Limiting distribution of the rightmost particle in catalytic branching Brownian motion*

Sergey Bocharov[†] Simon C. Harris[‡]

Abstract

We study the model of binary branching Brownian motion with spatially-inhomogeneous branching rate $\beta\delta_0(\cdot)$, where $\delta_0(\cdot)$ is the Dirac delta function and β is some positive constant. We show that the distribution of the rightmost particle centred about $\frac{\beta}{2}t$ converges to a mixture of Gumbel distributions according to a martingale limit. Our results form a natural extension to S. Lalley and T. Sellke [10] for the degenerate case of catalytic branching.

Keywords: Brownian motion; local time; catalytic branching.

1 Introduction and main results

1.1 Model

In this article we consider the model of branching Brownian motion with binary splitting and spatially inhomogeneous branching rate $\beta\delta_0(\cdot)$, where $\delta_0(\cdot)$ is the Dirac delta function and $\beta > 0$ is some constant.

In such a model we start with a single particle whose path $(X_t)_{t \geq 0}$ is distributed like a standard Brownian motion. Then, at a random time T (the branching time) satisfying

$$\mathbb{P}(T > t \mid (X_s)_{s \geq 0}) = e^{-\beta L_t},$$

where $(L_t)_{t \geq 0}$ is the local time at 0 of $(X_t)_{t \geq 0}$, the initial particle dies and is replaced with two new particles, which independently repeat the behaviour of their parent (that is, they move as Brownian motions until their split times when new particles emerge, etc.)

Informally, we can write $L_t = \int_0^t \delta_0(X_s) ds$ thus justifying calling the branching rate $\beta\delta_0(\cdot)$. Also, the branching in this model can only take place at the origin since $(L_t)_{t \geq 0}$ only grows on the zero set of $(X_t)_{t \geq 0}$ and stays constant elsewhere.

This model was first introduced by D.A. Dawson and K. Fleischmann in [3] and has been mostly studied in the context of superprocesses. See for example papers of K. Fleischmann and J-F. Le Gall [5] or J. Engländer and D. Turaev [4].

1.2 Main result

Before we state the main result of this article (Theorem 1.1) let us define the notation and recall some of the existing results for this catalytic model in [1].

Let us denote by P the probability measure associated to the branching process with E the corresponding expectation. We denote the set of all the particles in the system at time t by N_t . For every particle $u \in N_t$ we denote by X_t^u its spatial position at time t . Finally, we define

$$R_t := \sup_{u \in N_t} X_t^u, \quad t \geq 0$$

to be the rightmost particle.

Previously in [1] we have shown that

$$\frac{R_t}{t} \rightarrow \frac{\beta}{2} \quad \text{as } t \rightarrow \infty, \quad P\text{-a.s.} \tag{1.1}$$

In particular, we have shown that the particle that has maximal position at time t would have typically stayed near the origin up until time $\frac{t}{2}$ by behaving like a Brownian motion with drift of magnitude β towards the origin and then in the remaining time moved with positive drift of magnitude β to reach the critical level $\frac{\beta}{2}t$.

The aim of this paper is to prove that $R_t - \frac{\beta}{2}t$ converges in distribution to a non-trivial limit and to describe the limiting distribution.

Let us recall from [1] that the process

$$M_t := e^{-\frac{\beta^2}{2}t} \sum_{u \in N_t} e^{-\beta|X_t^u|}, \quad t \geq 0$$

is a P -martingale of mean 1 that converges almost surely to a strictly positive limit, which we denote by M_∞ .

We are now in the position to state our main result.

Theorem 1.1. *For a branching process initiated from $x \in \mathbb{R}$ and any $y \in \mathbb{R}$ we have*

$$\lim_{t \rightarrow \infty} P^x \left(R_t \leq \frac{\beta}{2}t + y \right) = E^x \exp \left\{ -e^{-\beta y} M_\infty \right\} \tag{1.2}$$

The limiting distribution is thus an average over a family of Gumbel distributions with scale parameter β^{-1} and random location $\beta^{-1} \log M_\infty$.

1.3 Comparison with other branching Brownian motion models

A similar formula for branching Brownian motion with spatially-homogeneous branching rate β was proved by S. Lalley and T. Sellke in [9]. Another similar formula for a general class of branching random walks in discrete time with spatially-homogeneous branching rate was recently obtained by M. Bramson, J. Ding and O. Zeitouni in [2]. However of particular relevance to our result is the following theorem due to Lalley and Sellke, which covers a certain class of spatially-inhomogeneous branching rates $\beta(x)$, not including the degenerate catalytic case $\beta\delta_0(x)$.

Theorem 1.2 (S. Lalley, T. Sellke, [10]). *Consider a binary branching Brownian motion with branching rate $\beta(x)$, where $\beta(\cdot)$ is a continuous function such that $\beta(x) \rightarrow 0$ as $|x| \rightarrow \infty$ and $\int_{-\infty}^{\infty} \beta(x)dx < \infty$. Let λ_0 be the largest positive eigenvalue of the differential operator $\mathcal{L} : g \mapsto \frac{1}{2}g'' + \beta g$ with the corresponding unique eigenfunction $\varphi_0(\cdot)$, normalised so that $\varphi_0(0) = 1$. Then*

$$\lim_{t \rightarrow \infty} P \left(R_t \leq \sqrt{\frac{\lambda_0}{2}}t + y \right) = E \exp \left\{ -Z_\infty \gamma e^{-\sqrt{2\lambda_0}y} \right\},$$

where Z_∞ is the a. s. limit of the martingale $Z_t = e^{-\lambda_0 t} \left(\int_{-\infty}^{\infty} \varphi_0(x)^2 dx \right)^{-1} \sum_{u \in N_t} \varphi_0(X_t^u)$, $t \geq 0$, $\gamma = \frac{1}{2\lambda_0} \int_{-\infty}^{\infty} e^{\sqrt{2\lambda_0 x}} \beta(x) \nu(dx)$ and $\nu(J) = \int_J \varphi_0(x) dx$.

The proof of Lalley and Sellke of Theorem 1.2 is based on stochastic comparison of the branching process with a Poisson tidal wave and involves a coupling argument. Rather than trying to adapt their proof to suit our model we take an alternative and more direct approach which can be summarised as follows.

