization is another interesting subject of possible research. From the theoretical point of view, the extension is straightforward, and the convergence proofs do not offer technical difficulties. The only real difficulty is that we need to project onto the feasible set, both in the extrapolation steps and in the SPG iterations. In theory, extrapolation can be avoided without affecting global convergence, but projections are essential in SPG iterations. Sometimes, the feasible polytope is such that projections are easy to compute. See [8]. In those cases, the extension of GENCAN would probably be quite efficient.

Acknowledgements.

The authors are very grateful to Nick Gould, who helped them in the use of the SIF language. We are also indebted to two anonymous referees whose comments helped us a lot to improve the final version of the paper.