In Section 2 we establish a formula for second moments of quantities of the form $\sum_{u \in N_t} f(X_t^u)$, which in itself is an interesting and useful result. We then use this formula to give a lower bound on $P(R_t > \frac{\beta}{2}t + y)$ via the Paley-Zygmund inequality. The corresponding upper bound trivially follows from the Markov inequality.

In Section 3, we can then show that if $|x_0(t)|$ is not too large and $z(t)$ goes to infinity not too fast, then

$$P^{x_0(t)} \left(R_t \leq \frac{\beta}{2}t + z(t) \right) \approx 1 - e^{-\beta|x_0(t)| - \beta z(t)} \tag{1.3}$$

for t large, this being made precise in Proposition 3.1. Heuristically, this follows since

$$P^0 \left(R_t > \frac{\beta}{2}t + z \right) \approx E^0 \left\{ \mathbf{1}_{\left\{ u \in N_t : X_t^u > \frac{\beta}{2}t + z \right\}} \right\} \sim e^{-\beta z}$$

when t and z are suitably large, and then, if T_0 is the time the initial particle hits the origin,

$$\begin{aligned} P^x \left(R_t > \frac{\beta}{2}t + z \right) &\approx E^x \left(\mathbf{1}_{\{T_0 \leq t\}} P^0 \left(R_{t-T_0} > \frac{\beta}{2}(t-T_0) + z + \frac{\beta}{2}T_0 \mid T_0 \right) \right) \\ &\sim E^x \left(\mathbf{1}_{\{T_0 \leq t\}} e^{-\beta(z + \frac{\beta}{2}T_0)} \right) \approx e^{-\beta z} E^x \left(e^{-\frac{\beta^2}{2}T_0} \right) = e^{-\beta z - \beta|x|}. \end{aligned}$$

We can then conclude the proof of the main result by carefully using (1.3) in the identity

$$P^x \left(R_t \leq \frac{\beta}{2}t + y \right) = E^x \left[\prod_{u \in N_s} P^{X_s^u} \left(R_{t-s} \leq \frac{\beta}{2}t + y \right) \right]$$

where, for s and t suitably large,

$$\begin{aligned} P^x \left(R_t \leq \frac{\beta}{2}t + y \right) &= E^x \left[\prod_{u \in N_s} P^{X_s^u} \left(R_{t-s} \leq \frac{\beta}{2}(t-s) + y + \frac{\beta}{2}s \right) \right] \\ &\approx E^x \left[\prod_{u \in N_s} \left(1 - e^{-\beta|X_s^u| - \beta(y + \frac{\beta}{2}s)} \right) \right] \\ &\approx E^x \left[\exp \left\{ - \sum_{u \in N(s)} e^{-\beta|X_s^u| - \beta(y + \frac{\beta}{2}s)} \right\} \right] \rightarrow E^x \exp \left\{ - e^{-\beta y} M_\infty \right\}. \end{aligned}$$

2 First and second moments computations

For $\lambda \in \mathbb{R}$ and $t \geq 0$ let us define

$$N_t^\lambda := \{u \in N_t : X_t^u \geq \lambda\}$$

to be the set of particles at time t which lie above level λ . In this section we are going to study the asymptotic properties of the first two moments of $|N_t^\lambda|$ for $\lambda = \frac{\beta}{2}t + y$.

2.1 ‘Many-to-One’ lemma and applications

Let us extend the branching process by introducing an infinite line of descent (a sequence of particles) which we call the spine and which is chosen uniformly at random

from all the possible lines of descent. More precisely, the spine starts with the initial particle of the branching process. It continues with one of the children of the initial particle chosen with probability $\frac{1}{2}$, then with one of the chosen child's child with probability $\frac{1}{2}$ and so on.

We let \tilde{P} be the extension of the probability measure P so that the branching process under \tilde{P} is defined together with the spine as described above. We denote the expectation associated to \tilde{P} by \tilde{E} . We also let ξ_t denote the position of the particle in the spine at time t . It is not hard to see that $(\xi_t)_{t \geq 0}$ is a Brownian Motion under \tilde{P} . We let $(\tilde{L}_t)_{t \geq 0}$ be the local time at 0 of $(\xi_t)_{t \geq 0}$.

Recall a special case of the 'Many-to-One' Lemma, as was used extensively in [1].

Lemma 2.1 ('Many-to-One' Lemma). *Suppose that $f(\cdot) : \mathbb{R} \rightarrow \mathbb{R}$ is a non-negative measurable function. Then*

$$E \sum_{u \in N_t} f(X_t^u) = \tilde{E} \left[f(\xi_t) e^{\beta \tilde{L}_t} \right].$$

Let us also recall a standard result (see e.g. [8]) that if $(X_t)_{t \geq 0}$ is a Brownian motion under \mathbb{P} and $(L_t)_{t \geq 0}$ is its local time at 0 then the joint density of X_t and L_t at any time $t > 0$ is

$$\mathbb{P}(X_t \in dx, L_t \in dl) = \frac{|x| + l}{\sqrt{2\pi t^3}} \exp \left\{ -\frac{(|x| + l)^2}{2t} \right\} dx dl, \quad x \in \mathbb{R}, l > 0. \tag{2.1}$$

Lemma 2.1 together with (2.1) yields the following simple formula for $E|N_t^\lambda|$.

Proposition 2.2. *For $\lambda > 0$*

$$E|N_t^\lambda| = \Phi\left(\beta\sqrt{t} - \frac{\lambda}{\sqrt{t}}\right) e^{-\frac{\beta^2}{2}t - \beta\lambda}, \tag{2.2}$$

where $\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-\frac{y^2}{2}} dy$ is the cumulative distribution function of a standard normal. In particular, for t sufficiently large so that $\frac{\beta}{2}t + y > 0$,

$$E|N_t^{\frac{\beta}{2}t+y}| = \Phi\left(\frac{\beta}{2}\sqrt{t} - \frac{y}{\sqrt{t}}\right) e^{-\beta y}. \tag{2.3}$$

Proof. Take $f(\cdot) = \mathbf{1}_{[\lambda, \infty)}(\cdot)$ in Lemma 2.1. Then

$$E|N_t^\lambda| = E \left[\sum_{u \in N_t} \mathbf{1}_{\{X_t^u \geq \lambda\}} \right] = \tilde{E} \left[\mathbf{1}_{\{\xi_t \geq \lambda\}} e^{\beta \tilde{L}_t} \right].$$

Substituting the joint density of ξ_t and \tilde{L}_t from (2.1) gives

$$\begin{aligned} E|N_t^\lambda| &= \int_0^\infty \int_\lambda^\infty e^{\beta l} \frac{x+l}{\sqrt{2\pi t^3}} \exp \left\{ -\frac{(x+l)^2}{2t} \right\} dx dl \\ &= \int_0^\infty e^{\beta l} \frac{1}{\sqrt{2\pi t}} \exp \left\{ -\frac{(\lambda+l)^2}{2t} \right\} dl \\ &= \int_0^\infty \frac{1}{\sqrt{2\pi t}} \exp \left\{ -\frac{1}{2t} (l - (\beta t - \lambda))^2 + \frac{\beta^2}{2}t - \beta\lambda \right\} dl \\ &= e^{\frac{\beta^2}{2}t - \beta\lambda} \int_{-(\beta\sqrt{t} - \frac{\lambda}{\sqrt{t}})}^\infty \frac{1}{\sqrt{2\pi}} e^{-\frac{z^2}{2}} dz \\ &= \Phi\left(\beta\sqrt{t} - \frac{\lambda}{\sqrt{t}}\right) e^{-\frac{\beta^2}{2}t - \beta\lambda}. \quad \square \end{aligned}$$

It follows from (2.3) that for any $y \in \mathbb{R}$ and $t > -\frac{2y}{\beta}$

$$E|N_t^{\frac{\beta}{2}t+y}| \leq e^{-\beta y} \tag{2.4}$$

and for a fixed $y \in \mathbb{R}$

$$E|N_t^{\frac{\beta}{2}t+y}| \rightarrow e^{-\beta y} \quad \text{as } t \rightarrow \infty. \tag{2.5}$$

2.2 ‘Many-to-Two’ lemma and applications

The second moment of $|N_t^\lambda|$ is harder to deal with. Recently Harris and Roberts [7] established a general ‘Many-to-Few’ lemma which allows computing k th moments of branching processes in a systematic way.

We shall first state the special case of this formula for binary catalytic branching in Lemma 2.3. Then we shall convert this formula into a more suitable form in Corollary 2.4 and then use this form to get a good estimate of $E[|N_t^\lambda|^2]$.

For this subsection we need to extend the branching process by introducing two independent spines. That is, we have two infinite lines of descent started from the initial particle of the branching process which then with probability $\frac{1}{2}$ independently of each other choose to follow one of the initial particle’s children and so on. We let \tilde{P}^2 be the extension of the probability measure P under which the branching process is defined with two independent spines.

Moreover, we want to define a new probability measure \tilde{Q}^2 so that under \tilde{Q}^2 the branching process with the two spines can be described as follows.

- We begin with a single particle moving as a Brownian motion and carrying two marks: 1 and 2.
- The particles in the system undergo binary fission and every time a particle branches every mark carried by that particle (there could be 0, 1 or 2 such marks) chooses to follow one of the children with probability $\frac{1}{2}$ independently of the other mark. Sequences of particles carrying marks 1 and 2 thus define two independent spines.
- The difference from \tilde{P}^2 is that under \tilde{Q}^2 particles carrying two marks will branch at rate $4\beta\delta_0(\cdot)$, particles carrying one mark will branch at rate $2\beta\delta_0(\cdot)$ and particles carrying no marks will branch at rate $\beta\delta_0(\cdot)$.

We let ξ_t^1 and ξ_t^2 be the positions of particles carrying marks 1 and 2 respectively so that $(\xi_t^1)_{t \geq 0}$ and $(\xi_t^2)_{t \geq 0}$ are two (correlated) Brownian motions. We let $(\tilde{L}_t^1)_{t \geq 0}$ and $(\tilde{L}_t^2)_{t \geq 0}$ be the corresponding local times. We also let T be the time when the two marks stop following the same particle (that is, the two spines separate from each other).

In such a setup we have the following special case of a result from [7]:

Lemma 2.3 (‘Many-to-Two’ Lemma). *Let $f(\cdot), g(\cdot) : \mathbb{R} \rightarrow \mathbb{R}$ be non-negative measurable functions. Then*

$$E \left[\left(\sum_{u \in N_t} f(X_t^u) \right) \left(\sum_{u \in N_t} g(X_t^u) \right) \right] = \tilde{Q}^2 \left(\mathbf{1}_{\{T > t\}} f(\xi_t^1) g(\xi_t^1) e^{3\beta \tilde{L}_t^1} \right) + \tilde{Q}^2 \left(\mathbf{1}_{\{T \leq t\}} f(\xi_t^1) g(\xi_t^2) e^{3\beta \tilde{L}_T^1} e^{\beta(\tilde{L}_t^1 - \tilde{L}_T^1)} e^{\beta(\tilde{L}_t^2 - \tilde{L}_T^2)} \right). \tag{2.6}$$

To make explicit calculations easier we simplify (2.6) in the following form:

Proposition 2.4. *Let $f(\cdot), g(\cdot) : \mathbb{R} \rightarrow \mathbb{R}$ be non-negative measurable functions and define*

$$S_f(t) := E \left(\sum_{u \in N_t} f(X_t^u) \right)$$

to be the first moment of $\sum_{u \in N_t} f(X_t^u)$. Then

$$E \left[\left(\sum_{u \in N_t} f(X_t^u) \right) \left(\sum_{u \in N_t} g(X_t^u) \right) \right] = S_{fg}(t) + 2 \int_0^t S_f(t-s) S_g(t-s) \frac{\partial}{\partial s} \left(2\Phi(\beta\sqrt{s}) e^{\frac{\beta^2}{2}s} \right) ds. \tag{2.7}$$

Proof of Proposition 2.4. Note that, from the definition of \tilde{Q}^2 ,

$$\tilde{Q}^2 \left(T > t \mid (\xi_s^1)_{s \geq 0} \right) = e^{-2\beta\tilde{L}_t^1}. \tag{2.8}$$

That is, the two spines will split apart at half of the branching rate $4\beta\delta(\cdot)$. Then the first term of (2.6) is just

$$\begin{aligned} \tilde{Q}^2 \left(\mathbf{1}_{\{T > t\}} f(\xi_t^1) g(\xi_t^1) e^{3\beta\tilde{L}_t^1} \right) &= \tilde{Q}^2 \left(\tilde{Q}^2 \left(\mathbf{1}_{\{T > t\}} f(\xi_t^1) g(\xi_t^1) e^{3\beta\tilde{L}_t^1} \mid (\xi_s^1)_{s \geq 0} \right) \right) \\ &= \tilde{Q}^2 \left(f(\xi_t^1) g(\xi_t^1) e^{3\beta\tilde{L}_t^1} e^{-2\beta\tilde{L}_t^1} \right) \\ &= S_{fg}(t) \end{aligned} \tag{2.9}$$

using Lemma 2.1 for the last equality. The second term is more complicated.

If we let $\hat{\xi}_t^{1,2} := \xi_{T+t}^{1,2} - \xi_T^{1,2}$, $t \geq 0$ and $\hat{L}_t^{1,2} := \tilde{L}_{T+t}^{1,2} - \tilde{L}_T^{1,2}$ then under \tilde{Q}^2 by the strong Markov property $(\hat{\xi}_t^{1,2})_{t \geq 0}$ are two independent Brownian motions, both independent of $(\xi_t^1)_{0 \leq t \leq T}$ with $(\hat{L}_t^{1,2})_{t \geq 0}$ their local times. Thus, noting that $\xi_T^{1,2} = 0$, the second term in (2.6) becomes

$$\begin{aligned} &\tilde{Q}^2 \left(\mathbf{1}_{\{T \leq t\}} f(\xi_t^1) g(\xi_t^2) e^{3\beta\tilde{L}_T^1} e^{\beta(\tilde{L}_t^1 - \tilde{L}_T^1)} e^{\beta(\tilde{L}_t^2 - \tilde{L}_T^2)} \right) \\ &= \tilde{Q}^2 \left(\mathbf{1}_{\{T \leq t\}} f(\hat{\xi}_{t-T}^1) g(\hat{\xi}_{t-T}^2) e^{3\beta\tilde{L}_T^1} e^{\beta\hat{L}_{t-T}^1} e^{\beta\hat{L}_{t-T}^2} \right) \\ &= \tilde{Q}^2 \left(\tilde{Q}^2 \left(\mathbf{1}_{\{T \leq t\}} f(\hat{\xi}_{t-T}^1) g(\hat{\xi}_{t-T}^2) e^{3\beta\tilde{L}_T^1} e^{\beta\hat{L}_{t-T}^1} e^{\beta\hat{L}_{t-T}^2} \mid T, (\xi_t^1)_{0 \leq t \leq T} \right) \right) \\ &= \tilde{Q}^2 \left(\mathbf{1}_{\{T \leq t\}} e^{3\beta\tilde{L}_T^1} S_f(t-T) S_g(t-T) \right) \end{aligned}$$

using Lemma 2.1 and independence of $(\hat{\xi}_t^1)_{t \geq 0}$ and $(\hat{\xi}_t^2)_{t \geq 0}$ of each other and of $(\xi_t^1)_{0 \leq t \leq T}$. Then

$$\begin{aligned} &\tilde{Q}^2 \left(\mathbf{1}_{\{T \leq t\}} e^{3\beta\tilde{L}_T^1} S_f(t-T) S_g(t-T) \right) \\ &= \tilde{Q}^2 \left(\tilde{Q}^2 \left(\mathbf{1}_{\{T \leq t\}} e^{3\beta\tilde{L}_T^1} S_f(t-T) S_g(t-T) \mid (\xi_s^1)_{s \geq 0} \right) \right) \\ &= \tilde{Q}^2 \left(\int_0^t e^{3\beta\tilde{L}_s^1} S_f(t-s) S_g(t-s) d(-e^{-2\beta\tilde{L}_s^1}) \right), \end{aligned}$$

where $d(-e^{-2\beta\tilde{L}_s^1})$ is the random probability measure induced by $\tilde{Q}^2(T \leq t \mid (\xi_s^1)_{s \geq 0}) = 1 - e^{-2\beta\tilde{L}_t^1}$ and we have used (2.8). Then noting that $d(-e^{-2\beta\tilde{L}_s^1}) = 2\beta e^{-2\beta\tilde{L}_s^1} d\tilde{L}_s^1$ (see e.g. [6], Chapter 0, Proposition 4.6) we get

$$\begin{aligned} &\tilde{Q}^2 \left(\int_0^t e^{3\beta\tilde{L}_s^1} S_f(t-s) S_g(t-s) d(-e^{-2\beta\tilde{L}_s^1}) \right) \\ &= \tilde{Q}^2 \left(\int_0^t e^{3\beta\tilde{L}_s^1} S_f(t-s) S_g(t-s) 2\beta e^{-2\beta\tilde{L}_s^1} d\tilde{L}_s^1 \right) \\ &= 2\tilde{Q}^2 \left(\int_0^t S_f(t-s) S_g(t-s) d(e^{\beta\tilde{L}_s^1}) \right). \end{aligned}$$

Finally, using integration-by-parts (see e.g. [6], Chapter 0, Proposition 4.5) and Fubini's theorem we get

$$\begin{aligned}
 & 2\tilde{Q}^2\left(\int_0^t S_f(t-s)S_g(t-s) d(e^{\beta\tilde{L}_s^1})\right) \\
 &= 2\tilde{Q}^2\left(f(0)g(0)e^{\beta\tilde{L}_t^1} - S_f(t)S_g(t) - \int_0^t \frac{\partial}{\partial s}(S_f(t-s)S_g(t-s)) e^{\beta\tilde{L}_s^1} ds\right) \\
 &= 2\left(f(0)g(0)\tilde{Q}^2(e^{\beta\tilde{L}_t^1}) - S_f(t)S_g(t) - \int_0^t \frac{\partial}{\partial s}(S_f(t-s)S_g(t-s)) \tilde{Q}^2(e^{\beta\tilde{L}_s^1}) ds\right) \\
 &= 2\int_0^t S_f(t-s)S_g(t-s) \frac{\partial}{\partial s}\left(\tilde{Q}^2(e^{\beta\tilde{L}_s^1})\right) ds \\
 &= 2\int_0^t S_f(t-s)S_g(t-s) \frac{\partial}{\partial s}\left(2\Phi(\beta\sqrt{s})e^{\frac{\beta^2}{2}s}\right) ds, \tag{2.10}
 \end{aligned}$$

which together with (2.9) gives the sought formula (2.7). □

As a simple application of (2.7) we get the following useful inequality.

Proposition 2.5. For all $y \in \mathbb{R}$, $t > -\frac{2y}{\beta}$

$$E\left[|N_t^{\frac{\beta}{2}t+y}|^2\right] \leq e^{-\beta y} + Ce^{-2\beta y}, \tag{2.11}$$

where $C > 0$ is some positive finite constant which doesn't depend on t or y .

Remark 2.6. One can also show that for a fixed $y \in \mathbb{R}$

$$\lim_{t \rightarrow \infty} E\left[|N_t^{\frac{\beta}{2}t+y}|^2\right] = e^{-\beta y} + 2(1 + \sqrt{2})e^{-2\beta y}, \tag{2.12}$$

but it's not so important for this paper.

Proof of Proposition 2.5. We substitute $f(\cdot) = g(\cdot) = \mathbf{1}_{[\frac{\beta}{2}t+y, \infty)}(\cdot)$ in (2.7) so that

$$E\left[|N_t^{\frac{\beta}{2}t+y}|^2\right] = E|N_t^{\frac{\beta}{2}t+y}| + 2\int_0^t \left[E|N_{t-s}^{\frac{\beta}{2}t+y}|\right]^2 \frac{\partial}{\partial s}\left(2\Phi(\beta\sqrt{s})e^{\frac{\beta^2}{2}s}\right) ds.$$

From (2.4) we know that for $t > -\frac{2y}{\beta}$ and $s \in [0, t]$ (so that also $t-s > -\frac{2}{\beta}(\frac{\beta}{2}s+y)$)

$$E|N_t^{\frac{\beta}{2}t+y}| \leq e^{-\beta y} \text{ and } E|N_{t-s}^{\frac{\beta}{2}t+y}| = E|N_{t-s}^{\frac{\beta}{2}(t-s)+\frac{\beta}{2}s+y}| \leq e^{-\beta(\frac{\beta}{2}s+y)}.$$

Thus, noting that $\frac{\partial}{\partial s}(2\Phi(\beta\sqrt{s})e^{\frac{\beta^2}{2}s}) > 0$ since $2\Phi(\beta\sqrt{s})e^{\frac{\beta^2}{2}s}$ is increasing in s , we get

$$\begin{aligned}
 E\left[|N_t^{\frac{\beta}{2}t+y}|^2\right] &\leq e^{-\beta y} + e^{-2\beta y} 2\int_0^t e^{-\beta^2 s} \frac{\partial}{\partial s}\left(2\Phi(\beta\sqrt{s})e^{\frac{\beta^2}{2}s}\right) ds \\
 &\leq e^{-\beta y} + Ce^{-2\beta y} \quad \forall t > -\frac{2y}{\beta},
 \end{aligned}$$

where $C = 2\int_0^\infty e^{-\beta^2 s} \frac{\partial}{\partial s}(2\Phi(\beta\sqrt{s})e^{\frac{\beta^2}{2}s}) ds < \infty$. □

Noting that $\{|N_t^{\frac{\beta}{2}t+y}| > 0\} = \{R_t > \frac{\beta}{2}t+y\}$ we establish the following simple corollary of Proposition 2.2 and Proposition 2.5.

Corollary 2.7. For all $y \in \mathbb{R}$, $t > -\frac{2y}{\beta}$

$$e^{-\beta y}(1 - Ce^{-\beta y})\Phi\left(\frac{\beta}{2}\sqrt{t} - \frac{y}{\sqrt{t}}\right)^2 < P\left(R_t > \frac{\beta}{2}t+y\right) < e^{-\beta y}.$$

So, in particular, $\liminf_{t \rightarrow \infty} P\left(R_t > \frac{\beta}{2}t + y\right), \limsup_{t \rightarrow \infty} P\left(R_t > \frac{\beta}{2}t + y\right) \sim e^{-\beta y}$ as $y \rightarrow \infty$.

Proof of Corollary 2.7. Paley-Zygmund and Markov inequality give

$$\frac{\left[E\left|N_t^{\frac{\beta}{2}t+y}\right|\right]^2}{E\left[\left|N_t^{\frac{\beta}{2}t+y}\right|^2\right]} \leq P\left(\left|N_t^{\frac{\beta}{2}t+y}\right| > 0\right) \leq E\left|N_t^{\frac{\beta}{2}t+y}\right|$$

Thus applying (2.3) and (2.11) to the lower bound and (2.4) to the upper bound gives us

$$\frac{\Phi\left(\frac{\beta}{2}\sqrt{t} - \frac{y}{\sqrt{t}}\right)^2 e^{-2\beta y}}{e^{-\beta y} + Ce^{-2\beta y}} \leq P\left(\left|N_t^{\frac{\beta}{2}t+y}\right| > 0\right) \leq e^{-\beta y}.$$

Then the lower bound satisfies

$$\begin{aligned} \frac{\Phi\left(\frac{\beta}{2}\sqrt{t} - \frac{y}{\sqrt{t}}\right)^2 e^{-2\beta y}}{e^{-\beta y} + Ce^{-2\beta y}} &= e^{-\beta y} \left(\frac{1}{1 + Ce^{-\beta y}}\right) \Phi\left(\frac{\beta}{2}\sqrt{t} - \frac{y}{\sqrt{t}}\right)^2 \\ &\geq e^{-\beta y} (1 - Ce^{-\beta y}) \Phi\left(\frac{\beta}{2}\sqrt{t} - \frac{y}{\sqrt{t}}\right)^2, \end{aligned}$$

which gives the desired inequality. □

3 Limiting distribution of the rightmost particle

This section contains the proof of Theorem 1.1. An important preliminary step of the proof is to establish the following consequence of Corollary 2.7.

Proposition 3.1. *Let $x_0(t)$ and $z(t)$ be such that $|x_0(t)| < \frac{1}{4\beta} \log t$ for t sufficiently large, $z(t) \rightarrow \infty$ and $z(t) = o(\log t)$ (that is, $\frac{z(t)}{\log t} \rightarrow 0$) as $t \rightarrow \infty$. Then for t sufficiently large*

$$1 - \theta_1(t)e^{-\beta|x_0(t)| - \beta z(t)} \leq P^{x_0(t)}\left(R_t \leq \frac{\beta}{2}t + z(t)\right) \leq 1 - \theta_2(t)e^{-\beta|x_0(t)| - \beta z(t)} \tag{3.1}$$

for some functions $\theta_1(\cdot), \theta_2(\cdot)$ such that $\theta_1(t), \theta_2(t) \rightarrow 1$ as $t \rightarrow \infty$.

Proof. Let T_0 be the first time the initial particle of the branching process (started from x_0) hits the origin. We fix $\alpha \in (0, \frac{1}{2})$ and write

$$\begin{aligned} P^{x_0(t)}\left(R_t \leq \frac{\beta}{2}t + z(t)\right) &= P^{x_0(t)}\left(R_t \leq \frac{\beta}{2}t + z(t), T_0 \leq \alpha t\right) \\ &\quad + P^{x_0(t)}\left(R_t \leq \frac{\beta}{2}t + z(t), T_0 > \alpha t\right) \end{aligned} \tag{3.2}$$

(the choice of α will become clear later in the proof). Then the first term of (3.2) can be written as

$$P^{x_0(t)}\left(R_t \leq \frac{\beta}{2}t + z(t), T_0 \leq \alpha t\right) = P^{x_0(t)}\left(\tilde{R}_{t-T_0} \leq \frac{\beta}{2}t + z(t), T_0 \leq \alpha t\right),$$

where $\tilde{R}_t := R_{t+T_0}, t \geq 0$ is the position of the rightmost particle of the subtree of the original branching process started from the origin at time T_0 . Then conditioning on T_0 and using the strong Markov property we get

$$\begin{aligned} P^{x_0(t)}\left(\tilde{R}_{t-T_0} \leq \frac{\beta}{2}t + z(t), T_0 \leq \alpha t\right) &= E^{x_0(t)}\left[E^{x_0(t)}\left(\mathbf{1}_{\{\tilde{R}_{t-T_0} \leq \frac{\beta}{2}t + z(t)\}} \mathbf{1}_{T_0 \leq \alpha t} \mid T_0\right)\right] \\ &= \int_0^{\alpha t} P\left(R_{t-s} \leq \frac{\beta}{2}t + z(t)\right) f_{T_0}(s) ds, \end{aligned} \tag{3.3}$$

where $f_{T_0}(s) = \frac{|x_0|}{\sqrt{2\pi s^3}} e^{-\frac{x_0^2}{2s}}$ is the probability density of T_0 .

Lower bound.

We first prove the lower bound of (3.1). From (3.2) and (3.3) we have

$$P^{x_0(t)}\left(R_t \leq \frac{\beta}{2}t + z(t)\right) \geq \int_0^{\alpha t} P\left(R_{t-s} \leq \frac{\beta}{2}t + z(t)\right) f_{T_0}(s) ds.$$

Then from Corollary 2.7 we know that for all t sufficiently large (so that $t + \frac{2}{\beta}z(t) > 0$)

$$\begin{aligned} \int_0^{\alpha t} P\left(R_{t-s} \leq \frac{\beta}{2}t + z(t)\right) f_{T_0}(s) ds &\geq \int_0^{\alpha t} \left(1 - \exp\left\{-\beta\left(\frac{\beta}{2}s + z(t)\right)\right\}\right) f_{T_0}(s) ds \\ &= P^{x_0(t)}(T_0 \leq \alpha t) - e^{-\beta z(t)} E^{x_0(t)}\left(e^{-\frac{\beta^2}{2}T_0} \mathbf{1}_{\{T_0 \leq \alpha t\}}\right) \\ &\geq P^{x_0(t)}(T_0 \leq \alpha t) - e^{-\beta z(t)} E^{x_0(t)}\left(e^{-\frac{\beta^2}{2}T_0}\right) \\ &= 1 - e^{-\beta z(t) - \beta|x_0(t)|} - P^{x_0(t)}(T_0 > \alpha t) \end{aligned}$$

using the fact that $E^{x_0(t)}\left(e^{-\frac{\beta^2}{2}T_0}\right) = e^{-\beta|x_0(t)|}$. Then since $P^{x_0(t)}(T_0 > \alpha t) \leq \frac{\sqrt{2}|x_0(t)|}{\sqrt{\pi\alpha t}}$ it follows that

$$P^{x_0(t)}\left(R_t \leq \frac{\beta}{2}t + z(t)\right) \geq 1 - \theta_1(t) e^{-\beta|x_0(t)| - \beta z(t)},$$

where $\theta_1(t) = 1 + P^{x_0(t)}(T_0 > \alpha t) e^{\beta|x_0(t)| + \beta z(t)} \rightarrow 1$ as $t \rightarrow \infty$ due to assumption that $|x_0(t)| < \frac{1}{4\beta} \log t$ for large enough t and $z(t) = o(\log t)$ as $t \rightarrow \infty$.

Upper bound.

The upper bound of 3.1 is proved similarly. From (3.2) and (3.3) we have

$$P^{x_0(t)}\left(R_t \leq \frac{\beta}{2}t + z(t)\right) \leq \int_0^{\alpha t} P\left(R_{t-s} \leq \frac{\beta}{2}t + z(t)\right) f_{T_0}(s) ds + P^{x_0(t)}(T_0 > \alpha t).$$

From Corollary 2.7 we know that for all t sufficiently large (so that $t + \frac{2}{\beta}z(t) > 0$)

$$\begin{aligned} \int_0^{\alpha t} P\left(R_{t-s} \leq \frac{\beta}{2}t + z(t)\right) f_{T_0}(s) ds &\leq \int_0^{\alpha t} \left[1 - \exp\left\{-\frac{\beta^2}{2}s - \beta z(t)\right\}\right] \left(1 - C \exp\left\{-\frac{\beta^2}{2}s - \beta z(t)\right\}\right) \Phi\left(\frac{\beta}{2}\sqrt{t-s} - \frac{\frac{\beta}{2}s + z(t)}{\sqrt{t-s}}\right)^2 f_{T_0}(s) ds \\ &\leq \int_0^{\alpha t} \left[1 - \exp\left\{-\frac{\beta^2}{2}s - \beta z(t)\right\}\right] \left(1 - C \exp\left\{-\beta z(t)\right\}\right) \Phi\left(\frac{\beta}{2}\sqrt{1-\alpha}\sqrt{t} - \frac{\beta\alpha\sqrt{t}}{2\sqrt{1-\alpha}} - \frac{z(t)}{\sqrt{1-\alpha}\sqrt{t}}\right)^2 f_{T_0}(s) ds \\ &\leq 1 - \hat{\theta}_2(t) \exp\{-\beta z(t)\} \int_0^{\alpha t} e^{-\frac{\beta^2}{2}s} f_{T_0}(s) ds, \end{aligned}$$

where

$$\hat{\theta}_2(t) = \left(1 - C \exp\left\{-\beta z(t)\right\}\right) \Phi\left(\frac{\beta}{2}\sqrt{1-\alpha}\sqrt{t} - \frac{\beta\alpha\sqrt{t}}{2\sqrt{1-\alpha}}\sqrt{t} - \frac{z(t)}{\sqrt{1-\alpha}\sqrt{t}}\right)^2 \rightarrow 1$$

as $t \rightarrow \infty$ due to the choice of $\alpha < \frac{1}{2}$. Thus

$$\begin{aligned} P^{x_0(t)}\left(R_t \leq \frac{\beta}{2}t + z(t)\right) &\leq 1 - \hat{\theta}_2(t) \exp\{-\beta z(t)\} \int_0^{\alpha t} e^{-\frac{\beta^2}{2}s} f_{T_0}(s) ds + P^{x_0(t)}(T_0 > \alpha t) \\ &= 1 - \hat{\theta}_2(t) \exp\{-\beta z(t)\} \left[E^{x_0(t)} e^{-\frac{\beta^2}{2}T_0} - E^{x_0(t)} \left(\mathbf{1}_{\{T_0 > \alpha t\}} e^{-\frac{\beta^2}{2}T_0} \right) \right] \\ &\quad + P^{x_0(t)}(T_0 > \alpha t) \\ &\leq 1 - \hat{\theta}_2(t) \exp\{-\beta z(t)\} \left[E^{x_0(t)} e^{-\frac{\beta^2}{2}T_0} - P^{x_0(t)}(T_0 > \alpha t) \right] \\ &\quad + P^{x_0(t)}(T_0 > \alpha t) \\ &= 1 - \theta_2(t) e^{-\beta|x_0(t)| - \beta z(t)}, \end{aligned}$$

where

$$\theta_2(t) = \hat{\theta}_2(t) \left(1 - e^{\beta|x_0(t)|} P^{x_0(t)}(T_0 > \alpha t) \right) - e^{\beta|x_0(t)| + \beta z(t)} P^{x_0(t)}(T_0 > \alpha t) \rightarrow 1$$

as $t \rightarrow \infty$ since $P^{x_0(t)}(T_0 > \alpha t) \leq \frac{\sqrt{2}|x_0(t)|}{\sqrt{\pi\alpha t}}$, $|x_0(t)| < \frac{1}{4\beta} \log t$ for large enough t and $z(t) = o(\log t)$ as $t \rightarrow \infty$ and this completes the proof of Proposition 3.1. \square

Let us now prove the main result of this paper. Namely, that for any $x, y \in \mathbb{R}$

$$\lim_{t \rightarrow \infty} P^x\left(R_t \leq \frac{\beta}{2}t + y\right) = E^x \exp\left\{-M_\infty e^{-\beta y}\right\}.$$

Proof of Theorem 1.1. Let us first assume that the branching process starts from 0. Note that for any $t > 0$ and $s < t$ by the Markov property we can write

$$\begin{aligned} P\left(R_t \leq \frac{\beta}{2}t + y\right) &= E\left(\prod_{u \in N_s} P^{X_s^u}\left(R_{t-s} \leq \frac{\beta}{2}t + y\right)\right) \\ &= E\left(\prod_{u \in N_s} P^{X_s^u}\left(R_{t-s} \leq \frac{\beta}{2}(t-s) + \frac{\beta}{2}s + y\right)\right). \end{aligned}$$

We take $s(t) = \sqrt{\log t}$ in the above formula so that conditions of Proposition 3.1 will apply. Then fixing an arbitrary $\epsilon > 0$ we write

$$\begin{aligned} &\prod_{u \in N_{s(t)}} P^{X_{s(t)}^u}\left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y\right) \\ &= \mathbf{1}_{\{R_{s(t)} \leq (\frac{\beta}{2} + \epsilon)s(t)\}} \prod_{u \in N_{s(t)}} P^{X_{s(t)}^u}\left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y\right) \\ &\quad + \mathbf{1}_{\{R_{s(t)} > (\frac{\beta}{2} + \epsilon)s(t)\}} \prod_{u \in N_{s(t)}} P^{X_{s(t)}^u}\left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y\right) \end{aligned}$$

and as we know from (1.1), $\mathbf{1}_{\{R_{s(t)} > (\frac{\beta}{2} + \epsilon)s(t)\}} \rightarrow 0$ almost surely and hence also

$$\mathbf{1}_{\{R_{s(t)} > (\frac{\beta}{2} + \epsilon)s(t)\}} \prod_{u \in N_{s(t)}} P^{X_{s(t)}^u}\left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y\right) \leq \mathbf{1}_{\{R_{s(t)} > (\frac{\beta}{2} + \epsilon)s(t)\}} \rightarrow 0$$

almost surely as $t \rightarrow \infty$. On the other hand, we would like to show that on the event $\{R_{s(t)} \leq (\frac{\beta}{2} + \epsilon)s(t)\}$

$$\prod_{u \in N_{s(t)}} P^{X_{s(t)}^u}\left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y\right) \rightarrow \exp\{-e^{-\beta y} M_\infty\} \quad (3.4)$$

Upper bound of (3.4). On the event $\{R_{s(t)} \leq (\frac{\beta}{2} + \epsilon)s(t)\}$ we have

$$\begin{aligned} & \prod_{u \in N_{s(t)}} P^{X_{s(t)}^u} \left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y \right) \\ &= \exp \left\{ \sum_{u \in N_{s(t)}} \log P^{X_{s(t)}^u} \left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y \right) \right\} \\ &\leq \exp \left\{ \sum_{u \in N_{s(t)}} \log \left(1 - \theta_2 (t-s(t)) e^{-\beta |X_{s(t)}^u| - \frac{\beta^2}{2}s(t) - \beta y} \right) \right\} \end{aligned}$$

for t large enough and where $\theta_2(t) \rightarrow 1$ as $t \rightarrow \infty$ according to Proposition 3.1. Then since $\log(1-x) \leq -x$ for all $x \in \mathbb{R}$ we get (on the event $\{R_{s(t)} \leq (\frac{\beta}{2} + \epsilon)s(t)\}$)

$$\begin{aligned} & \prod_{u \in N_{s(t)}} P^{X_{s(t)}^u} \left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y \right) \\ &\leq \exp \left\{ -\theta_2(t-s(t)) e^{-\beta y} \sum_{u \in N_{s(t)}} e^{-\beta |X_{s(t)}^u| - \frac{\beta^2}{2}s(t)} \right\} \\ &= \exp \left\{ -\theta_2(t-s(t)) e^{-\beta y} M_{s(t)} \right\} \\ &\rightarrow \exp \left\{ -e^{-\beta y} M_\infty \right\}. \end{aligned}$$

Lower bound of (3.4). Similarly, on the event $\{R_{s(t)} \leq (\frac{\beta}{2} + \epsilon)s(t)\}$ we have that $|X_{s(t)}^u| \leq (\frac{\beta}{2} + \epsilon)s(t) = (\frac{\beta}{2} + \epsilon)\sqrt{\log t}$ for all $u \in N_{s(t)}$ and so by Proposition 3.1

$$\begin{aligned} & \prod_{u \in N_{s(t)}} P^{X_{s(t)}^u} \left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y \right) \\ &\geq \exp \left\{ \sum_{u \in N_{s(t)}} \log \left(1 - \theta_1 (t-s(t)) e^{-\beta |X_{s(t)}^u| - \frac{\beta^2}{2}s(t) - \beta y} \right) \right\} \end{aligned}$$

for t large enough and where $\theta_1(t) \rightarrow 1$ as $t \rightarrow \infty$. Then since $\log(1-x) \geq \frac{\log(1-x_*)}{x_*}x$ for all $x \in [0, x_*]$ we get by taking $x = \theta_1 (t-s(t)) e^{-\beta |X_{s(t)}^u| - \frac{\beta^2}{2}s(t) - \beta y}$ and $x_* = \theta_1 (t-s(t)) e^{-\frac{\beta^2}{2}s(t) - \beta y}$ that

$$\begin{aligned} & \prod_{u \in N_{s(t)}} P^{X_{s(t)}^u} \left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y \right) \\ &\geq \exp \left\{ \frac{\log \left(1 - \theta_1 (t-s(t)) e^{-\frac{\beta^2}{2}s(t) - \beta y} \right)}{\theta_1 (t-s(t)) e^{-\frac{\beta^2}{2}s(t) - \beta y}} \theta_1 (t-s(t)) e^{-\beta y} \sum_{u \in N_{s(t)}} e^{-\beta |X_{s(t)}^u| - \frac{\beta^2}{2}s(t)} \right\} \\ &\rightarrow \exp \left\{ -e^{-\beta y} M_\infty \right\} \end{aligned}$$

using L'Hopitale's rule when taking the limit of the fraction. So we have proved that

$$\mathbf{1}_{\{R_{s(t)} \leq (\frac{\beta}{2} + \epsilon)s(t)\}} \prod_{u \in N_{s(t)}} P^{X_{s(t)}^u} \left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y \right) \rightarrow \exp \left\{ -e^{-\beta y} M_\infty \right\}.$$

Thus also almost surely

$$\prod_{u \in N_{s(t)}} P^{X_{s(t)}^u} \left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y \right) \rightarrow \exp \left\{ -e^{-\beta y} M_\infty \right\}$$

and by bounded convergence

$$E\left[\prod_{u \in N_s(t)} P^{X_s^u}\left(R_{t-s(t)} \leq \frac{\beta}{2}(t-s(t)) + \frac{\beta}{2}s(t) + y\right)\right] \rightarrow E\left[\exp\left\{-e^{-\beta y} M_\infty\right\}\right].$$

For an arbitrary starting point x let T_0 be the time the initial particle first hits the origin, $\tilde{R}_t := R_{t+T_0}$ and $\tilde{M}_t := e^{\frac{\beta^2}{2}T_0} M_{t+T_0}$, $t \geq 0$. Then by the strong Markov property we get

$$\begin{aligned} &P^x\left(R_t \leq \frac{\beta}{2}t + y\right) \\ &= P^x\left(R_t \leq \frac{\beta}{2}t + y, T_0 > t\right) + P^x\left(R_t \leq \frac{\beta}{2}t + y, T_0 \leq t\right) \\ &= P^x\left(R_t \leq \frac{\beta}{2}t + y, T_0 > t\right) + P^x\left(\tilde{R}_{t-T_0} \leq \frac{\beta}{2}(t-T_0) + \frac{\beta}{2}T_0 + y, T_0 \leq t\right) \\ &\rightarrow 0 + E^x\left(\exp\left\{-e^{-\frac{\beta^2}{2}T_0 - \beta y} \tilde{M}_\infty\right\}\right) \\ &= E^x\left(\exp\left\{-e^{-\beta y} M_\infty\right\}\right). \quad \square \end{aligned}$$
